11 **Abstract.** Measurements of surface ozone (O₃), PM_{2.5} and its major secondary components (SO₄²⁻,
12 NO₃⁻, NH₄⁺, and OC), mixing layer height (MLH) and other meteorological parameters were made in
13 the North China Plain (NCP) during warm seasons (June–July) in 2021. The observation results
14 showed that the summertime regional MDA8 O₃ initially increased and reached the maximum (158.47
15 μg m⁻³) when MLH at around 900–1200 m, then turned to decrease with further evolution of MLH.
16 Interestingly, synchronized increases in PM_{2.5} concentration along with the development of the mixing
17 layer (MLH < 1200 m) have been witnessed, and the positive response of PM_{2.5} to MLH was
18 significantly associated with the increase in SO₄²⁻ and OC. It was found that this increasing trend of
19 PM_{2.5} with elevated MLH was not only determined by the effect of wet deposition process but also by
20 the enhanced secondary chemical formation, which was related to appropriate meteorological
21 conditions (50 % < RH < 70 %) and increased availability of atmospheric oxidants. Air temperature
22 played a minor role in the change characteristics of PM_{2.5} concentration, but greatly controlled the
23 competing role of SO₄²⁻ and NO₃⁻. The concentrations of SO₄²⁻ and OC increased synchronously with
24 elevated MDA8 O₃ concentration, and the initial increase of PM_{2.5} along with the increased MLH
25 corresponded well with that of MDA8 O₃. We highlight that the correlation between MLH and
26 secondary air pollutants should be treated with care in hot seasons, and the impact of atmospheric
27 oxidation capacity on surface PM_{2.5} change profile along with the evolution of mixing layer should be
28 considered when developing PM_{2.5}-O₃ coordinated control strategies.

29

30

31

32 **1 Introduction**

33 Surface ozone (O_3) and $PM_{2.5}$ (atmospheric fine particles with an aerodynamic diameter of less
34 than $2.5 \mu m$) are important air pollutants in the atmosphere and have aroused a lot of attention from the
35 public due to their adverse health impact (Jiang et al., 2018; Cohen et al., 2017; Gao and Ji, 2018).
36 Even though stringent clean air actions have been implemented in China during the past decade, high
37 concentrations of O_3 and/or $PM_{2.5}$ exceeding the national air quality standards still occurred during
38 warm seasons (June–August) in China, especially in the North China Plain (NCP), the economic center
39 of China (Dai et al., 2023). O_3 is a secondary pollutant originated from photochemical oxidation of
40 volatile organic compounds (VOC) and carbon monoxide (CO) in the presence of nitrogen oxides
41 (NO_x), and $PM_{2.5}$ is mainly determined by the atmospheric processes of emissions and secondary
42 formation from gaseous precursors. In addition to air pollutant emissions, meteorological conditions
43 play critical roles in the formation of $PM_{2.5}$ and O_3 (Miao et al., 2021). Mixing layer height (MLH),
44 which influences the vertical mixing within the pollution mixing layer and determines the dilution of
45 pollutants emitted near the ground (Haman et al., 2014; Zhu et al., 2018; Lou et al., 2019), often serves
46 as a critical physical parameter in atmospheric environmental evaluation. Elucidating the association of
47 MLH with surface O_3 and $PM_{2.5}$ is fundamental for the development of $PM_{2.5}$ - O_3 coordinated control
48 strategies.

49 The response of air pollution to MLH was changeable and complicated (Miao et al., 2021).
50 Previous works frequently assumed that the narrowing of mixing layer resulted in accumulation of
51 pollutants near the ground and the increase in MLH was expected to reduce $PM_{2.5}$ concentration due to
52 dilution (Murthy et al., 2020; Du et al., 2013). However, the relationship between mixing layer
53 structure and $PM_{2.5}$ concentration depends on the site, observation period, and the properties of MLH
54 retrievals (Geiß et al., 2017). Even though the link between $PM_{2.5}$ concentrations and MLH has been
55 investigated in many studies, most observations were conducted in winter conditions and few studies in
56 hot seasons. Interestingly, in some cities, such as Delhi (Murthy et al., 2020) and Shanghai (Pan et al.,
57 2019; Miao et al., 2021), the increase in $PM_{2.5}$ has been observed when MLH increased during
58 summertime. As for O_3 , the relationship between the changes in the MLH and O_3 concentrations is very
59 complex. Both increase or decrease of O_3 has been observed corresponded to the growth of MLH. To
60 first order, O_3 concentration decreases along with the increase of MLH owing to dilution. Second, an

61 increase in MLH generally promotes the downward mixing of upper air containing higher O₃ (Ma et al.,
62 2021; Haman et al., 2014; Xu et al., 2018). In addition, the meteorological conditions along with the
63 changes of MLH can influence O₃ concentrations through effecting O₃ gaseous precursors or
64 production rates (Porter and Heald, 2019; Zhang et al., 2022). The combined effects of these processes
65 ultimately determine whether O₃ decreases or increases.

66 Other meteorological variables in the mixing layer were also found to significantly affect PM_{2.5}
67 and O₃ concentrations. The poor air quality in the NCP was tightly associated with near-surface
68 southerly winds and warm stagnant conditions during summertime (Zhang et al., 2015a). The increase
69 in PM_{2.5} concentration often coincided with high relative humidity (RH) conditions (Liu et al., 2017b),
70 which was beneficial to liquid-phase heterogeneous reactions and fine particle hygroscopic growth
71 (Seinfeld and Pandis, 2006; Wang et al., 2016; Zhang et al., 2015b). Temperature was essential to
72 secondary chemical reaction (Dawson et al., 2007). The increase in temperature can promote chemical
73 reaction rates, but also stimulate the evaporation of semi-volatile aerosol components, such as nitrate
74 (Wen et al., 2018). For O₃, elevated O₃ concentrations generally happened on days with strong sunlight
75 and low wind speeds, which favored the photochemical production and the accumulation of O₃ and its
76 precursors. Several studies have shown that O₃ was significantly positive correlated with temperature,
77 but negatively correlated with RH (Li et al., 2021; Hou and Wu, 2016; Steiner et al., 2010).

