Abstract. Measurements of surface ozone (O_3), $PM_{2.5}$ and its major secondary components (SO_4^{2-} , NO_3^- , NH_4^+ , and OC), mixing layer height (MLH) and other meteorological parameters were made in the North China Plain (NCP) during the warm season (June–July) in 2021. The observation results showed that the summertime regional MDA8 O_3 initially increased and reached the maximum value ($195.88 \mu g m^{-3}$) when the MLH ranged from approximately 900 to 1800 m, after which the concentration of O_3 decreased with further increase in MLH. Interestingly, synchronous increases in $PM_{2.5}$ concentration along with the development of the mixing layer (MLH < 1200 m) were observed, and the positive response of $PM_{2.5}$ to MLH was significantly associated with the increase in SO_4^{2-} and OC. It was found that this increasing trend of $PM_{2.5}$ with elevated MLH was driven not only by the wet deposition process but also by the enhanced secondary chemical formation, which was related to appropriate meteorological conditions ($50 \% < RH < 70 \%$) and increased availability of atmospheric oxidants. Air temperature played a minor role in the change characteristics of $PM_{2.5}$ concentration, but greatly controlled the different change characteristics of SO_4^{2-} and NO_3^- . The concentrations of $PM_{2.5}$, its major secondary components, and SOR and NOR increased synchronously with elevated MDA8 O_3 concentrations, and the initial increase in $PM_{2.5}$ along with increased MLH corresponded well with that of MDA8 O_3 . We highlight that the correlation between MLH and secondary air pollutants should be treated with care in hot weather, and the superposition-composite effects of $PM_{2.5}$ and O_3 along with the evolution of mixing layer should be considered when developing $PM_{2.5}$ - O_3 coordinated control

30 strategies.

31

32

33 **1 Introduction**

34 Surface ozone (O_3) and $PM_{2.5}$ (atmospheric fine particles with an aerodynamic diameter of less
35 than $2.5\ \mu\text{m}$) are important air pollutants in the atmosphere and have aroused a lot of attention from the
36 public due to their adverse health impacts (Jiang et al., 2018; Cohen et al., 2017; Gao and Ji, 2018).
37 Even though stringent clean air actions have been implemented in China during the past decade, high
38 concentrations of O_3 and/or $PM_{2.5}$ exceeding national air quality standards, still occurred during the
39 warm season, especially in the North China Plain (NCP), the economic centre of China (Dai et al.,
40 2023). O_3 is a secondary pollutant that originates from the photochemical oxidation of volatile organic
41 compounds (VOC) and carbon monoxide (CO) in the presence of nitrogen oxides (NO_x). The level of
42 $PM_{2.5}$ is mainly determined by pollutant emissions and secondary formation from gaseous precursors.
43 In addition to air pollutant emissions, meteorological conditions play critical roles in the formation of
44 $PM_{2.5}$ and O_3 (Miao et al., 2021). The mixing layer height (MLH), which influences vertical mixing
45 within the pollution mixing layer and determines the dilution of pollutants emitted near the ground
46 (Haman et al., 2014; Zhu et al., 2018; Lou et al., 2019), often serves as a critical physical parameter in
47 atmospheric environmental evaluation. Elucidating the association of MLH with surface O_3 and $PM_{2.5}$
48 is fundamental for the development of $PM_{2.5}$ - O_3 coordinated control strategies.

49 The response of air pollution to the MLH is variable and complicated (Miao et al., 2021). In
50 previous studies, it was often assumed that the narrowing of the mixing layer resulted in the
51 accumulation of pollutants near the ground and the increase in MLH was expected to reduce $PM_{2.5}$
52 concentration due to dilution (Murthy et al., 2020; Du et al., 2013). However, the relationship between
53 mixing layer structure and $PM_{2.5}$ concentration depends on the site, observation period, and the
54 properties of MLH retrievals (Geiß et al., 2017; Lu et al., 2019). Although the link between $PM_{2.5}$
55 concentration and MLH has been investigated in many studies, most observations were conducted in
56 winter conditions and comparatively few in hot weather. Interestingly, in some cities, such as Delhi
57 (Murthy et al., 2020) and Shanghai (Pan et al., 2019; Miao et al., 2021), an increase in $PM_{2.5}$ was
58 observed when the MLH increased during summer. As for O_3 , the relationship between the changes in
59 the MLH and O_3 concentrations is very complex. Both increase or decrease of O_3 has been observed
60 corresponded to the growth of MLH. Generally, the O_3 concentration decrease with an increase in
61 MLH owing to dilution. However, an increase in the MLH generally promotes the downward mixing of

62 upper air containing higher O₃ (Ma et al., 2021; Haman et al., 2014; Xu et al., 2018). In addition, the
63 meteorological conditions along with the changes of MLH can influence O₃ concentrations through
64 effecting O₃ gaseous precursors or production rates (Porter and Heald, 2019; Zhang et al., 2022). The
65 combined effects of these processes ultimately determine whether the concentration of O₃ decreases or
66 increases.

67 Other meteorological variables in the mixing layer were also found to significantly affect PM_{2.5}
68 and O₃ concentrations. Poor air quality in the NCP was closely associated with near-surface southerly
69 winds and warm stagnant conditions during summer (Zhang et al., 2015a). The increase in PM_{2.5}
70 concentration often coincided with high relative humidity (RH) conditions (Liu et al., 2017b), which
71 was beneficial to liquid-phase heterogeneous reactions and fine particle hygroscopic growth (Seinfeld
72 and Pandis, 2006; Wang et al., 2016; Zhang et al., 2015b). Temperature was essential to secondary
73 chemical reaction (Dawson et al., 2007). The increase in temperature not only promoted chemical
74 reaction rates, but also stimulated the evaporation of semi-volatile aerosol components, such as nitrate
75 (Wen et al., 2018). As for O₃, elevated concentrations generally occurred on days with strong sunlight
76 and low wind speeds, which favoured photochemical production and the accumulation of O₃ and its
77 precursors. Several studies have shown that O₃ was significantly positively correlated with temperature,
78 but negatively correlated with RH (Li et al., 2021; Hou and Wu, 2016; Steiner et al., 2010).

79 In recent years, long-term PM_{2.5} composition measurements in the NCP have revealed an increase
80 in the contributions of secondary species, e.g., sulfate (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺), and
81 organic matter (OM) (Cheng et al., 2019; Wang et al., 2022b). As air quality improved (PM_{2.5} < 50
82 μg m⁻³), the correlation between O₃ and PM_{2.5} tended to change from negative to positive in China
83 (Chu et al., 2020). One possible reason is that when the PM_{2.5} concentration is low, PM_{2.5} does not
84 reduce actinic flux and HO₂ radical significantly. On the other hand, PM_{2.5} and O₃ tend to be positively
85 correlated, possibly due to their common precursors, such as VOCs and NO_x, and their simultaneous
86 generation in photochemical reactions. In addition, the generation of O₃ enhances the atmospheric
87 oxidation capacity and catalyzes the generation of the secondary PM_{2.5} (Cheng et al., 2019; Kang et al.,
88 2021; Wu et al., 2022). Although some studies have discussed the correlations between MLH and some
89 secondary pollutants, the understanding of the interaction between O₃ and PM_{2.5} (including its major
90 components) along with the evolution of the mixing layer during warm season, remained poor, owing
91 to the limited observations of PM_{2.5} chemical species involved. Regional-scale observation can

92 represent the variation characteristics of an area and avoid spatial heterogeneity between sites.
 93 However, to the best of our knowledge, previous observational studies were mostly limited to specific
 94 cities. Thus, rather than drawing conclusions based on individual datasets, an analysis of multiple data
 95 sources is needed to determine the overall trends.

96 According to the hourly concentrations of PM_{2.5} and MDA8 O₃ in China over the years of
 97 2013–2020, the months of June and July can well represent the typical characteristics of O₃–PM_{2.5}
 98 coordinated pollution during warm season in the NCP (Dai et al., 2023). To enhance the understanding
 99 of the linkages between the mixing layer structure and air pollution, in this study, a regional-scale field
 100 observation of meteorological factors, O₃, PM_{2.5} concentration and its secondary composition were
 101 conducted in the NCP, from 1 June to 31 July, 2021. For the first time, the potential associations
 102 between ground-level observed O₃, PM_{2.5} and its dominant components, and mixing layer
 103 meteorological conditions in the NCP during summer are presented and discussed.

104 2 Data and methods

105 2.1 Measurements

106

107 **Figure 1.** Location of monitoring stations in the North China Plain.

