**Abstract.** We compare the main atmospheric drivers of the melt season over the Greenland Ice Sheet (GrIS) in ERA5 and ERA-Interim (ERA-Interim) in their overlapping period 1979–2018. In summer, ERA5 differs significantly from ERA-Interim, especially in the melt regions: ~~averaged~~. Small scale ERA5- ERA-Interim differences near the ice sheet's margins and over steep slopes can be explained by the different resolution while the large scale differences indicate a different representation of physical processes in the two reanalyses: Averaged over the lower parts of the GrIS, mean near-surface air temperature is 1 K lower, while the mean downward shortwave radiation at the surface is on average  $15 \text{ W m}^{-2}$  higher than in ERA-Interim. Comparison with observational weather station data shows a significant warm bias in ERA-Interim and for ERA5 a significant positive bias in downward shortwave radiation. Consequently, methods that previously estimated the GrIS surface mass balance from the ERA-Interim surface energy balance need to be carefully recalibrated before converting to ERA5 forcing.

## 10 1 Introduction

Greenland summer temperatures are experiencing a persistent ~~warming~~ positive trend. In coastal instrumental temperature records, Hanna et al. (2021) diagnose a significant 1.7 K increase from 1991 to 2019, and ~~in an ensemble mean of~~ SSP5-8.5 projections ~~, a mean warming of is projected for~~ yields a warming of 5.3 K from the first to the last two decades of the 21st century. ~~The associated reduction in Greenland Ice Sheet's surface mass balance (SMB) leads to more runoff~~ Considering a wider range of scenarios, projections generally indicate warming over Greenland, which is weaker than across the remaining Arctic, slightly stronger than the global trends, and mostly comparable to trends over northern hemisphere land surfaces (Climate Change , IPCC, Fig. 4.19). The associated increase in surface melt and runoff leads to a reduction in the GrIS SMB that ultimately raises the global sea level. According to the conservative estimate of Hanna et al. (2021), the equivalent sea level rise amounts to more than 10 cm by the end of this century for the SSP5-8.5 scenario. Surface mass and energy balance models (EBMs hereafter), such as BESSI (Born et al., 2019) or dEBM (Krebs-Kanzow et al., 2021), represent the key physical processes that determine the surface mass balance, and they can be used to directly infer changes in SMB from basic surface climate variables which typically include surface downward shortwave and longwave radiation, near-surface air temperature, and precipitation.

EBMs provide a low-cost alternative to computationally intensive regional climate model simulations to downscale the SMB and reproduce the narrow ablation zone along the lower elevated ice sheet margins. In a model intercomparison (Fettweis et al., 2020), EBMs were shown to be able to reconstruct the 1979–2012 SMB of the GrIS from relatively coarse-resolution ERA-Interim climate reanalysis, even though EBMs proved to be somewhat less skillful than regional climate models (RCMs), which may be partly related to the relatively coarse resolution of the ERA-Interim forcing (approximately 79 km) compared to the higher resolution of participating RCMs of up to 5.5 km. However, ERA-Interim was suspended in 2018 and is replaced by the ongoing ERA5 reanalysis product, which provides higher horizontal resolution (approximately 30 km) and dates further back to 1959. Thus, the potential and relevance of EBMs have increased when used in combination with this higher-resolution climate forcing now available.

It is, therefore, desirable to update current SMB simulations based on EBMs to ERA5 forcing and, where necessary, to adjust existing EBM parameters, which will require an assessment of the differences between the two data products due to changes in the near-surface radiation scheme, cloud scheme, or surface boundary layer. To this end, we compare key climate properties between ERA5 and ERA-Interim to complement previous comparisons (Wang et al., 2019; King et al., 2022; Delhasse et al., 2020) focussing on the Greenland (summer) surface energy balance.