78 Secondary PM_{2.5} species, e.g., sulfate (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺), and organic
79 matter (OM), have increased dramatically in recent years (Cheng et al., 2019; Wang et al., 2022b), and
80 the correlation between O₃ and PM_{2.5} tended to change from negative to positive from 2013 to 2018 in
81 China (Chu et al., 2020). Previous studies have reported that the increased O₃ concentration may cause
82 the enhancement of atmospheric oxidation capacity, thus influencing the chemical compositions,
83 formation pathways, and evolution processes of PM_{2.5} (Cheng et al., 2019; Kang et al., 2021). Even
84 though some studies have discussed the correlations between MLH and some secondary pollutants, the
85 understanding of the interaction between O₃ and PM_{2.5} (including its major components) along with the
86 evolution of mixing layer during warm seasons remained poor owing to the limited observations of
87 PM_{2.5} chemical species involved. The regional-scale observation can represent the variation
88 characteristics for this area and avoid the spatial heterogeneity between the sites. However, to the best
89 of our knowledge, previous observational studies were mostly limited to specific cities. Therefore, it's
90 encouraged to analyze multiple data sources to determine overall trends rather than making conclusions

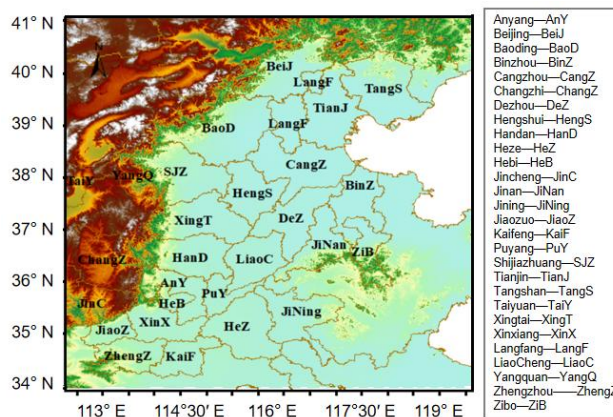

91 based on a single dataset.

92 To enhance the understanding of the linkages between mixing layer structure and air pollution, in
 93 this study, a regional-scale field observation of meteorological factors, O₃, PM_{2.5} concentration and its
 94 secondary composition were conducted in the North China Plain (NCP) during a period of severe
 95 photochemical pollution (June–July) in 2021. For the first time, the potential association among
 96 ground-level observed O₃, PM_{2.5} and its dominant components, and mixing layer meteorological
 97 conditions will be explored in the NCP during summertime.

98 **2 Data and methods**

99 **2.1 Measurements**

100

101 **Figure 1.** Location of monitoring stations in the NCP.

102 In this study, observation was made in the North China Plain (NCP) from June 1 to July 31, 2021.
 103 The air pollution observation stations in the NCP covered two megacities (BeiJ and TianJ) and 26
 104 surrounding cities. The geographic locations of these stations are marked in Figure 1. The ground-level
 105 O₃, PM_{2.5} and its major components (SO₄²⁻, NO₃⁻, NH₄⁺, and OC), and meteorological variables were
 106 obtained from the platform of National Atmospheric Particulate Chemical-Speciation-Network, which
 107 is established for improving the understanding of the heavy pollution formation mechanism in the NCP
 108 and supporting the decision-making of local governments and state administration. Near-ground
 109 meteorological variables included the relative humidity (RH), wind speed (WS), temperature, air
 110 pressure and daily accumulated precipitation. Mass concentrations of SO₄²⁻, NO₃⁻, and NH₄⁺ in PM_{2.5}
 111 were continuously measured at a 1-h resolution by MARGA (model ADI 2080) or AIM-IC (URG

112 9000D) equipped with a PM_{2.5} sampling inlet. Organic carbon (OC) was measured online by Sunset
113 Semi-Continuous Carbon Analyzer (Sunset Laboratory Inc, USA). PM_{2.5}, O₃, and other gaseous
114 pollutants, such as NO₂ and SO₂, were recorded hourly, mainly based on Thermo Scientific samplers
115 and analyzers. Detailed descriptions of these online sampling instruments can be found in our previous
116 works (Kong et al., 2018; Liu et al., 2017a; Pang et al., 2020; Wang et al., 2022b). In this work, O₃
117 concentration was characterized by the daily maximum 8-h average (MDA8), and the other pollutants
118 were obtained and recorded by the daily mean in each site to avoid the effect of diurnal variability. The
119 vertical profiles of O₃ and aerosol characteristics in BeiJ, SJZ and TangS were measured by the DIAL
120 system, which was developed by the Anhui Institute of Optics and Fine Mechanics (Chinese Academy
121 of Sciences). The overall structure of the DIAL consists of three systems: a emitting system, a
122 receiving system, and a data acquisition system, and the detail information can be found in the work by
123 Wang et al. (2021).

124 2.2 The calculation of mixing layer heights

125 From the perspective of atmospheric turbulent motion, the height of the interface, where
126 turbulence is discontinuous, is usually referred to as the mixing layer height (MLH; Stull, 1988). MLH
127 can not be obtained through conventional surface meteorological observations, and it is necessary to
128 use meteorological elements, such as temperature, RH, and air pressure for diagnosis. However, owing
129 to the difficulty in obtaining the vertical distribution of turbulent parameters, in practical applications,
130 MLH is usually determined from the thermal and dynamic effects reflecting turbulent motion. The
131 work by Wang et al. (2022c) has pointed out that the lifting condensation level (LCL) satisfying the
132 supersaturated state can be approximated to MLH. According to the method proposed by Wang et al.
133 (2017), MLH is calculated based on the following equation and represented by air pressure (p):

$$134 \text{ MLH} \approx \text{LCL} = 6.11 \times 10^2 \times \left(\frac{0.622 + 0.622 \frac{e_s}{p - e_s}}{0.622 \frac{e_s}{p - e_s}} \right), \quad (1)$$

$$135 e_s = 6.22 \times \exp \frac{17.13(T - 273.16)}{T - 38}, \quad (2)$$

136 where e_s represents saturated water vapor pressure, T is temperature (K). According to the relationship
137 between air pressure and height, the units of MLH can be converted to the height expression in meters:

$$138 \int_{p_0}^{p_z} dp = - \int_0^z \rho_0 g dz, \quad (3)$$

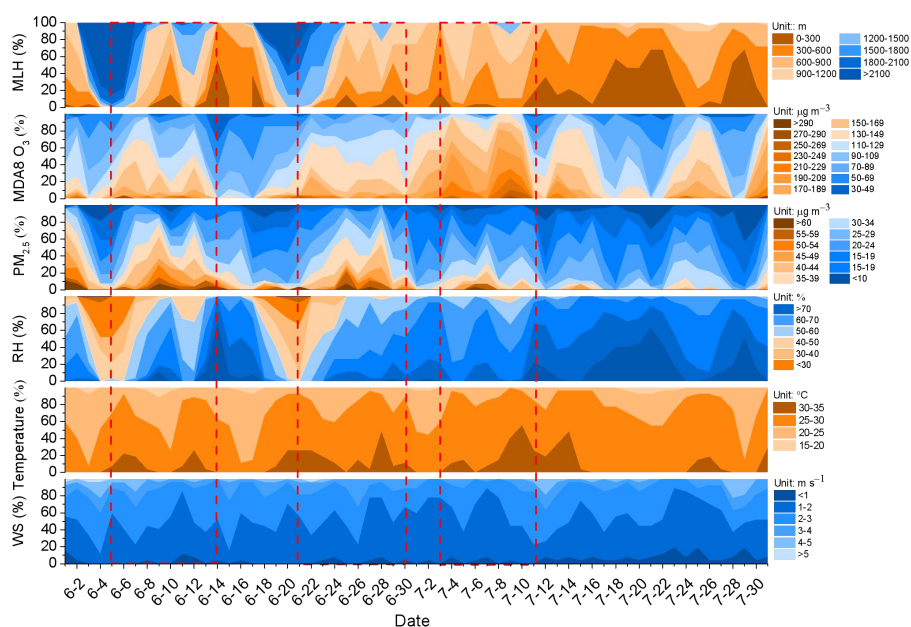

139 where z is the height, ρ_0 is the density of gas, p_z and p_0 represent the air pressure in the height of z and

140 0, respectively.