108 Observations were made in the NCP from 1 June to 31 July 2021. Air pollution observation
 109 stations covered two megacities (BeiJ and TianJ) and 26 surrounding cities. The geographical locations
 110 of these stations are shown in Figure 1. The NCP is bordered by the Taihang Mountains to the west, the

111 Yan Mountains to the north, and the Bohai Sea in the east. The hourly concentrations of ground-level
112 O₃, PM_{2.5} and its major components (SO₄²⁻, NO₃⁻, NH₄⁺, and organic carbon [OC]), and meteorological
113 variables, including air temperature, relative humidity (RH), wind speed (WS) and direction (WD), and
114 24-h accumulated precipitation, at the sites were obtained from the platform of National Atmospheric
115 Particulate Chemical-Speciation-Network, which is established for improving the understanding of the
116 heavy pollution formation mechanism in the NCP and supporting the decision-making of local
117 governments and state administration. Hourly SO₂, NO₂, O₃, PM_{2.5} and its chemical compositions were
118 recorded in the PM_{2.5} component network, which was selected following the Technical Regulation for
119 Selection of Ambient Air Quality Monitoring Station published by the Ministry of Ecology and
120 Environment of the People's Republic of China (HJ664-2013). The monitoring sites of the PM_{2.5}
121 component network were mostly set up within the cities and reflected the average pollution level of
122 each city. Details of the near-ground observation stations of the PM_{2.5} component network were listed
123 in Table S1. Mass concentrations of SO₄²⁻, NO₃⁻, and NH₄⁺ in PM_{2.5} were continuously measured at a
124 1-h resolution by MARGA (model ADI 2080) or AIM-IC (URG 9000D) equipped with a PM_{2.5}
125 sampling inlet. These two IC-based online instruments have shown good performance through
126 instrument intercomparison studies or comparison to offline filters under clean to moderately polluted
127 conditions (Markovic et al., 2012; Wu and Wang, 2007; Park et al., 2013; Rumsey et al., 2014). OC
128 was measured online by Sunset Semi-Continuous Carbon Analyzer (Sunset Laboratory Inc, USA). The
129 concentration of OM was obtained by multiplying the OC concentration by a factor of 1.6 (Li et al.,
130 2021). PM_{2.5}, O₃, NO₂ and SO₂ concentrations were recorded hourly using Thermo Fisher Scientific
131 samplers and analyzers. Detailed descriptions of these online sampling instruments can be found in our
132 previous works (Kong et al., 2018; Liu et al., 2017a; Pang et al., 2020; Wang et al., 2022b). The
133 meteorological variables were recorded in the national meteorological observation stations, and the
134 information of each station was obtained from the public website of the China Meteorological
135 Administration (<http://data.cma.cn/data/cdcindex/cid/0b9164954813c573.html>). The temporal
136 resolution of air temperature, RH, WS and WD was 1 hour. To avoid the influence of diurnal boundary
137 layer cycles, this study focused on the relationship between the daily mean air pollutants and
138 meteorological factors. The daily mean meteorological factors, PM_{2.5} and its major secondary
139 components were calculated from the hourly data, and the daily O₃ concentration was characterized by
140 the maximum daily 8 h average ozone (MDA8 O₃). Details for the near-ground observation species and

141 the metrics were shown in Table S2.

142 To better demonstrate the overall change characteristics of the regional air pollution and
143 meteorological conditions during the observation period, the occurrence frequency (%), which is the
144 proportion of the cities at each air pollutant or methodology level, was calculated based on the
145 following equation:

$$146 \text{ Occurrence frequency}_{X}^{\text{level}} = \frac{N_X^{\text{level}}}{\text{Total } N_X} \times 100 \% \quad (1)$$

147 where X means the air pollutants or methodology factors, N_X^{level} represents the number of cities at each
148 X level, and Total N_X represents the total number of cities.

149 **2.2 The calculation of MLH**

150 In recent years, many works have progressed in the atmospheric boundary layer characteristics,
151 and analyzed the impacts of these parameter on air pollution (Haugen et al., 1971; Wang et al., 2014;
152 Zhang et al., 2005). However, the way the boundary layer describes the influences of air pollution is
153 easily duplicated and confused (Niu et al., 2017). For air pollution measurement, one of selected
154 functionalities of parameterization scheme for pollution mixing layer is to judge whether an air mass
155 over a specific locality satisfies the “static and stable” attribute or not. Therefore, in this work, to
156 express the basic physics for diagnosing meteorological conditions, we used the concept of pollution
157 MLH proposed by Wang et al. (2017), which was based on the classical synoptic theory according to
158 the level of the convective condensation layer, and the details of this method can be seen in previous
159 work (Wang and Yang, 2000; Wang et al., 2017).

160 To be specific, we defined the height close to the cloud base as the height of the super-saturation
161 layer (H_{SSL}). The isentropic atmospheric process meets the level of the convective condensation
162 layer (LCL) in the supersaturation state, that is, it is very close to the H_{SSL} . An iterative algorithm
163 was used to work out the H_{SSL} (Wang and Yang, 2000):

$$164 H_{\text{SSL}} \approx \text{LCL} = 6.11 \times 10^2 \times \left(\frac{0.622 + 0.622 \frac{e_s}{p - e_s}}{0.622 \frac{e_s}{p - e_s}} \right), \quad (2)$$

$$165 e_s = 6.22 \times \exp \frac{17.13(T - 273.16)}{T - 38}, \quad (3)$$

166 where e_s represents the saturated water vapour pressure, and T is the temperature (K). Eq. (2) can be
167 used to calculate the H_{SSL} which is favourable for pollutant mixing and is represented by (P). Below
168 this height, the atmosphere gets supersaturated, causing the pollution mixing and wetting process in the

169 low altitude to continue, so this height is called the height of pollution mixing layer (MLH). Thus,
170 MLH can be derived in the following expression:

$$171 \quad \overline{\text{MLH}} \approx \text{H_SSL} \approx \text{LCL} = 6.11 \times 10^2 \times \left(\frac{0.622 + 0.622 \frac{e_s}{p - e_s}}{0.622 \frac{e_s}{p - e_s}} \right), \quad (4)$$

172 According to the relationship between air pressure and height, the units of MLH can be converted to
173 the height (in m) as follows:

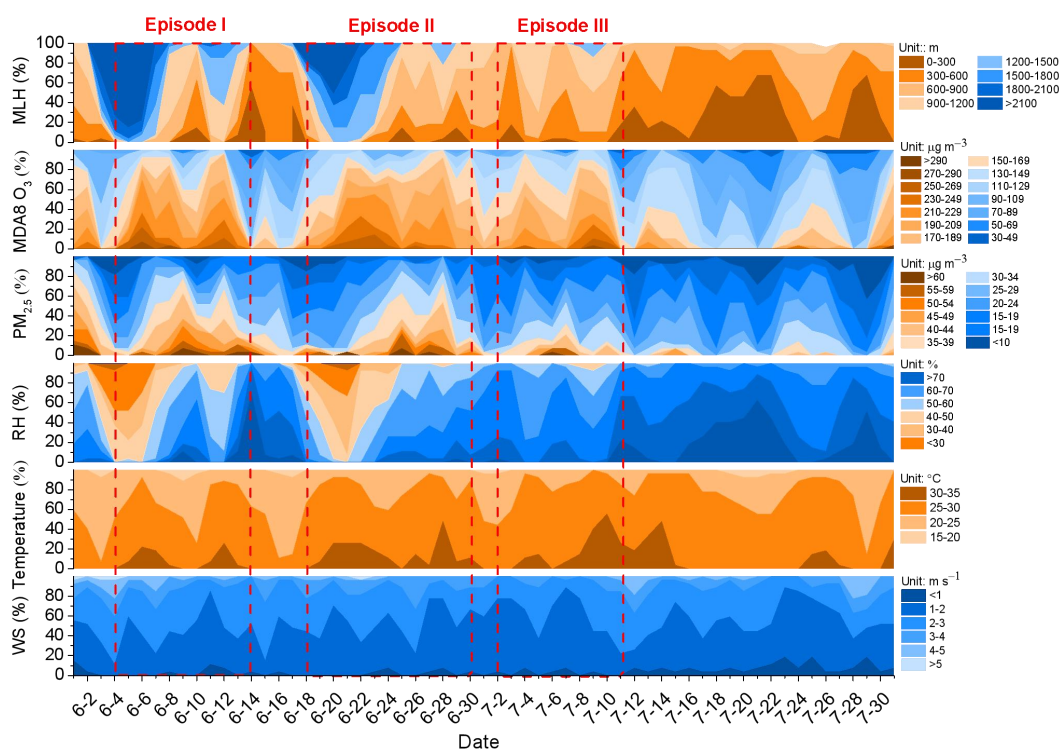

$$174 \quad \int_{p_0}^{p_z} dp = - \int_0^z \rho_0 g dz, \quad (5)$$

175 where z is the height, ρ_0 is the density of gas, p_z and p_0 represent the air pressure in the height of z and
176 0, respectively.

177 Several works have verified the reliability of the results based on this method. Using this method,
178 Wang et al. (2017) well characterized the features of the mixing layer height in highly-sensitive areas
179 of pollution in China. Wang et al. (2022c) also used this method to explore $\text{PM}_{2.5}$ and O_3
180 superposition-composite pollution events during spring 2020 in Beijing, China, and the hourly
181 evolution of MLH, O_3 , and $\text{PM}_{2.5}$ during the observation period was analyzed. In addition, Niu et al.
182 (2017) has applied this method to Beijing, and the results showed that the pollution mixing layer could
183 effectively represent the change characteristics of the haze pollution process. In this work, we applied
184 this method to investigate the impact of MLH on the change characteristics of ozone and fine
185 particulate matter.

186 **3 Results and discussion**

187 **3.1 General characteristics**

188

189 **Figure 2.** Occurrence frequency (%) of PM_{2.5}, MDA8 O₃, and meteorological factors under different
 190 levels in the NCP from June 1 to July 31, 2021. The color shading represents different categories
 191 classified by PM_{2.5}, MDA8 O₃, and meteorological factors. Boxed areas delineated by red dashes
 192 represent three typical PM_{2.5} and O₃ co-polluted episodes: June 4–14 (Episode I), June 18–29 (Episode
 193 II), and July 2–11 (Episode III), 2021.