## 2 Data and method

We use two global atmospheric reanalysis datasets produced by the European Centre for Medium-Range Weather Forecasts (ECMWF). The ~~Reanalysis-Era-Interim~~ (ECMWF Reanalysis - Interim (ERA-Interim, henceforth ERAI)) covers the period from January 1979 to August 2019 and has a spatial resolution of about 80 km with 60 vertical levels over Greenland. The more recent ECMWF Reanalysis v5 (ERA5) begins in January ~~1959~~1940, runs until the present, and has a finer resolution of about 30 km with 137 vertical levels. We compare climate properties that primarily control surface ablation over the Greenland Ice Sheet (GrIS) for those years entirely covered by both the ERA-Interim and ERA5 data sets, namely the joint period 1979–2018. Specifically, we compare the 2m-air temperature (~~T2M~~T2m), downward shortwave radiation at the surface (SWD), effective atmospheric emissivity ( $\epsilon$ ), and ~~cloud cover~~ (CCdownward longwave radiation at the surface (LWD)).

The analysis focuses on the summer months (June, July, and August; hereafter JJA) and the lower parts of the ice sheets between sea level and 2000 m elevation. The effective atmospheric emissivity  $\epsilon$  is derived from the ~~downward longwave radiation (LWD) at the surface and T2M~~ LWD and T2m according to the Stefan-Boltzmann-Law:

$$\epsilon = \frac{LWD}{\sigma T_{2M}^4} - \frac{LWD}{\sigma T_{2m}^4} \quad (1)$$

where  $\sigma$  is the Stefan-Boltzmann constant.

For these variables, we analyse mean differences (Fig. 1) and standard deviations (Fig. S1 in the supplement) of corresponding ERA5 - ERAI differences for the summers in the 1979–2018 overlap period. A corresponding comparison of the annual fields can be found in the supplement (Fig. S2, S3). All climate variables considered were bilinearly interpolated to the 1 km

55 grid used by the Ice Sheet Model Intercomparison Project for CMIP6 (ISMIP6); (Note that effective emissivity is calculated from the coarse resolution LWD and ~~T2M~~T2m and then interpolated).

We also scale temperatures with respect to a common orography, the 1 km ISMIP6 orography  $H_{ice}$  (Morlighem et al., 2014), to reduce those temperature differences which are related to differences in topography between both reanalyses (resulting from the higher horizontal resolution in ERA5). To this end, a lapse rate of  $\gamma = -0.005 \text{ K m}^{-1}$  is applied to adjust ERA5 and ERAI  
60 2m-air temperatures:

$$\underline{\underline{T2M}} \underline{\underline{T2m}} = \underline{\underline{T2M}} \underline{\underline{T2m}}_{int} + \gamma(H_{ice} - H_{int}) \quad (2)$$