141 **3 Results and discussions**

142 **3.1 General characteristics**

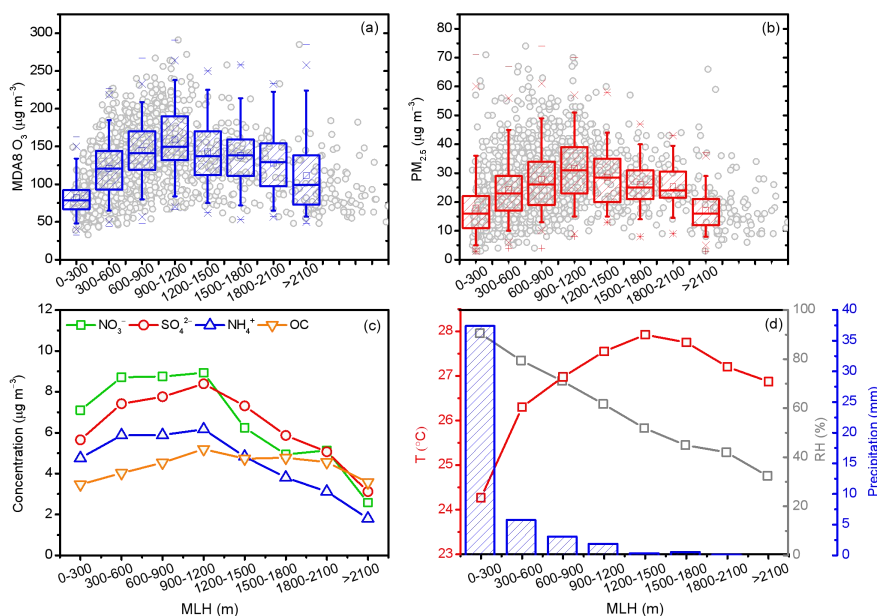

143
 144 **Figure 2.** The frequency (% , ratio of occurrence cities to total NCP cities) of PM_{2.5}, MAD8 O₃, and
 145 meteorological factors in the NCP from June 1 to July 31, 2021. The color shading represents different
 146 categories classified by PM_{2.5}, MDA8 O₃, and meteorological factors. The red dash boxes represent
 147 three typical PM_{2.5} and O₃ pollution episodes.

148 The summertime change characteristics of ground-level meteorological factors (MLH, RH,
 149 temperature, and WS), MDA8 O₃, PM_{2.5} and its major components in the NCP were demonstrated in
 150 Figure 2 and Figure S1. From June 1 to July 31, 2021, regional PM_{2.5} pollution processes corresponded
 151 well with the increasing processes of MDA8 O₃, and three concurring PM_{2.5} and O₃ pollution episodes
 152 have happened: June 5–14 (Episode I), June 21–30 (Episode II), and July 3–11 (Episode III), 2021.
 153 During the observation period, the change characteristics of PM_{2.5} and MDA8 O₃ concentrations were
 154 closely related to the evolution of mixing layer and associated meteorological conditions. Along with
 155 the reduction of MLH in Episode I and II, regional MDA8 O₃ and PM_{2.5} concentration both gradually
 156 climbed up. When MLH fell in the range of 900–1500 m, MDA8 O₃ concentration reached the

157 maximum with about 60 % areas higher than $130 \mu\text{g m}^{-3}$. When MLH further decreased, MDA8 O_3
 158 turned to decline, while $\text{PM}_{2.5}$ continued to increase until regional MLH lower than 600 m. In Episode
 159 III, the MLH in most cities was around 600–1200 m, and the regional MDA8 O_3 pollution conditions
 160 were much serious than other episodes, with 80 % MDA8 O_3 values higher than $150 \mu\text{g m}^{-3}$. Generally,
 161 the concentration peaks of $\text{PM}_{2.5}$ lagged behind that of MDA8 O_3 along with the reduction of MLH.
 162 Besides, we found that the change characteristics of SO_4^{2-} and NO_3^- were different (Figure S1), and the
 163 regional peaks of these two components were inconsistent, especially in Episode II. With the evolution
 164 of MLH, NO_3^- climbed up and peaked in June 24 when regional MLH lower that 900 m, while SO_4^{2-}
 165 reached the maximum in June 28 when MLH was around 900–1500 m. This may be related to other
 166 synchronized mixing layer meteorology factors, such as RH and temperature. For example, the
 167 evolution of mixing layer often accompanied with changes in temperature. The increase in temperature
 168 can promote the chemical formation rate of these secondary components, but also stimulate the
 169 volatilization of NO_3^- to gaseous state (HNO_3) and lead to the decrease in NO_3^- concentration. Further
 170 analysis about the response of O_3 , $\text{PM}_{2.5}$ and its secondary components to different mixing layer
 171 meteorology factors will be conducted in the following sections.