194 The summertime change characteristics of ground-level meteorological factors (MLH, RH,
 195 temperature, and WS), MDA8 O₃, PM_{2.5} and its major components in the NCP were shown in Figures 2
 196 and S1. The primary atmospheric pollutant in the NCP during the summer was O₃, and the
 197 concentrations of MDA8 O₃ averaged over all sites in the NCP varied from 74.94 to 219.28 µg m⁻³,
 198 with the mean value of 151.72 µg m⁻³ (Table 1). O₃ pollution lasted for nearly the entire observation
 199 period and was characterized by frequent and long-lasting pollution episodes. The PM_{2.5} concentration
 200 was much lower comparing with O₃ during the observation period. The mean, maximum, and
 201 minimum of the regional daily mean PM_{2.5} concentration was 25.62, 45.62, and 11.32 µg m⁻³,
 202 respectively. NO₃⁻ was the prominent PM_{2.5} component, with the mean concentration of 7.76 µg m⁻³.
 203 According to the National Ambient Air Quality Standard of China (GB3095-2012), the daily PM_{2.5}
 204 averages in “2+26” cities can meet the Level II standard of 75 µg m⁻³, while exceeding the level I
 205 standard (35 µg m⁻³). As shown in Figure 2, the regional PM_{2.5} pollution processes corresponded well
 206 with the increasing processes of MDA8 O₃. Here, we define a O₃–PM_{2.5} co-polluted episode as a set of

207 continuous days (longer than 4 days) with MDA8 O₃ and daily mean PM_{2.5} (in more than 10 % NCP
 208 cities) exceeding 160 and 35 µg m⁻³, respectively. On the basis of this criterion, three typical O₃-PM_{2.5}
 209 co-polluted episodes were selected: June 4–14 (Episode I), June 18–29 (Episode II), and July 2–11
 210 (Episode III), 2021.

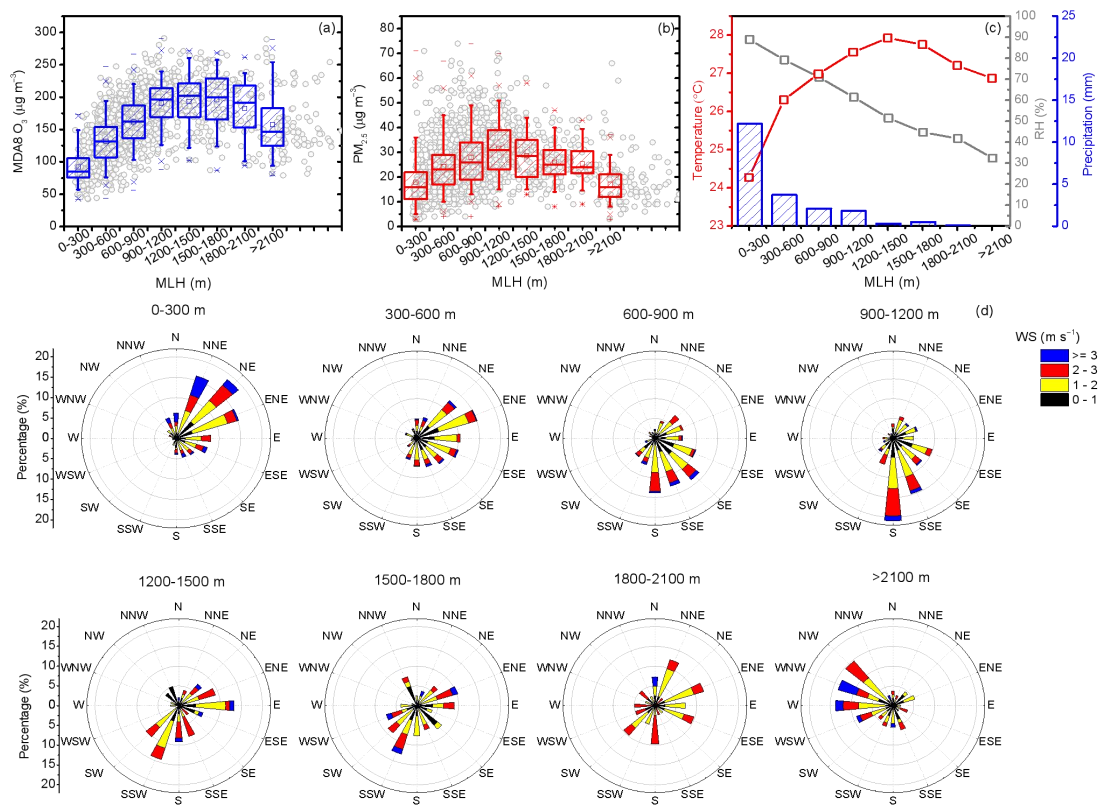

211 During these three typical episodes, the synchronous change characteristics of air pollutants and
 212 the mixing layer meteorology were analyzed. In Episode I and II, when MLH was higher than 2100 m,
 213 both MDA8 O₃ and PM_{2.5} concentrations were low. Along with the reduction in MLH (from
 214 1800–2100 m to 1200–1800 m), regional MDA8 O₃ and PM_{2.5} concentrations both gradually increased.
 215 When MLH fell in the range of 1200–1800 m, MDA8 O₃ concentration reached the maximum with
 216 approximately 80 % areas having levels greater than 170 µg m⁻³. With a further decrease in MLH,
 217 MDA8 O₃ declined, whereas PM_{2.5} remained stable or continued to increase, when the regional MLH
 218 was in the range of 600–1200 m. In Episode III, the MLH in most cities was lower than 1200 m, and
 219 the regional MDA8 O₃ and PM_{2.5} pollution conditions were lighter than other episodes, with 80 % of
 220 the PM_{2.5} values less than 35 µg m⁻³. It is interesting to note that the change characteristics of SO₄²⁻ and
 221 NO₃⁻ differed (Figure S1), and the regional peaks of these two components were inconsistent,
 222 especially in Episode II. With the evolution of MLH, NO₃⁻ climbed up and peaked on June 24 when
 223 regional MLH lower than 900 m, and SO₄²⁻ reached the maximum on June 28 when MLH was
 224 approximately 900–1500 m. This may be related to other synchronized mixing layer meteorological
 225 factors, such as RH and temperature. For example, the evolution of the mixing layer is often
 226 accompanied by changes in temperature. The increase in temperature can promote the chemical
 227 formation rate of these secondary components, but also stimulate the volatilization of NO₃⁻ to gaseous
 228 state (HNO₃), which leads to the decrease in NO₃⁻ concentration. Further analysis of the responses of
 229 O₃, PM_{2.5} and its secondary components to different mixing layer meteorological factors is presented in
 230 the following sections.

231 Table 1. General information on O₃-PM_{2.5} co-polluted episodes from June 1 to July 31, 2021.

	Episode I			Episode II			Episode III			Summer

232 3.2 Evolution of ozone with mixing layer meteorology

233 **Figure 3.** Variation characteristics of (a) MDA8 O₃, (b) PM_{2.5}, (c) temperature, RH, 24-h precipitation,
 234 and (d) WS and WD in different MLH conditions. Box plots in (a) and (b) show the inter quartile range
 235 (the distance between the bottom and the top of the box), median (the band inside the box), and 95 %
 236 confidence interval (whiskers above and below the box) of the data.

237 To quantify the effect of MLH on near-ground O₃ concentrations, relationships between MLH and
 238 MDA8 O₃ were analyzed (Figure 3a). A data binning method was used to remove the expected

239 day-to-day atmospheric variability from the sampling uncertainty (Dian et al., 2010), which has been
240 applied in other studies (Lou et al., 2019). The MLH was grouped into 8 classes of 300 m width: 0–300,
241 300–600, 600–900, 900–1200, 1200–1500, 1500–1800, 1800–2100 and > 2100 m. It was found that
242 MDA8 O₃ concentration dramatically increased when MLH fell in the range of 0–900 m, and leveled
243 off when MLH at approximately 900–1800 m, with the maximum MDA8 O₃ of 195.88±42.76 μg m⁻³,
244 after which the concentration began to decrease with further development of MLH. This nonlinear
245 relationship between MDA8 O₃ and MLH was is consistent with the results reported by Zhao et al.
246 (2019), which found that the O₃ concentration was highest at medium boundary layer heights
247 (1200–1500 m) during summertime in Shijiazhuang, China.