172 **3.2 Evolution of ozone with mixing layer meteorology**

173

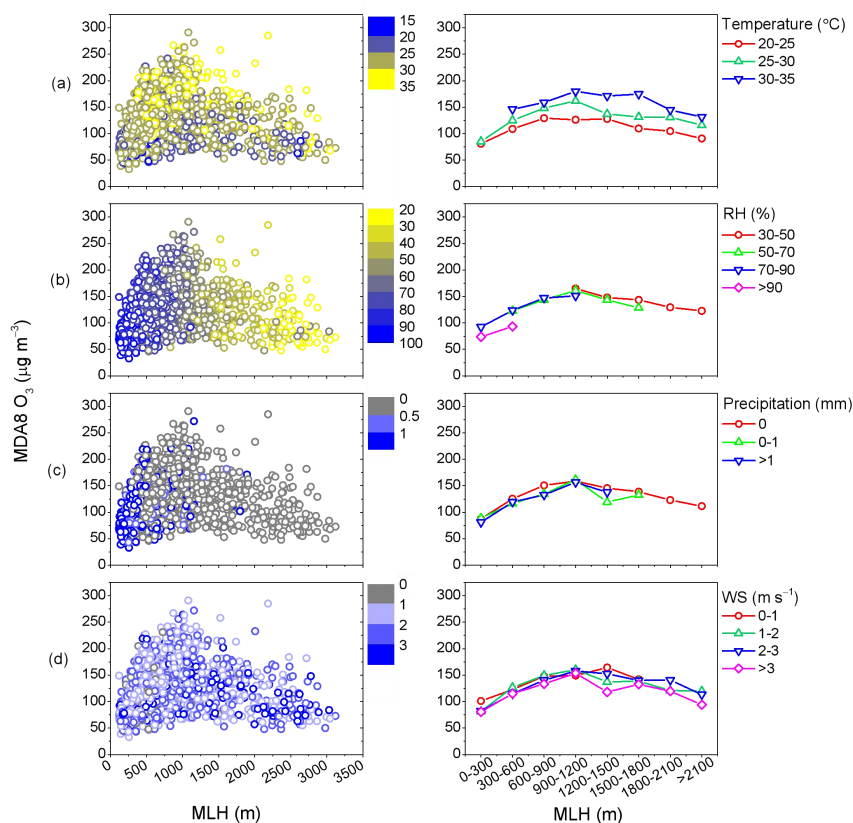

174 **Figure 3.** The variation characteristics of (a) MDA8 O₃, (b) PM_{2.5}, (c) major secondary aerosol species,
175 and (d) meteorological parameters in different MLH conditions. Box plots in (a) and (b) show the inter
176 quartile range (the distance between the bottom and the top of the box), median (the band inside the
177 box), and 95 % confidence interval (whiskers above and below the box) of the data.

178 To quantify the effect of MLH on near-ground O₃ concentrations, relationships between MLH and
179 MDA8 O₃ were analyzed (Figure 3a). Here we used a data binning method to remove the expected
180 day-to-day atmospheric variability from sampling uncertainty (Dian et al., 2010), which has been
181 applied elsewhere (Lou et al., 2019). The MLH was grouped into 8 classes with 300 m width: 0–300,
182 300–600, 600–900, 900–1200, 1200–1500, 1500–1800, 1800–2100 and > 2100 m. It was found that
183 MDA8 O₃ concentration initially increased and reached the maximum ($158.47 \pm 44.54 \mu\text{g m}^{-3}$) when
184 MLH at around 900–1200 m, then turned to decrease with further development of MLH. This nonlinear
185 relationship between MDA8 O₃ and MLH was inconsistent with previous studies, in which high O₃
186 concentrations corresponded to a low boundary layer height (NASTRO, 2000), but consistent with the
187 results conducted by Zhao et al. (2019) and Reddy et al. (2012). The work by Zhao et al. (2019) found
188 that O₃ concentration was the highest at medium boundary layer heights (1200–1500 m) in
189 Shijiazhuang, China. In India, days of higher O₃ concentrations were also associated with higher
190 boundary layer height (Reddy et al., 2012).

191 This relationship observed between MDA8 O₃ and MLH can be explained by two dominant
192 processes: vertical transport or photochemical formation. Previous works have shown that higher
193 height of mixing layer can lead to the mixing of near surface air with the O₃ rich air aloft, resulting in
194 the observed enhancements in surface O₃ concentration (Reddy et al., 2012). Besides, the evolution of
195 mixing layer were strongly associated with the change of other meteorological conditions, such as air
196 temperature, RH and precipitation. The increase of MLH often coincided with higher air
197 temperature, lower RH, and less precipitation (Figure 3d), which were more conducive to O₃
198 production (Ma et al., 2021; Haman et al., 2014; Xu et al., 2018). Under this meteorological condition,
199 the photochemical formation of O₃ was more intense, and exceeded the influence of vertical dilution.
200 As shown in Figure 4a–b, as the MLH fixed, MDA8 O₃ concentration climbed up with increase in
201 temperature but decrease in RH levels. Possible reasons for these results could be: (1) the increase in
202 RH can contribute to the depletion of O₃, and lead to weakened O₃ related photochemical reaction (Ma
203 et al., 2021; Yu, 2019); and (2) the rise of temperature can accelerate the emission rate of gaseous

204 precursors, such as biogenic VOCs and soil NO_x (Dang et al., 2021; Porter and Heald, 2019), and also
 205 stimulate the photochemical reaction rate in the generation of O₃ (Ma et al., 2021). In comparison, the
 206 effects of precipitation and WS to the initial growth of MAD8 O₃ were inapparent in this work.

207
 208 **Figure 4.** The distribution characteristics of the MDA8 O₃ concentrations with the evolution of MLH
 209 under different (a) temperature, (b) RH, (c) precipitation, and (d) WS conditions.

210 **3.3 Evolution of PM_{2.5} and its secondary compositions with mixing layer meteorology**

211 The concentration distribution of surface PM_{2.5} in different MLH bins has been shown in Figure
 212 3b. Interestingly, PM_{2.5} showed similar change profile as MDA8 O₃, which initially increased and then
 213 declined along with the growth of MLH. PM_{2.5} concentration reached the maximum of 31.65 µg m⁻³
 214 when MLH fell in the range of 900–1200 m, and the concentration has increased by 1.51 µg m⁻³
 215 through the rise phase for the variation of 100 m MLH. This phenomenon was quite different with the
 216 results in cold seasons (Pan et al., 2019; Du et al., 2013; Murthy et al., 2020). The narrowing of mixing