248 The relationship observed between MDA8 O₃ and MLH is complex. Previous studies have shown
249 that a higher MLH can lead to the mixing of near-surface air with the O₃ rich air aloft, resulting in
250 enhanced surface O₃ concentrations (Reddy et al., 2012). Concurrently, the evolution of the mixing
251 layer was strongly associated with the changes in other meteorological conditions, such as air
252 temperature, RH and precipitation, which can also affect the O₃ concentration (Haman et al., 2014).
253 The combined effects of these processes ultimately determine whether ground-level O₃ increases along
254 the evolution of the mixing layer. The increase in the MLH often coincides with higher air
255 temperature, lower RH, and less precipitation (Figure 3c), and this combination of factors is more
256 conducive to O₃ production (Ma et al., 2021; Xu et al., 2018). As shown in Figure 4a–c, as the MLH
257 remained constant, the MDA8 O₃ concentration climbed up with the increase in air temperature but
258 decrease in RH and precipitation levels. Possible reasons for these results are: (1) the increase in RH
259 contributes to the depletion of O₃, and leads to weakened O₃ related photochemical reaction (Ma et al.,
260 2021; Yu, 2019); (2) due to higher RH or rain fall, gaseous precursors and O₃ are washed out from the
261 atmosphere through wet deposition (Reddy et al., 2012); and (3) the rise of temperature accelerates the
262 emission rate of gaseous precursors, such as biogenic VOCs and soil NO_x (Dang et al., 2021; Porter
263 and Heald, 2019), and also stimulates the photochemical reaction rate in the generation of O₃ (Ma et al.,
264 2021). Wind fields also alter surface O₃ concentrations by transporting O₃ or its precursors into and out
265 of the region (Ma et al., 2021). As shown in Figure S2, during the entire campaign, the NCP was
266 dominated by winds from the northeast and south (45°–225°). Because more than 75 % WD were in
267 the range of 45°–225°, the WD was classified into four categories: 45°–90°, 90°–135°, 135°–180°, and
268 180°–225°. As shown in Figure 3d, along with the evolution of the mixing layer, the WD gradually

269 changed from the northeast (MLH=0–600 m) to the southeast (MLH=600–900 m) and south
 270 (MLH=900–1200 m). Southerly winds can transport the gaseous pollutants or O₃ from the southern
 271 part of the plain area to the northern part, and the Taihang mountains may block pollutant transport,
 272 leading to pollutant accumulation at the foot of the Taihang Mountains. It should be noted that the
 273 concentration of MDA8 O₃ was higher when the plain was dominated by southerlies (180°–225°) when
 274 MLH was lower than 1200 m (Figure 4e). Generally, WS can affect the diffusion of air pollutants.
 275 Owing to the limited dilution and dispersion effects of weak winds, the MDA8 O₃ concentrations at low
 276 wind speed (0–1 m s⁻¹) were relatively higher than those of the other WS conditions (Figure 4d).

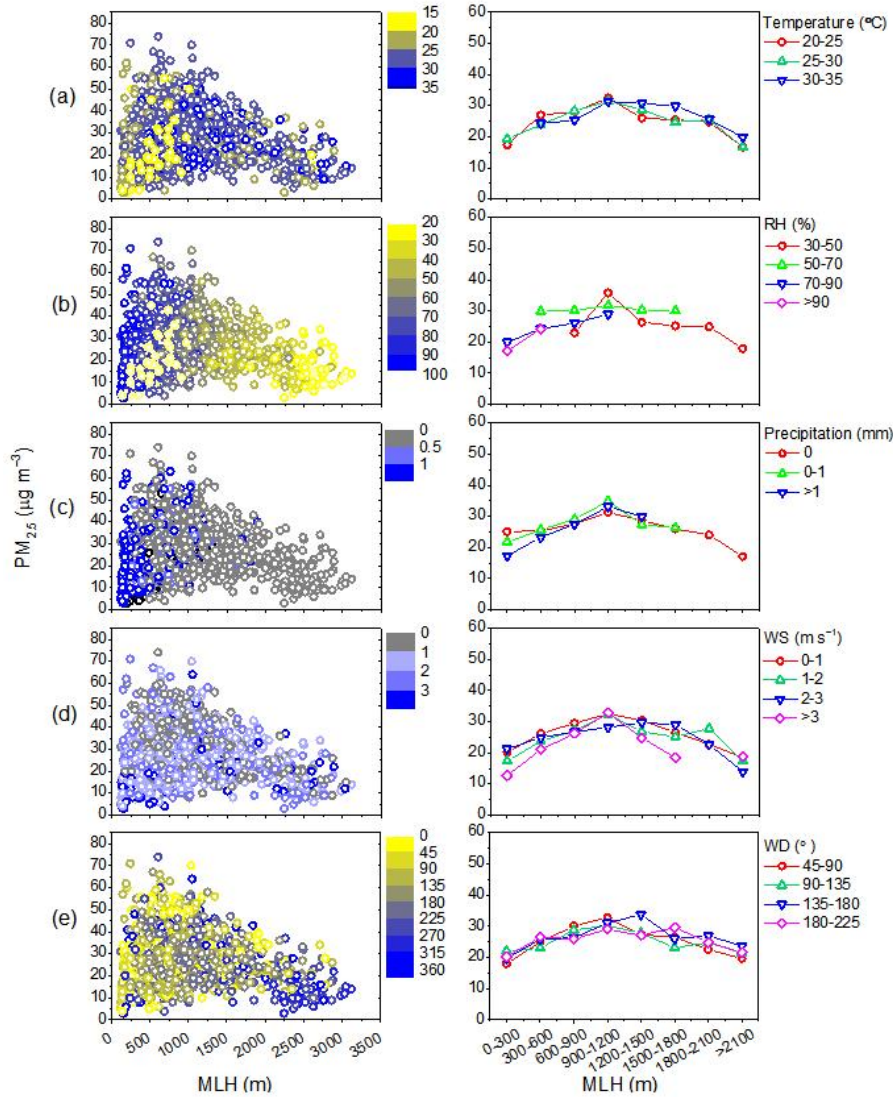

277
 278 **Figure 4.** Distribution characteristics of the MDA8 O₃ concentrations with the evolution of MLH under
 279 different (a) temperature, (b) RH, (c) precipitation, (d) WS, and (e) WD conditions.

280 **3.3 Evolution of PM_{2.5} and its secondary compositions with mixing layer meteorology**

281 The concentration distribution of surface PM_{2.5} in different MLH bins was shown in Figure 3b.
 282 Interestingly, PM_{2.5} showed a similar change profile as MDA8 O₃, which initially increased and then
 283 declined with the growth of MLH. PM_{2.5} concentration reached the maximum of 31.65 μg m⁻³ when
 284 MLH fell in the range of 900–1200 m, and the concentration has increased by 1.51 μg m⁻³ through the
 285 rise phase for the variation of 100 m MLH. This phenomenon differs from the results obtained in the
 286 cold season (Pan et al., 2019; Du et al., 2013; Murthy et al., 2020). It has been suggested that the
 287 narrowing of the mixing layer compressed air pollutants into a shallow layer, resulting in elevated
 288 pollution levels; thus, MLH has been illustrated as the key factor that aggravated the haze events in
 289 large cities of China in winter. However, the response of PM_{2.5} concentration to MLH is not only
 290 determined by the vertical stratification of the mixing layer, but also by local sources, secondary
 291 chemical formation, wet deposition, and the wind field (Lu et al., 2019; Geiß et al., 2017; Pan et al.,
 292 2019; Miao et al., 2021; Lou et al., 2019). It should be noted that in this work, there were still some
 293 extremely high PM_{2.5} values under low MLH conditions, as shown in Figure 3b. This phenomenon will
 294 be discussed in the following part when exploring the effect of precipitation.

295
 296 Figure 5. Variation characteristics of (a) SO₄²⁻, (b) NO₃⁻, (c) NH₄⁺, and (d) OC in different MLH
 297 conditions. Box plots show the inter quartile range (the distance between the bottom and the top of the
 298 box), median (the band inside the box), and 95 % confidence interval (whiskers above and below the
 299 box) of the data.

300

301 **Figure 6.** Distribution characteristics of the $PM_{2.5}$ concentrations with the evolution of MLH under
 302 different (a) temperature, (b) RH, (c) precipitation, (d) WS, and (e) WD conditions.

303 The response of $PM_{2.5}$ concentrations to mixing layer structure was the net effect of the changes in
 304 $PM_{2.5}$ major chemical components, such as SO_4^{2-} , NO_3^- , NH_4^+ , and OC. The changes in the major
 305 components of $PM_{2.5}$ due to the evolution of the mixing layer were shown in Figure 5. All the
 306 secondary components showed increasing trends when MLH was lower than 1200 m, with SO_4^{2-} and
 307 OC showing the highest increment, followed by NO_3^- and NH_4^+ . When MLH changed from 300–600
 308 m to 900–1200 m, the increment was not significant for NO_3^- and NH_4^+ . As NH_3 was generally
 309 abundantly supplied in the NCP, the formation of NH_4^+ was predominantly controlled by the reaction of
 310 ammonia with sulfate and nitrate aerosols, and the changes in NH_4^+ were a consequence of the changes
 311 in SO_4^{2-} and NO_3^- (Chow et al., 2022). When $MLH < 1200$ m, the mass fraction of NO_3^- was higher
 312 than SO_4^{2-} in $PM_{2.5}$ (Figure S3), and the change characteristics of NH_4^+ along with the evolution of

313 mixing layer were consistent with that of NO_3^- . The mass ratio of SO_4^{2-} to NO_3^- gradually increased
314 along with the development of mixing layer. When MLH was higher than 1200m, SO_4^{2-} surpassed
315 NO_3^- and became the dominant $\text{PM}_{2.5}$ component. The difference in the relationships between these
316 aerosol species and MLH reflected the intrinsic complexity mechanisms of $\text{PM}_{2.5}$ formation, which
317 were probably related to other meteorological parameters, such as temperature, RH, precipitation, WS,
318 and WD. To understand how the other meteorological factors impacted the relationship between MLH
319 and $\text{PM}_{2.5}$, we analyzed the statistics on the concentration distribution of $\text{PM}_{2.5}$ and its dominant
320 components with the increase in MLH under different RH, temperature, precipitation, WS, and WD
321 conditions (Figures 6 and 7).