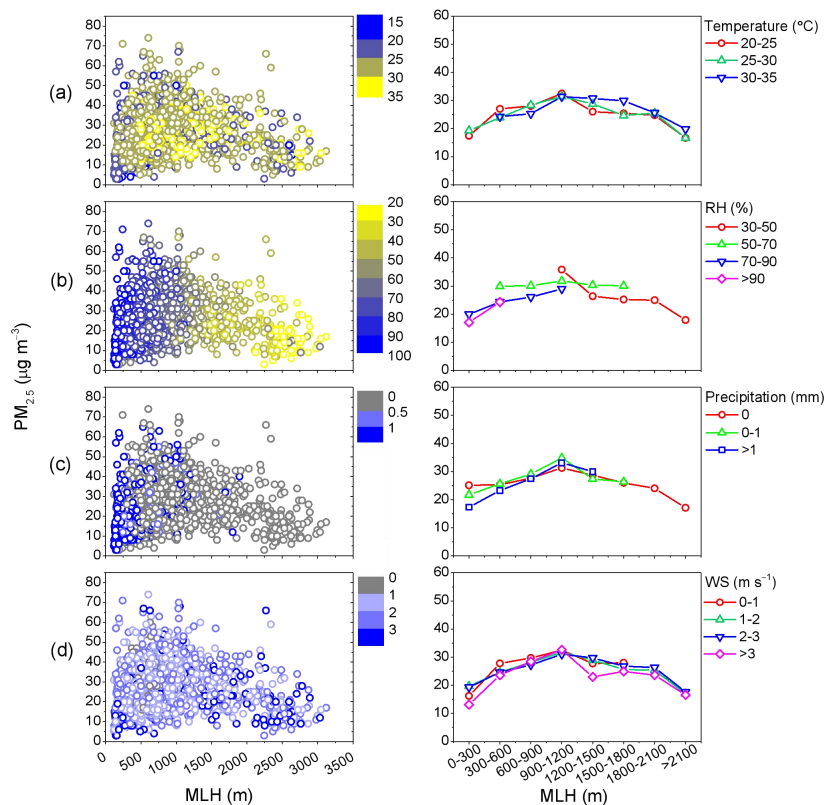

217 layer can inhibit the vertical dilution and dispersion of pollutants and make pollutants accumulate
218 locally, MLH thus has been illustrated as the key factor to aggravate the haze events in large cities of
219 China in winter. However, the response of $PM_{2.5}$ concentration to MLH is not only determined by the
220 vertical stratification of the mixing layer, but also by local sources, secondary chemical formation, wet
221 deposition, and the wind field. Previous works also found that the statistical relationship between the
222 daily MLH and air pollution levels can become uncorrelated or even positive (Lu et al., 2019; Geiß et
223 al., 2017). Distinct correlations between primary, secondary pollutants and MLH during summer and
224 winter observations were observed (Geiß et al., 2017). The work by Geiß et al. (2017) found little
225 correlation between MLH and $PM_{2.5}$ in Berlin during hot seasons. The observation in Shanghai found
226 that the $PM_{2.5}$ diurnal variation presented different patterns in summer and winter (Pan et al., 2019).
227 The $PM_{2.5}$ diurnal peaks in winter well corresponded to the low mixing layer conditions (200-300 m),
228 while in summer, the diurnal $PM_{2.5}$ concentration peaked in medium mixing layer condition (1000 m).
229 The work by Miao et al. (2021) found that the summertime concurring $PM_{2.5}$ and O_3 pollution in
230 Shanghai usually occurred on the days with deep afternoon planetary boundary layer. Based on the
231 summertime soundings from China for the period from 2014 to 2017, Lou et al. (2019) found that the
232 relationships between the boundary layer height (BLH) and $PM_{2.5}$ were variable under different BLH
233 regimes, and the aerosol loadings increases with the increasing BLH for the Stable Boundary Layer.
234 Noted that in this work there were still some extreme high $PM_{2.5}$ values under low MLH condition as
235 shown in Figure 3b, and this phenomenon will be discussed in the following part when exploring the
236 effect of precipitation.

237 The response of $PM_{2.5}$ concentrations to mixing layer structure was the net effect of the changes in
238 $PM_{2.5}$ major chemical components, such as SO_4^{2-} , NO_3^- , NH_4^+ , and OC. Interestingly, the change
239 profiles of these $PM_{2.5}$ components to the evolution of MLH were different. As shown in Figure 3c,
240 SO_4^{2-} and OC both increased and reached the maximum values when MLH in the range of 900–1200m,
241 with the values of $8.39 \pm 3.03 \mu g m^{-3}$ and $5.20 \pm 1.90 \mu g m^{-3}$, respectively. However, NO_3^- and NH_4^+
242 slightly increased when MLH lower than 600m, and kept almost stable when MLH in the range of
243 600–1200m, then significantly decreased with further increase of MLH. The increasing trend (MLH <
244 1200m) of $PM_{2.5}$ was mainly attributed to the enhancement of SO_4^{2-} and OC. The mass ratio of SO_4^{2-} to
245 NO_3^- gradually increased along with the development of mixing layer (Figure S2). When MLH higher
246 than 1200m, SO_4^{2-} surpassed NO_3^- and became the dominant $PM_{2.5}$ component. Changes in NH_4^+ were

247 a consequence of the changes in SO_4^{2-} and NO_3^- . The difference in the relationships between these
 248 aerosol species and MLH reflected the intrinsic complexity mechanisms of $\text{PM}_{2.5}$ formation, which
 249 were probably related to other meteorological parameters, such as temperature, RH, precipitation and
 250 WS. In order to understand how the other meteorological factors impacted the relationship between
 251 MLH and $\text{PM}_{2.5}$, we demonstrated the statistics on the concentration distribution of $\text{PM}_{2.5}$ and its
 252 dominant components with the increase of MLH under different RH, temperature, precipitation and
 253 WS conditions in Figure 5 and Figure 7.

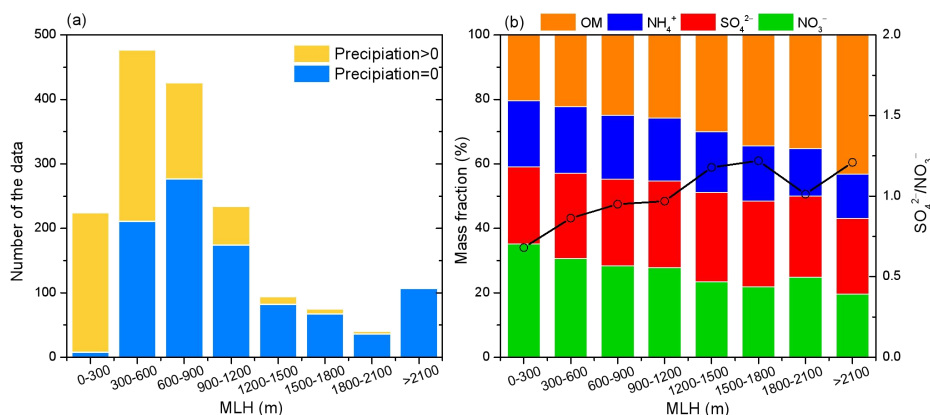

254
 255 **Figure 5.** The distribution characteristics of the $\text{PM}_{2.5}$ concentrations with the evolution of MLH under
 256 different (a) temperature, (b) RH, (c) precipitation, and (d) WS conditions.

257 Temperature is not only essential to the secondary chemical reaction of trace gases, but also the
 258 gas-particle partitioning of volatile $\text{PM}_{2.5}$ species. The response of $\text{PM}_{2.5}$ and its dominant components
 259 to MLH followed similar change characteristics under different temperature conditions, all increasing
 260 with the development of mixing layer when MLH lower than 1200m. The response of $\text{PM}_{2.5}$ to
 261 temperature was largely the result of competing changes in NO_3^- and SO_4^{2-} concentrations with a

262 smaller role played by organics (Figure 7). Specifically, as the MLH fixed, SO_4^{2-} concentration
 263 climbed up with increasing temperature level, while the concentration of NO_3^- declined when
 264 temperature kept going up. Higher temperature may lead to rapid oxidation of SO_2 to SO_4^{2-} . However,
 265 the partitioning of semi-volatile nitrate is temperature-dependent. Higher temperature prompts the
 266 partitioning of nitrate to HNO_3 , thus nitrate tends to exit in the particulate phase, resulting in a
 267 significant decrease in NO_3^- and NH_4^+ concentrations.

268 The response of $\text{PM}_{2.5}$ and its dominant components to the evolution of mixing layer was more
 269 sensitive to RH, and distinct distribution characteristics under different RH ranges have been observed
 270 in Figure 5 (b) and Figure 7 (b). When MLH fell in the range of 600–900 m, the concentration of $\text{PM}_{2.5}$
 271 and its major components mostly decreased with RH elevating from 50–70 % to 70–90 %. Previous
 272 works have shown that when RH higher than 60%, local humidity-related physicochemical processes
 273 play important roles in transforming the gases to aerosols (Wang et al., 2022d; Liu et al., 2020). We
 274 considered that the RH range from 50% to 70% was more beneficial to the aqueous chemical
 275 production of major $\text{PM}_{2.5}$ components, then led to the increase of $\text{PM}_{2.5}$ concentration. It is worth
 276 noting that as MLH fixed ($0 < \text{MLH} < 300$ m), when RH rose from 70–90 % to > 90 %, the
 277 concentration of $\text{PM}_{2.5}$ and its major components severely dropped, which was probably related to the
 278 fast hygroscopic growth and enhanced wet deposition processes.

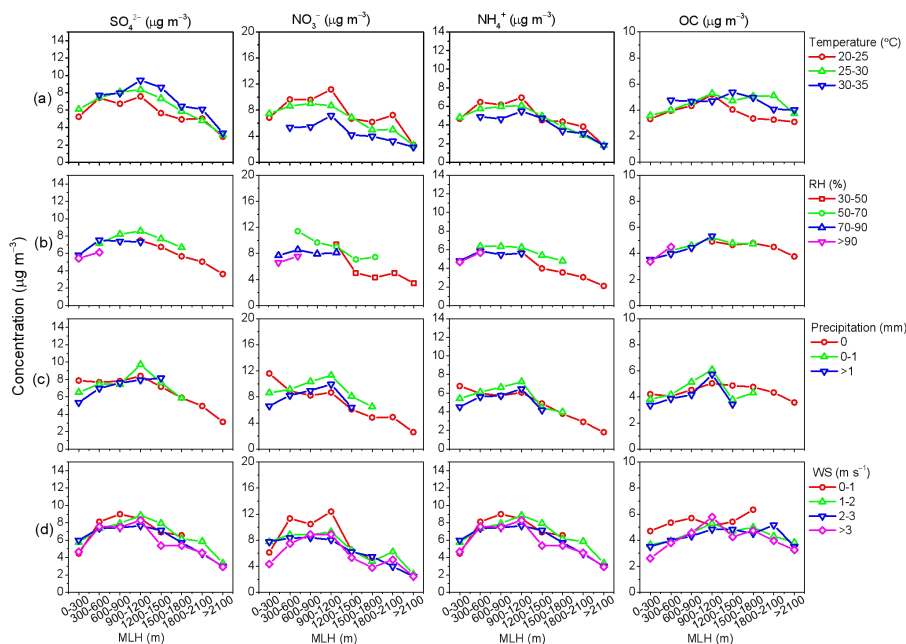

279
 280 **Figure 6.** (a) The number distributions of the data when the daily precipitation larger than 0 mm or
 281 equal to 0 mm along with the evolution of MLH. (b) The mass fractions of major $\text{PM}_{2.5}$ components
 282 and the mass ratio of SO_4^{2-} to NO_3^- along with the evolution of MLH when the daily precipitation
 283 equal to 0 mm.

284 All aerosol species have wet deposition as a major sink, so precipitation is expected to have
285 significant effects on $PM_{2.5}$ concentrations. As shown in Figure 5 (c), changes in the concentrations of
286 $PM_{2.5}$ was sensitive to the rain events. When MLH fell in the range of 0–300 m, the concentration of
287 $PM_{2.5}$ obvious decreased during rainfall period. Interestingly, when no rainfall occurred, even though
288 $PM_{2.5}$ concentration kept stable under low MLH condition, the response of $PM_{2.5}$ concentrations to
289 MLH still followed upward trend with MLH increasing from 300–600 to 900–1200 m. The observed
290 $PM_{2.5}$ concentrations under moderate MLH condition (900–1200 m) was around $31.34 \mu\text{g m}^{-3}$, which
291 was still about six times higher than the WHO's $PM_{2.5}$ guideline value ($5 \mu\text{g m}^{-3}$, World Health
292 Organization, 2021). As for specific aerosol species, NO_3^- and NH_4^+ concentration showed two obvious
293 peaks, with one in the range of 0–300 m, and the other in 900–1200 m. Under low MLH condition, the
294 concentrations of NO_3^- and NH_4^+ were high, with NO_3^- as the dominant species in $PM_{2.5}$ as shown in
295 Figure 6 (b). With the growth of MLH, NO_3^- and NH_4^+ initially decreased, but turned to increase again
296 when MLH in the range of 900–1200 m. As for SO_4^{2-} and OM ($\text{OC} \times 1.6$), the concentrations obvious
297 increased with the elevation of MLH and has exceeded that of NO_3^- when MLH higher than 1200 m.
298 As shown in Figure 6 (a), low mixing layer generally accompanied with cloudy and rainy conditions
299 during summertime in the NCP in 2021, and only small fraction of days without rainfall has been
300 captured during this period. Therefore, despite some high $PM_{2.5}$ or major aerosol species values have
301 been witnessed under low MLH condition, the overall trend in Figure 3 (b) was still upwards along
302 with the growth of mixing layer (MLH < 1200 m). The upward trend under medium MLH condition
303 indicated that the particle removal by precipitation was potentially important but not the only
304 controlling factor driving this growing trend, and the enhancement of secondary aerosol formation due
305 to appropriate chemical reaction environment should be considered.

306 WS can represent the atmospheric dissipation potential in the horizontal directions (Zhu et al.,
307 2018). Low WS generally suggested weak pressure gradients and potentially a more favorable
308 meteorological condition for $PM_{2.5}$ enhancement (Ma et al., 2021). As expected, the concentrations of
309 $PM_{2.5}$ and its aerosol species gradually decreased with the increase of WS. However, the response of
310 these air pollutants to MLH followed similar upward trends under different WS conditions (MLH <
311 1200 m). This indicated that the elevation of $PM_{2.5}$ and its aerosol species along with the evolution of
312 mixing layer (MLH < 1200 m) was not attributed to the effect of horizontal diffusion.