322 Temperature is not only essential for the secondary chemical reaction of trace gases but also for
323 the gas-particle partitioning of volatile $\text{PM}_{2.5}$ species. The response of $\text{PM}_{2.5}$ and its dominant
324 components to MLH, followed similar change characteristics under different temperature conditions,
325 all increasing with the development of the mixing layer when MLH was lower than 1200 m. The
326 response of $\text{PM}_{2.5}$ to temperature was largely the result of opposite changes in NO_3^- and SO_4^{2-}
327 concentrations with a smaller role played by organics (Figure 7). Specifically, as MLH kept constant,
328 SO_4^{2-} concentration climbed up with increasing temperature level, while the concentration of NO_3^-
329 declined when temperature kept going up. Higher temperature may promote faster oxidation of SO_2 to
330 SO_4^{2-} , resulting in a significant increase in SO_4^{2-} concentrations. Unlike SO_4^{2-} , which predominantly
331 exists in the particle phase, NO_3^- could be either presented as nitric acid (HNO_3) in the gas phase or as
332 ammonium nitrate (NH_4NO_3) in the particle phase (Chow et al., 2022). Temperature strongly
333 influenced the partitioning of nitrate between the gas and particle phases. Higher temperature prompts
334 the partitioning of nitrate to HNO_3 ; thus, nitrate tends to exit in the gas phase, resulting in a significant
335 decrease in NO_3^- and NH_4^+ concentrations.

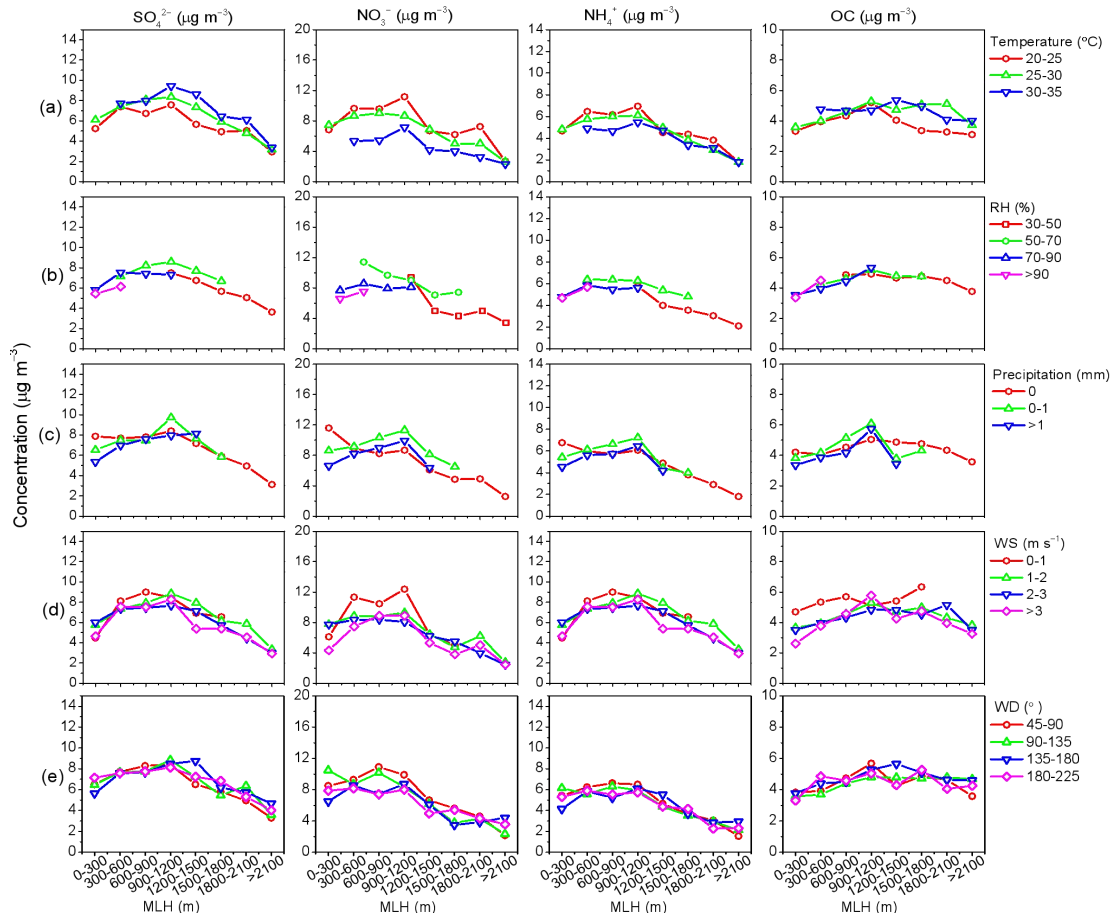

336 The response of $\text{PM}_{2.5}$ and its dominant components to the evolution of the mixing layer was more
337 sensitive to RH, and the distinct distribution characteristics under different RH ranges were shown in
338 Figures 6 (b) and 7 (b). When MLH fell in the range of 300–900 m, the concentration of $\text{PM}_{2.5}$ (Figure
339 6b) and its major components (Figure 7b) mostly decreased with RH rising from 50–70 % to 70–90 %.
340 Previous studies have shown that when RH higher than 60%, local humidity-related physicochemical
341 processes play important roles in transforming the gases into aerosols (Wang et al., 2022d; Liu et al.,
342 2020). We considered that the RH range from 50% to 70% was more beneficial for the aqueous

343 chemical production of major PM_{2.5} components, thus leading to the increase in PM_{2.5} concentration. It
344 is worth noting that when MLH fell in the range of 0–300 m, with RH increasing from 70–90 % to >
345 90 %, the concentration of PM_{2.5} (Figure 6b) and its major components (Figure 7b) severely decreased,
346 which was probably related to the fast hygroscopic growth and enhanced wet deposition processes.

347 All aerosol species have wet deposition as a major sink; therefore, precipitation is expected to
348 have significant effects on PM_{2.5} concentrations. As shown in Figure 6(c), changes in the
349 concentrations of PM_{2.5} were sensitive to rain events. When the MLH fell in the range of 0–300 m, the
350 concentration of PM_{2.5} significantly decreased during the rainfall period. Interestingly, when no rainfall
351 occurred, even though the PM_{2.5} concentration kept stable under low MLH conditions, its response of
352 PM_{2.5} concentrations to MLH followed an upward trend as the MLH increased from 300–600 to
353 900–1200 m. As for specific aerosol species (Figure 7c), NO₃⁻ and NH₄⁺ concentration showed two
354 prominent peaks, with one in the range of 0–300 m, and the other in 900–1200 m. Under low MLH
355 condition, the concentrations of NO₃⁻ and NH₄⁺ were high, with NO₃⁻ as the dominant species in PM_{2.5}
356 (Figure 8b). With the growth of MLH, NO₃⁻ and NH₄⁺ initially decreased, but turned to increase again
357 when MLH fell in the range of 900–1200 m. As for SO₄²⁻ and OC, the concentrations increased with
358 the elevation of MLH and has exceeded that of NO₃⁻ when MLH was higher than 1200 m. As shown in
359 Figure 8 (a), low mixing layer was generally accompanied by cloudy and rainy conditions during
360 summer in the NCP in 2021, and only a small fraction of days without rainfall were captured during
361 this period. Therefore, despite some high PM_{2.5} or major aerosol species values have been witnessed
362 under low MLH conditions, the overall trend in Figure 3 (b) was still upward along with the growth of
363 the mixing layer (MLH < 1200 m). The increase in PM_{2.5} and its major chemical components under
364 medium MLH conditions was not only associated with the weaker particle removal process by
365 precipitation, but also related to the enhancement of secondary aerosol formation due to the appropriate
366 chemical reaction environment.

367 WS can represent the atmospheric dissipation potential in the horizontal directions (Zhu et al.,
368 2018). Low WS generally suggests weak pressure gradients and potentially more favourable
369 meteorological conditions for PM_{2.5} enhancement (Ma et al., 2021). As expected, the concentrations of
370 PM_{2.5} (Figure 6d) and its aerosol species (Figure 7d) gradually decreased with increasing WS. The
371 response of these air pollutants to the MLH followed similar upward trends under different WS
372 conditions (MLH < 1200 m). Compared with O₃, the impact of WD along with the increase in MLH

373 seems different for PM_{2.5} and its dominant components. When the MLH fell in the range of 600–1200
 374 m, the NCP was dominated by southeast or southern winds (Figure 3d). However, when southeast or
 375 south winds prevailed, the corresponding PM_{2.5} and its dominant component concentrations were
 376 comparable or even lower than in other WD situations (Figures 6e and 7e). This indicated that regional
 377 transport was not the dominant factor leading to the elevation of PM_{2.5} and its aerosol species along
 378 with the evolution of the mixing layer (MLH < 1200 m).

379 **Figure 7.** Distribution characteristics of NO₃⁻, SO₄²⁻, NH₄⁺, and OC concentrations with the evolution
 380 of MLH under different conditions: (a) temperature, (b) RH, (c) precipitation, (d) WS, and (e) WD.

381

382 **Figure 8.** (a) Number distributions of the data when the daily precipitation larger than 0 mm or equal to
 383 0 mm along with the evolution of MLH. (b) Mass fractions of major PM_{2.5} components and the mass
 384 ratio of SO₄²⁻ to NO₃⁻ along with the evolution of MLH when the daily precipitation equal to 0 mm.

385 3.4 Superposition-composite effects of PM_{2.5} and O₃ with the evolution of mixing layer

386 3.4.1 A case study of the typical PM_{2.5}-O₃ co-polluted episode

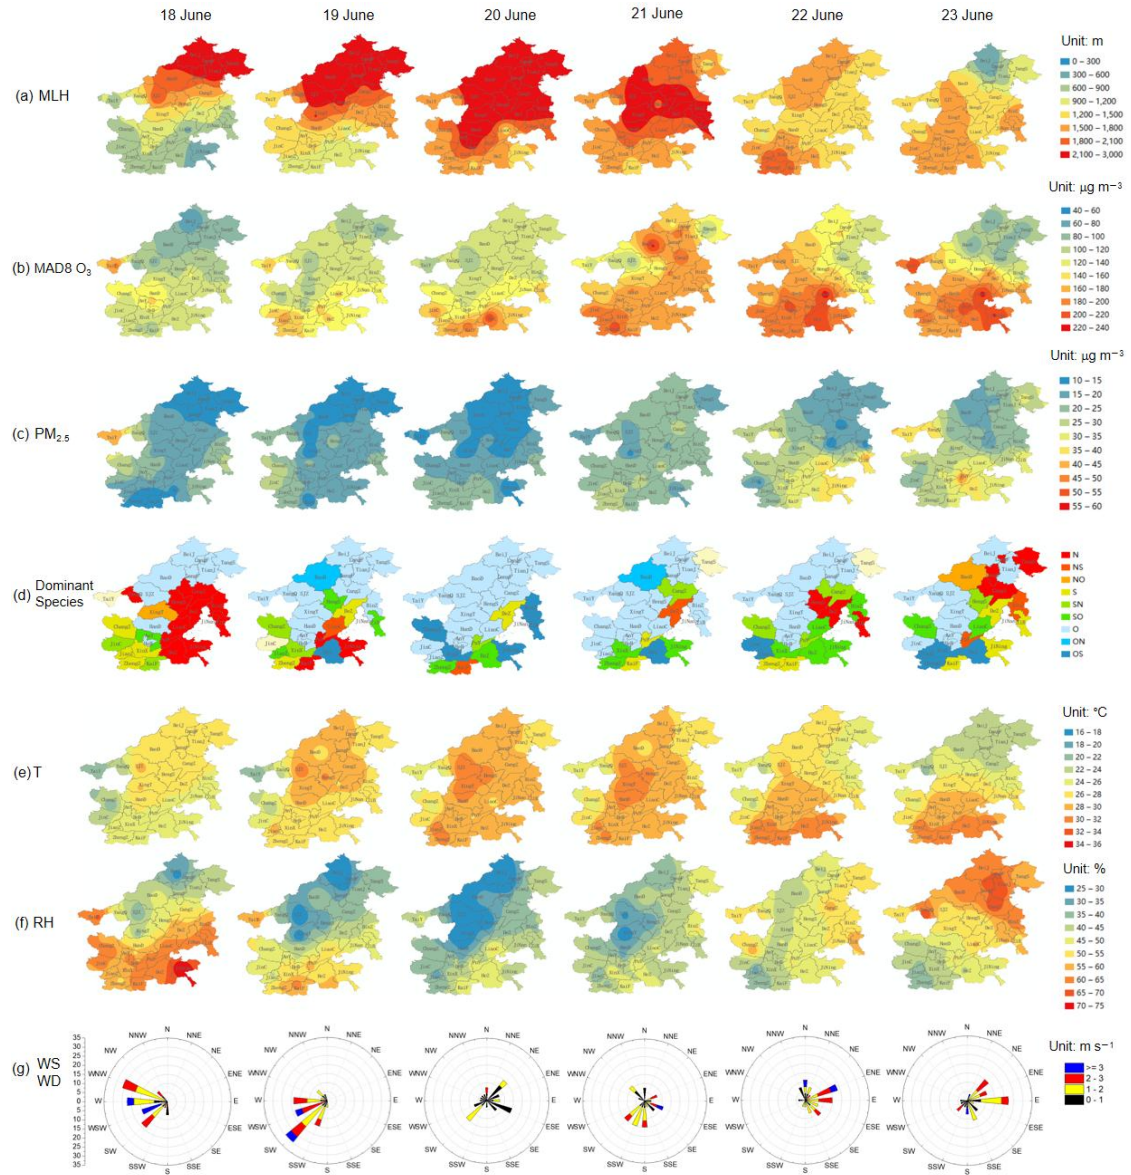

387 Previous results have indicated that MDA8 O₃ and PM_{2.5} concentrations were closely related to
 388 the evolution of the MLH. The increasing trend of PM_{2.5} concentration with the development of mixing
 389 layer under medium MLH condition indicated that the evolution of the mixing layer was not a simple
 390 physical dilution process, and its influence on the enhanced secondary photochemical formation should
 391 also be considered. We illustrated the relationship between the mixing layer and pollutant levels in
 392 Figures 9 and 10, showing a typical PM_{2.5}-O₃ co-polluted episode (Episode II) during June 18–29, 2021.
 393 On June 18–20, the MLH gradually increased from 600–1200 m to 1500–3000 m in the southern and
 394 eastern parts of the NCP, and the PM_{2.5} and MDA8 O₃ concentrations concurrently increased and
 395 showed similar spatial distributions. The WS dropped significantly on 20 June, and the value was lower
 396 than 1 m s⁻¹ in most cities. On 21–23 June, the MLH began to decrease from 1500–3000 m to
 397 1200–1800 m, PM_{2.5} and MDA8 O₃ concentrations further increased, and the areas of high PM_{2.5}
 398 concentrations also coincided well with those of MDA8 O₃ concentrations. During 24–25 June, the
 399 MLH continued to decrease, with some values even lower than 300 m. The MLH for the areas with
 400 high MDA8 O₃ was in the range of 900–1500 m. Interestingly, the synchronized spatial change
 401 characteristics of PM_{2.5} and MDA8 O₃ were consistent when MLH fell in the range of 900–1200 m, but
 402 inconsistent when MLH was lower than 600 m. Significant rise of PM_{2.5} concentration was observed in

403 some cities with MLH lower than 300 m. It is noted that the dominant chemical composition of PM_{2.5}
404 in these areas was NO₃⁻. On 28 June, the rise in MLH was observed in the central and the southern part
405 in the NCP, and a surge in MDA8 O₃ and PM_{2.5} concentrations occurred: with 160–220 and 40–50 μg
406 m⁻³ respectively. In general, most cities were dominated by weak winds from the east and southeast,
407 which favoured the formation of secondary pollutants from gaseous precursors transported from the
408 southeast part and promoted the accumulation of air pollutants.

409 To better understand this PM_{2.5}-O₃ co-polluted event, here we classified the observations during
410 this typical event into four categories: O₃ polluted days (O₃PD; MDA8 O₃ concentration > 160 μg m⁻³
411 and PM_{2.5} < 35 μg m⁻³), PM_{2.5} polluted days (PM_{2.5}PD; MDA8 O₃ concentration < 160 μg m⁻³ and
412 PM_{2.5} > 35 μg m⁻³), O₃-PM_{2.5} co-pollution days (O₃-PM_{2.5}CPD; MDA8 O₃ concentration > 160 μg m⁻³
413 and PM_{2.5} > 35 μg m⁻³), and non-polluted days (NPD; MDA8 O₃ < 80 μg m⁻³ and PM_{2.5} < 35 μg m⁻³).
414 The meteorological and chemical characteristics of the O₃-PM_{2.5}CPD, O₃PD, PM_{2.5}PD, and NPD were
415 presented in Figure 11. The results indicated that the values of MLH on O₃-PM_{2.5}CPD were between
416 those on O₃PD and PM_{2.5}PD at approximately 900 m. On O₃-PM_{2.5}CPD, the oxidation ratio of sulfate
417 (SOR, the molar ratio of sulfate to the sum of sulfate and SO₂) and oxidation ratio of nitrate (NOR, the
418 molar ratio of nitrate to the sum of nitrate and NO₂) were the highest, with values of 0.44 and 0.33,
419 respectively, which indicated the strong secondary formation of SO₄²⁻ and NO₃⁻ promoted by high O₃
420 concentration. The PM_{2.5}PD occurred when MLH was lower than 650 m, and the percentage of NO₃⁻
421 was the highest on PM_{2.5}PD. The rise in PM_{2.5} in some cities under low MLH conditions, may be
422 attributed to three mechanisms. The first is the accumulation effect due to unfavourable diffusion
423 conditions when MLH decreased. Secondly, these cities experienced little rain, and the effect of wet
424 deposition was weak. In addition, the corresponding low T and high RH stimulated the formation of
425 NO₃⁻ from gaseous state (HNO₃). On the O₃PD, the MLH was approximately 1300 m, and the NOR
426 turned to decrease, demonstrating a more significant role of the partitioning process between gas and
427 aerosols than that of the atmospheric oxidation process at this stage. On the NPD, the MLH was the
428 highest, with a value of approximately 2400 m, and the PM_{2.5} chemical composition was dominated by
429 OM.