313

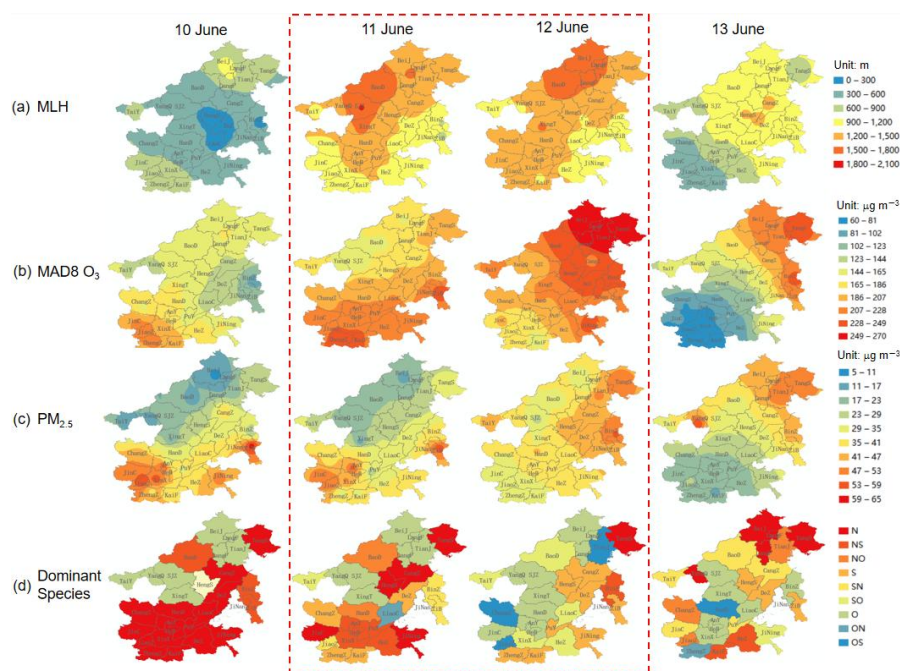

314 **Figure 7.** The distribution characteristics of NO_3^- , SO_4^{2-} , NH_4^+ , and OC concentrations with the
 315 evolution of MLH under different (a) temperature, (b) RH, (c) precipitation, and (d) WS conditions.

316 **3.4 Impact of atmospheric oxidation capacity on surface $\text{PM}_{2.5}$ change profile**

317 The above analysis shows that MDA8 O_3 and $\text{PM}_{2.5}$ concentrations were closely related to the
 318 evolution of BLH. The increasing trend of $\text{PM}_{2.5}$ concentration with the development of mixing layer
 319 under medium MLH condition discussed before indicated that the evolution of mixing layer was not a
 320 simple physical dilution process, and its influence on the enhanced secondary photochemical formation
 321 should be considered as well. Interestingly, in this work we found three concurring $\text{PM}_{2.5}$ and MDA8
 322 O_3 pollution cases along with the development of mixing layer: June 10–13, June 26–29, and July 9–11.
 323 Figure 8 demonstrated a case study to illustrate the detailed regional change characteristics of MLH,
 324 MDA8 O_3 , $\text{PM}_{2.5}$ and its chemical compositions from 10 to 13 on June 2021. It was found that during
 325 this period, MLH evolved substantially, with the daily height varying from 300–600 m to 900–1500 m.
 326 Concurrently, $\text{PM}_{2.5}$ and MDA8 O_3 concentrations also increased, and the areas of highest $\text{PM}_{2.5}$
 327 concentrations coincided well with those of highest MDA8 O_3 concentrations. In general, most cities
 328 during this period were in the steady conditions with high temperature and low humidity. The vertical
 329 profiles of O_3 concentration (24-h averaged) and extinction coefficient in TangS, BeiJ, and SJZ (Figure

330 9) indicated that the elevation of O_3 during this period was mainly resulted from the vertical transport
 331 from higher mixing layer, while the increase of $PM_{2.5}$ was not attributed to regional transport, but
 332 probably enhanced O_3 related secondary aerosol formation. It was found that the increase of $PM_{2.5}$ was
 333 mainly due to the enhanced formation of SO_4^{2-} and OC. The chemical composition of $PM_{2.5}$ changed
 334 substantially in the NCP during this observation period: NO_3^- decreased with the development of
 335 mixing layer in June 11 and 12, and the areas dominated by NO_3^- gradually withdrew, while the
 336 contribution of SO_4^{2-} and OC in $PM_{2.5}$ significantly increased.

337
 338 **Figure 8.** The spatial distribution of (a) MLH, (b) MDA8 O_3 , (c) $PM_{2.5}$, and (d) the dominant $PM_{2.5}$
 339 chemical component (N: NO_3^- dominant, NS: NO_3^- and SO_4^{2-} dominant, NO: NO_3^- and OM dominant,
 340 S: SO_4^{2-} dominant, SN: SO_4^{2-} and NO_3^- dominant, SO: SO_4^{2-} and OM dominant, O: OM dominant, ON:
 341 OM and NO_3^- dominant, OS: OM and SO_4^{2-} dominant) from June 10 to 13, 2021. The dominant $PM_{2.5}$
 342 chemical component type was identified as the method proposed by Wang et al. (2022b).

343

344 **Figure 9.** The vertical profiles of O₃ concentration (24-h averaged) and extinction coefficient in (a)

345 BeiJ, (b) SJZ, and (c) TangS in June 12, 2021

346

347 **Figure 10.** Box plots showing the statistics of (a) PM_{2.5}, (b) NOR and SOR, (c) SO₄²⁻, (d) NO₃⁻, (e)

348 NH₄⁺, and (f) OC for different MDA8 O₃ conditions (< 120 µg m⁻³, 120–160 µg m⁻³, > 160 µg m⁻³).

349 The distance between the bottom and the top of the box reflects the inter quartile range; the line and

350 square in between are the median and mean values, respectively. The whiskers above and below the

351 box refer the 95 % confidence interval of the data. Note that rainy days were excluded.

352 Figure 10 displays the box-and-whisker plots of PM_{2.5} and its major components for different

353 MDA8 O₃ conditions. To isolate the impacts of precipitation on PM_{2.5} concentration, these rainy days

354 when the daily rainfall amount greater than 0 mm were excluded in this section. Here the concentration