430 To explore the relevance of hourly O₃, PM_{2.5}, its components, and MLH, we have taken PuY and
431 HeZ as examples. Figure S4 plotted the day-to-day variations along with the diurnal variations in O₃,
432 PM_{2.5}, its components, and MLH in PuY and HeZ during Episode II (June 18–29, 2021). The results

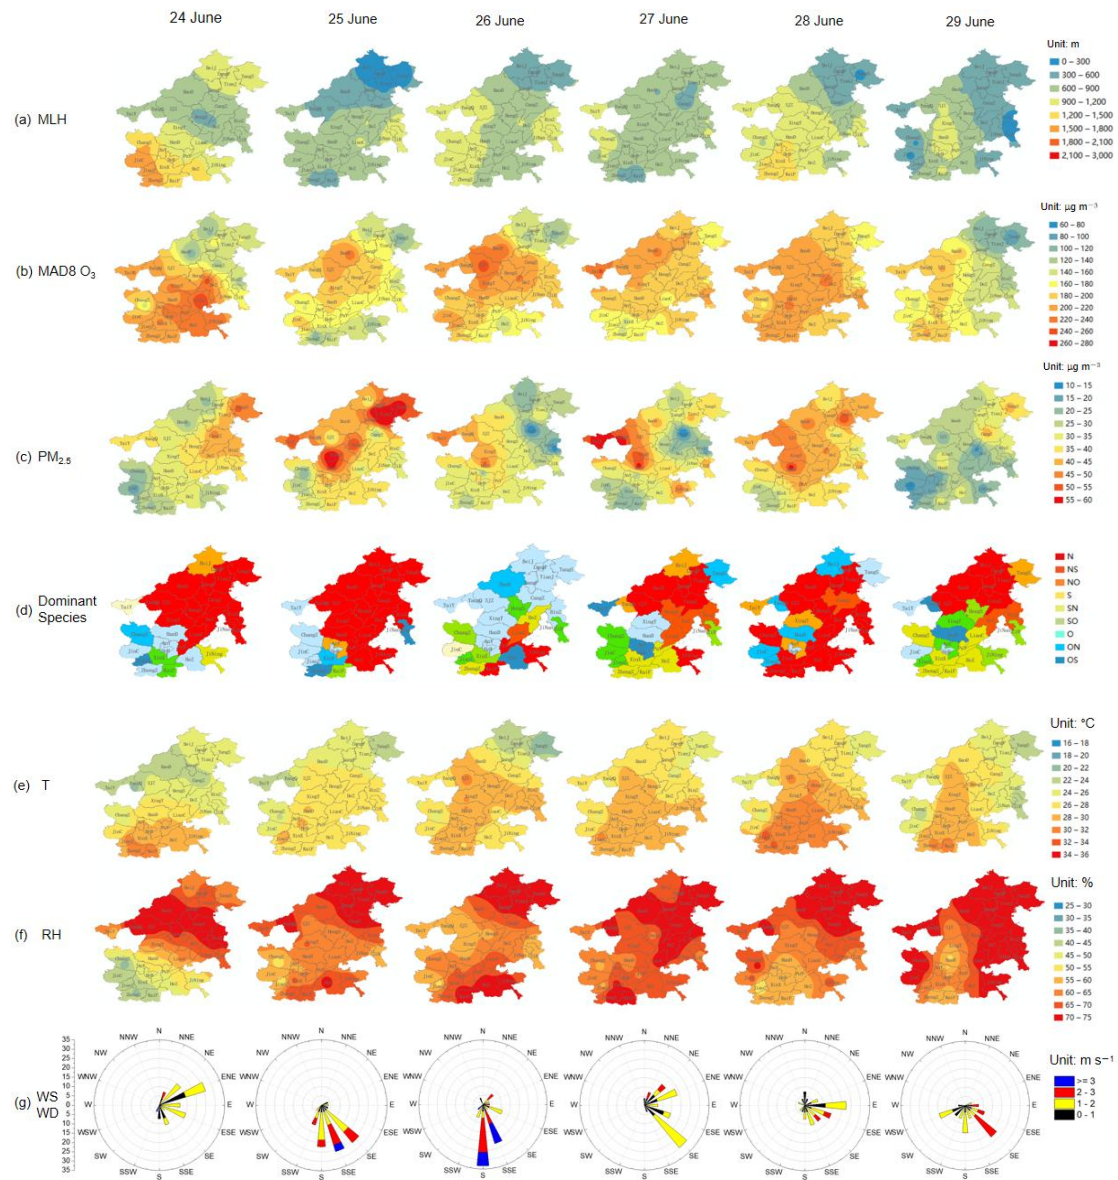

433 showed that there was large diurnal and day-to-day variability in O₃ and PM_{2.5} levels. Diurnal
434 variations in MLH were clearly visible (Figure S5), with an increase in MLH during the daytime and a
435 decrease at night. The concentration of PM_{2.5} increased with the decrease in MLH at night, but the
436 concentration of O₃ increased with an increase in MLH during the daytime. Interestingly, we observed
437 noontime soar of SO₄²⁻ and OC concentrations in PuY, and the values of SOR remained stable or even
438 increased at noon. Additionally, O₃ and PM_{2.5} gradually accumulated with the development of mixing
439 layer during June 18–21 and 26–28, which can be attributed to the O₃ and PM_{2.5}
440 superposition-composite effects. The decrease in PM_{2.5} during the daytime with the rise in MLH, can
441 be offset partly by an increment in secondary pollutant formation derived from O₃ growth. Then, with
442 the decrease in MLH at night, the concentration of the original existing PM_{2.5} increased owing to
443 unfavourable diffusion. In general, the conclusions of this study are only suitable for the day-to-day
444 relationship between air pollutants and MLH. Hourly relationships are much more complicated and
445 require further analysis.
446

447

448

449 **Figure 9.** Spatial distribution of (a) MLH, (b) MDA8 O₃, (c) PM_{2.5}, (d) the dominant PM_{2.5} chemical
 450 component (N: NO₃⁻ dominant, NS: NO₃⁻ and SO₄²⁻ dominant, NO: NO₃⁻ and OM dominant, S: SO₄²⁻
 451 dominant, SN: SO₄²⁻ and NO₃⁻ dominant, SO: SO₄²⁻ and OM dominant, O: OM dominant, ON: OM
 452 and NO₃⁻ dominant, OS: OM and SO₄²⁻ dominant), (e) T, and (f) RH, (g) the overall change
 453 characteristics of WS and WD in the NCP from June 18 to 23, 2021. The dominant PM_{2.5} chemical
 454 component type was identified as the method proposed by Wang et al. (2022b): if the mass fraction of
 455 the maximum component was 1.2 times higher than that of the secondary one, the former was
 456 considered as the dominant factor, otherwise both dominated PM_{2.5} formation.

457

458

459 **Figure 10.** Spatial distribution of (a) MLH, (b) MDA8 O₃, (c) PM_{2.5}, (d) the dominant PM_{2.5} chemical
 460 component (N: NO₃⁻ dominant, NS: NO₃⁻ and SO₄²⁻ dominant, NO: NO₃⁻ and OM dominant, S: SO₄²⁻
 461 dominant, SN: SO₄²⁻ and NO₃⁻ dominant, SO: SO₄²⁻ and OM dominant, O: OM dominant, ON: OM
 462 and NO₃⁻ dominant, OS: OM and SO₄²⁻ dominant), (e) T, and (f) RH, (g) the overall change
 463 characteristics of WS and WD in the NCP from June 24 to 29, 2021. The dominant PM_{2.5} chemical
 464 component type was identified as the method proposed by Wang et al. (2022b): if the mass fraction of
 465 the maximum component was 1.2 times higher than that of the secondary one, the former was
 466 considered as the dominant factor, otherwise both dominated PM_{2.5} formation.

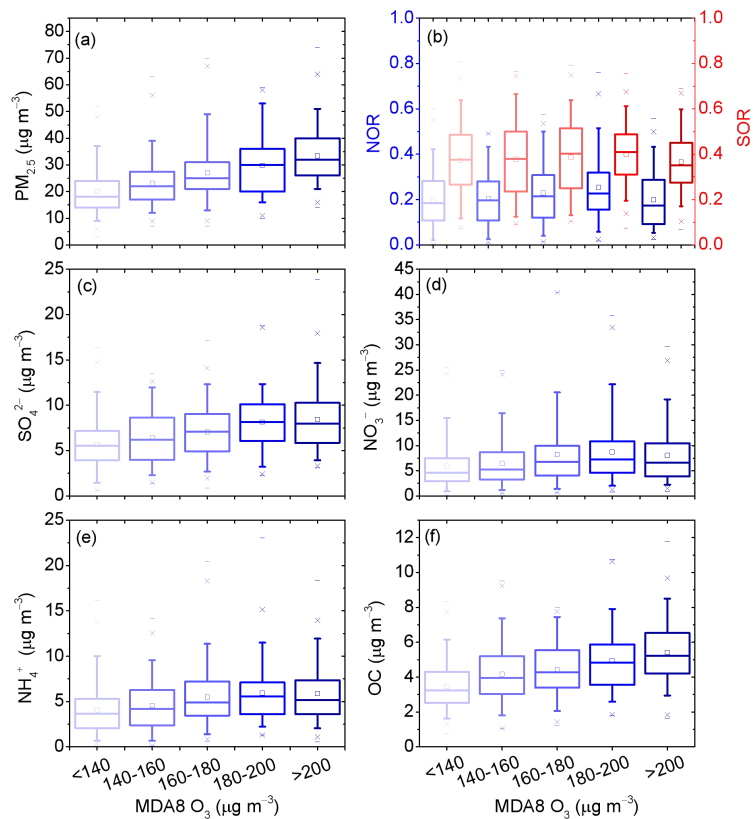

467

468 **Figure 11.** Distribution characteristics of (a) NOR and SOR, and (b) the mass fractions of major PM_{2.5}

469 components, MLH, RH, and temperature under O₃-PM_{2.5} CPD, O₃ PD, PM_{2.5} PD, and NPD conditions

470 from June 24 to 29, 2021.