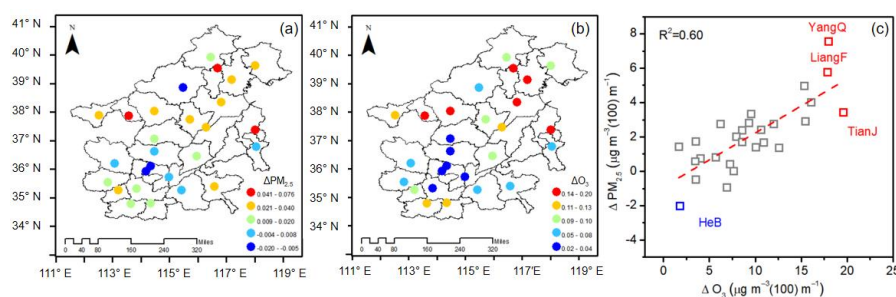

355 of $PM_{2.5}$ was found to increase synchronously with elevated MDA8 O_3 concentration, especially when
356 MDA8 O_3 increased from < 120 to $120\text{--}160 \mu\text{g m}^{-3}$. This summertime collaborative growth process of
357 $PM_{2.5}\text{--}O_3$ has also been observed in other works (Wang et al., 2022a; Wu et al., 2022). It's noted that
358 the elevation of $PM_{2.5}$ was mainly due to the changes in SO_4^{2-} and OC, which was consistent with the
359 conclusion discussed before. With elevated MDA8 O_3 concentration, the oxidation ratio of sulfate
360 (SOR, the molar ratio of sulfate to the sum of sulfate and SO_2) significantly increased, which indicated
361 the strong formation of secondary SO_4^{2-} promoted by high atmospheric oxidation capacity. However,
362 the oxidation ratio of nitrate (NOR, the molar ratio of nitrate to the sum of nitrate and NO_2) turned to
363 decreased when MDA8 $O_3 > 160 \mu\text{g m}^{-3}$, demonstrating a more significant role of partitioning process
364 between gas and aerosol than the atmospheric oxidation process under this stage. As the MLH fixed
365 ($900 \text{ m} < \text{MLH} < 1200 \text{ m}$), SO_4^{2-} concentration climbed up with enhanced MDA8 O_3 concentration,
366 while the concentration of NO_3^- declined (Figure S3). This result further demonstrated the conclusion
367 discussed above: the formation of SO_4^{2-} and OC was closely associated with the enhanced MDA8 O_3
368 concentration, while the change characteristics of NO_3^- was mainly determined by the partitioning
369 process between gas and aerosol.

370 To verify the potential impact of photochemical oxidation to the increase of $PM_{2.5}$ concentration
371 with mixing layer development, the changes in $PM_{2.5}$ and MDA8 O_3 along with the increase of MLH
372 were quantified in the “2+26” cities in the NCP. Linear regression equations between air pollutants and
373 MLH were fitted during the initial increasing stage ($300 < \text{MLH} < 1200 \text{ m}$) and their slopes were given
374 in Figure 11. The slopes indicated the rates of the maximum changes in air pollutant concentration for a
375 unit change in MLH (100 m). The slopes of $PM_{2.5}$ and O_3 were expressed as $\Delta PM_{2.5}$ and ΔO_3 ($\mu\text{g m}^{-3}$
376 (100 m^{-1})). It was found that $\Delta PM_{2.5}$ was closely related to ΔO_3 ($R^2=0.60$), and obvious spatial
377 difference in $\Delta PM_{2.5}$ and ΔO_3 was witnessed in the NCP during the observation period. $\Delta PM_{2.5}$ and ΔO_3
378 both showed high values in TianJ, YangQ, and LangF, with values of 3.43 and $19.56 \mu\text{g m}^{-3} (100 \text{ m}^{-1})$
379 in TianJ, 7.56 and $18.00 \mu\text{g m}^{-3} (100 \text{ m}^{-1})$ in YangQ, and 5.75 and $17.85 \mu\text{g m}^{-3} (100 \text{ m}^{-1})$ in LangF,
380 respectively. Comparing with these cities, $\Delta PM_{2.5}$ and ΔO_3 were lowest in HeB, with the value of 1.80
381 and $-2.02 \mu\text{g m}^{-3} (100 \text{ m}^{-1})$, respectively, which implied that the secondary formation here was weak
382 and the surface $PM_{2.5}$ change characteristic was dominantly controlled by local emissions or vertical
383 diffusion effect.

384 Comparing with winter, the photochemistry in summer is quite active due to the strong solar

385 radiation. Even though deep MLH prefers to the dilution of air pollutants, higher MLH can also
 386 promote secondary chemical feedback through enhancing the availability of atmospheric oxidation
 387 capacity (such as changes in O_3) along with appropriate meteorological condition. This conclusion
 388 corresponded well to the finding based on chemical transport model (Dai et al., 2023), which proposed
 389 strong chemical production of secondary aerosols when planetary boundary layer height was about
 390 946.1m on O_3 - $PM_{2.5}$ co-pollution days. The strong chemical productions in the oxidative atmosphere at
 391 medium MLH condition may overcome the dilution effect on $PM_{2.5}$ induced by mixing layer
 392 development, leading to higher $PM_{2.5}$ level at the ground level.

393
 394 **Figure 11.** The spatial distribution of (a) $\Delta PM_{2.5}$ and (b) ΔO_3 . (c) The relationships between $\Delta PM_{2.5}$ and
 395 ΔO_3 in the NCP during summertime. The corresponding correlation coefficients (R^2) was given at the
 396 top of the panel.

397 4 Conclusions

398 Mixing layer height (MLH) was generally considered as a critical physical parameter in
 399 atmospheric environmental evaluation. It is assumed that extended mixing layer may lead to the
 400 dilution of air pollutants and thus tend to decrease surface concentrations. Several publications have
 401 indeed reported such anti-correlations in cold seasons. However, the understanding of the interaction
 402 between near surface O_3 and $PM_{2.5}$ (including its major components) along with the evolution of
 403 mixing layer during warm seasons remained poor. Furthermore, previous observational studies were
 404 mostly limited to a specific city. This paper is devoted to these topics by examining the response of
 405 MDA8 O_3 , $PM_{2.5}$, and its major components to the changes in mixing layer meteorology in the North
 406 China Plain (NCP) during summertime. We showed that MDA8 O_3 initially increased and then
 407 decreased with the growth of MLH. The maximum turning point of MLH was around 900–1200 m. As

408 for near-ground $PM_{2.5}$, similar non-linear change profile was found, with the maximum value of 31.65
409 $\mu g m^{-3}$ under medium MLH condition (900–1200 m), which was quite different from the results
410 conducted in cold seasons. Compared with winter, the occurrence of low MLH during summertime in
411 the NCP was mostly accompanied with cloudy or rainy conditions, which promoted wet deposition and
412 led to low concentrations of $PM_{2.5}$ at the ground level. Under medium MLH condition, strong chemical
413 productions of SO_4^{2-} and OC occurred along with appropriate mixing layer meteorology, where RH
414 was around 50–70 %, and the availability of atmospheric oxidants (i.e., O_3) increased. The strong
415 chemical productions at medium MLH conditions may offset the diffusion effect on $PM_{2.5}$ induced by
416 mixing layer development, resulting in higher $PM_{2.5}$ levels. The chemical characteristics of $PM_{2.5}$
417 significantly changed along with the growth of MLH. The composited concentration of NO_3^- was the
418 highest under low MLH condition, while the composited concentrations of SO_4^{2-} and OC obviously
419 increased under medium MLH condition. Temperature was the key factor controlling the competing
420 changes in NO_3^- and SO_4^{2-} concentrations in $PM_{2.5}$. We conclude that the MLH can be an indicator of
421 air pollutants in cold seasons, but the correlation between MLH and air pollutants, such as O_3 and
422 $PM_{2.5}$, should be treated with care in hot seasons. At least for the observation period in the NCP this
423 was not the case. Although several studies have examined the change characteristics of MLH and its
424 influence on ground-level O_3 and $PM_{2.5}$, it remains challenging to elucidate the mechanism underlying
425 the complex relationships. To better understand the complex interactions between MLH, air pollution,
426 and chemical processing, there is a need to have more extended data sets in time and space. Besides,
427 the aids of explicit models should be needed in the future.