471 **3.4.2 Interaction between PM_{2.5} and O₃ along with the evolution of MLH**

472

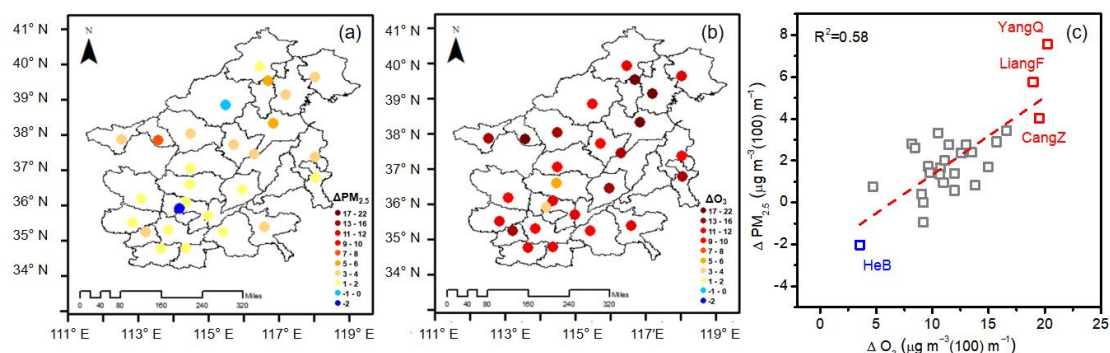

473 **Figure 12.** Box plots showing the statistics of (a) PM_{2.5}, (b) NOR and SOR, (c) SO₄²⁻, (d) NO₃⁻, (e)
474 NH₄⁺, and (f) OC for different MDA8 O₃ conditions (< 140, 140–160, 160–180, 180–200, and > 200
475 μg m⁻³). The distance between the bottom and the top of the box reflects the inter quartile range; the
476 line and square in between are the median and mean values, respectively. The whiskers above and
477 below the box refer the 95 % confidence interval of the data. Note that rainy days were excluded.

478 Figure 12 displays the box-and-whisker plots of PM_{2.5} and its major components for different
479 MDA8 O₃ conditions. To isolate the impacts of precipitation on PM_{2.5} concentration, these rainy days
480 when the daily rainfall amount greater than 0 mm were excluded. Here the concentrations of PM_{2.5} and
481 its major components were found to increase synchronously with elevated MDA8 O₃ concentration,
482 especially when MDA8 O₃ increased from < 140 to 180–200 μg m⁻³. This summertime collaborative
483 growth process of PM_{2.5}-O₃ has also been observed in other studies (Wang et al., 2022a; Wu et al.,
484 2022). With elevated MDA8 O₃ concentration, SOR and NOR both slightly increased, and reached the
485 maximum when MDA8 O₃ at around 160–200 μg m⁻³, which indicated the strong secondary formation
486 of SO₄²⁻ and NO₃⁻ promoted by high O₃ concentration. When MDA8 O₃ increased from 180–200 to >
487 200 μg m⁻³, the concentrations of NO₃⁻, NH₄⁺, and SO₄²⁻ kept stable or began to decrease, and the
488 values of SOR and NOR decreased synchronously. During this stage, the high O₃ concentration often
489 accompanied by dry and hot meteorological conditions, which was not beneficial to aqueous chemical
490 production and was conducive to the partitioning of nitrate to the gas phase.

491 To verify the potential impact of photochemical oxidation to the increase of PM_{2.5} concentration
492 with mixing layer development, the changes in PM_{2.5} and MDA8 O₃ along with the increase of MLH
493 were quantified in the “2+26” cities in the NCP. Linear regression equations between air pollutants and
494 MLH were fitted during the initial increasing stage (300 m < MLH < 1200 m) and their slopes were
495 shown in Figure 13. The slopes indicated the rates of the maximum changes in air pollutant
496 concentration per unit change in the MLH (100 m). The slopes of PM_{2.5} and O₃ were expressed as
497 ΔPM_{2.5} and ΔO₃ (μg m⁻³ (100) m⁻¹). It was found that ΔPM_{2.5} was closely related to ΔO₃ (R²=0.58), and
498 spatial difference in ΔPM_{2.5} and ΔO₃ was witnessed in the NCP during the observation period. ΔPM_{2.5}
499 and ΔO₃ both showed high values in YangQ, , LangF and CangZ, with values of 7.56 and 20.24 μg m⁻³
500 (100) m⁻¹ in YangQ, 5.75 and 18.97 μg m⁻³ (100) m⁻¹ in LangF, and 4.02 and 19.49 μg m⁻³ (100) m⁻¹ in
501 CangZ, respectively. Comparing with these cities, ΔPM_{2.5} and ΔO₃ were lowest in HeB, with the value
502 of 3.54 and -2.02 μg m⁻³ (100) m⁻¹, respectively, which implied that the secondary formation here was

503 weak and the surface $PM_{2.5}$ change characteristic was dominantly controlled by local emissions or
 504 vertical diffusion effect.

505 Compared to winter, photochemistry in summer is quite active because of strong solar radiation.
 506 Although a deep MLH favors the dilution of air pollutants, a higher MLH can also promote secondary
 507 chemical feedback by enhancing the availability of atmospheric oxidation capacity (such as changes in
 508 O_3) along with appropriate meteorological conditions. This conclusion corresponds well with the
 509 findings based on the chemical transport model (Dai et al., 2023), which proposed strong chemical
 510 production of secondary aerosols when the planetary boundary layer height was approximately 946.1m
 511 on O_3 - $PM_{2.5}$ co-pollution days. The strong chemical productions in the oxidative atmosphere at
 512 medium MLH condition may overcome the dilution effect on $PM_{2.5}$ induced by mixing layer
 513 development, leading to higher $PM_{2.5}$ level at the ground level. However, it should be noted that the
 514 conclusions of this study are only suitable for summertime regional observations, especially for warm
 515 and humid season. Conditions were different in winter (much lower O_3 levels). More extended
 516 observations in time and space are needed in the future to further examine and better understand the
 517 complex interactions between MLH, air pollution, and chemical processing.

518
 519 **Figure 13.** Spatial distribution of (a) $\Delta PM_{2.5}$ and (b) ΔO_3 . (c) The relationships between $\Delta PM_{2.5}$ and
 520 ΔO_3 in the NCP during summertime. The corresponding correlation coefficients (R^2) was given at the
 521 top of the panel.

522 4 Conclusions

523 The MLH is generally considered as a critical physical parameter in atmospheric environmental
 524 evaluation. It is assumed that an extended mixing layer may lead to the dilution of air pollutants and
 525 thus tend to decrease surface concentrations. Several publications have indeed reported such

526 anti-correlations in cold seasons. However, the understanding of the interaction between near surface
527 O₃ and PM_{2.5} (including its major components) along with the evolution of the mixing layer during
528 warm season, remains poor. Furthermore, previous observational studies were mostly limited to
529 specific cities. This paper is devoted to these topics by examining the response of MDA8 O₃, PM_{2.5},
530 and its major components to the changes in mixing layer meteorology in the NCP during summer. We
531 showed that MDA8 O₃ initially increased and then decreased with the growth of MLH. The maximum
532 turning point of the MLH was approximately 900–1800 m. As for near-ground PM_{2.5}, a similar
533 non-linear change profile was found, with the maximum value of 31.65 μg m⁻³ under medium MLH
534 condition (900–1200 m), which was quite different from the results conducted in cold season.
535 Compared to winter, the occurrence of low MLH during summer in the NCP was mostly accompanied
536 by cloudy or rainy conditions, which promoted wet deposition and led to low concentrations of PM_{2.5} at
537 the ground level. Under medium MLH condition, strong chemical productions of SO₄²⁻ and OC
538 occurred along with appropriate mixing layer meteorology, where RH was around 50–70 %, and the
539 availability of atmospheric oxidants (i.e., O₃) increased. Strong chemical productions under medium
540 MLH conditions may offset the diffusion effect on PM_{2.5} induced by the mixing layer development,
541 resulting in higher PM_{2.5}. The chemical characteristics of PM_{2.5} changed significantly with the growth
542 of MLH. The composited concentration of NO₃⁻ was the highest under low MLH condition, while the
543 composited concentrations of SO₄²⁻ and OC increased under medium MLH condition. Temperature was
544 the key factor controlling the different changes in NO₃⁻ and SO₄²⁻ concentrations in PM_{2.5}. We
545 conclude that MLH can be an indicator of air pollutants in cold seasons, but the correlation between
546 MLH and air pollutants, such as O₃ and PM_{2.5}, should be treated with care during hot season. At least
547 for the observation period in the NCP this was not the case. Although several studies have examined
548 the change characteristics of the MLH and its influence on ground-level O₃ and PM_{2.5}, it remains
549 challenging to elucidate the mechanisms underlying these complex relationships. In this study, we did
550 not quantify the sensitivity of O₃ and PM_{2.5} to different meteorological factors and chemical processes.
551 To better understand the complex interactions among MLH, air pollution, and chemical processing, a
552 more detailed consideration of the aids of explicit models should be needed in the future. We also note
553 that the present study is only confined to summer conditions (including two summer months) in the
554 NCP, and the conclusions are likely to differ for other seasons and regions. Therefore, more extensive
555 observations in time and space are required in the future.