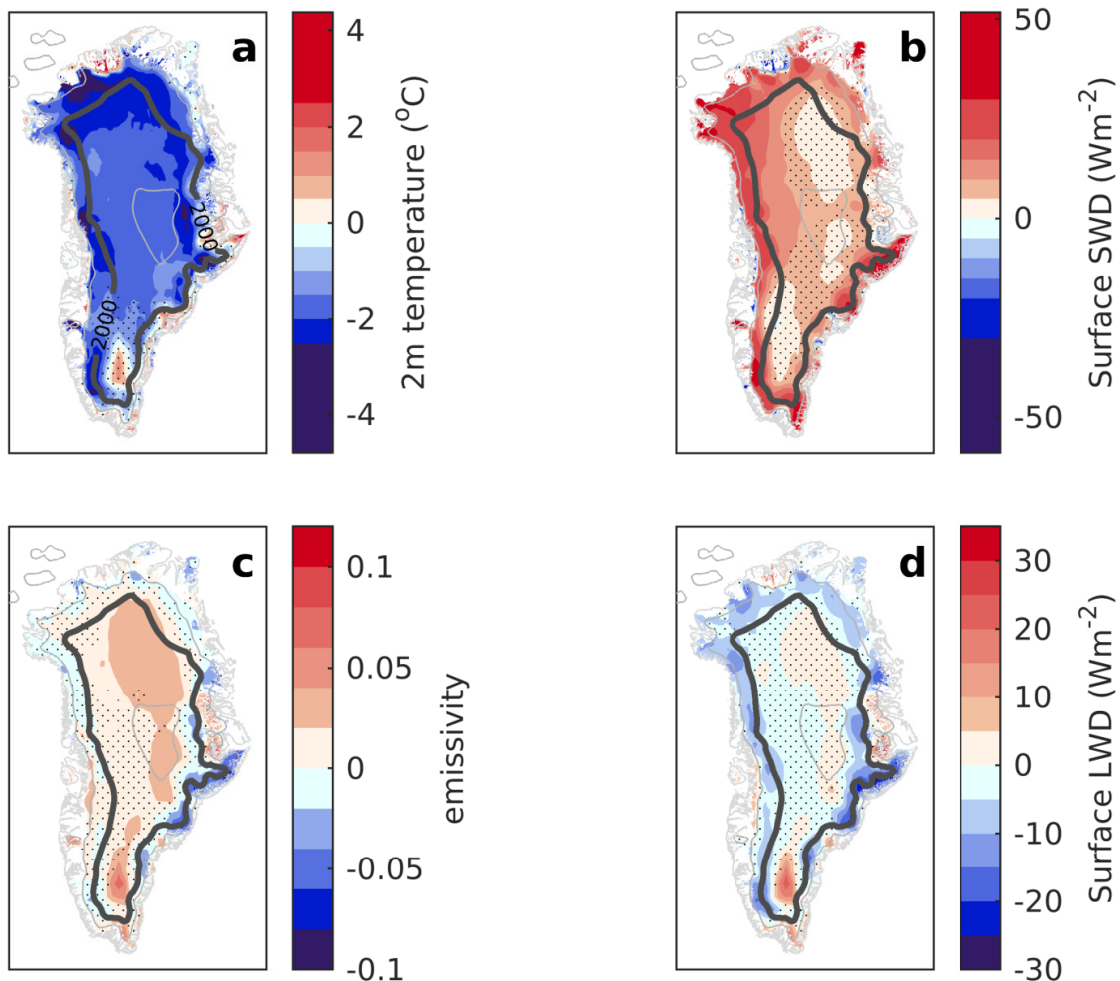

where ~~T2M~~T2m<sub>int</sub> and  $H_{int}$  are the interpolated near-surface air temperature and surface elevation from the respective reanalysis data sets (i.e., ERA5 or ERA-Interim), ~~respectively~~. The applied lapse rate is at the low end of summer lapse rates over Greenland slopes estimated from ERA5 and ERA-Interim 2m-air temperatures, which typically vary between  $-5 \text{ K km}^{-1}$   
65 and  $-7 \text{ K km}^{-1}$  (Fig. S4) in agreement with climate simulations (Erokhina et al., 2017). A comparison of the mean ~~T2M~~T2m ERA5-ERA-Interim biases for different lapse rate choices ( $0 \text{ K km}^{-1}$ ,  $-5 \text{ K km}^{-1}$ ,  $-7 \text{ K km}^{-1}$ ,  $-10 \text{ K km}^{-1}$ ) is provided in the supplement (Fig. S5, S6)

To also compare the reanalysis data to observational data, we bilinearly interpolate ~~T2M~~T2m, SWD, and emissivity ( $\epsilon$ ) ~~and LWD~~ from the 1 km grid to locations of automatic weather stations (AWS) from the PROMICE network (Fausto et al., 2021; Ahlstrom et al., 2008). We consistently apply ~~a~~the lapse rate correction ~~to downscale T2M of~~  $-5 \text{ K km}^{-1}$  ~~to downscale T2m~~ to the altitude of the weather stations and compare it to monthly mean near-surface air temperature measurements. A comparison with uncorrected temperatures is given in the supplement (Fig. S7). ~~In addition, we compare the corresponding reanalysis data with monthly mean downward shortwave radiation observations and effective emissivities calculated from in situ longwave radiation and near-surface temperature measurements.~~ This comparison with observational data is similar, but not identical, to  
75 parts of Delhasse et al. (2020) because we use a different interpolation strategy and apply a lapse rate correction to account for altitude differences.

### 3 Differences between ERA5 and ERAI in summer

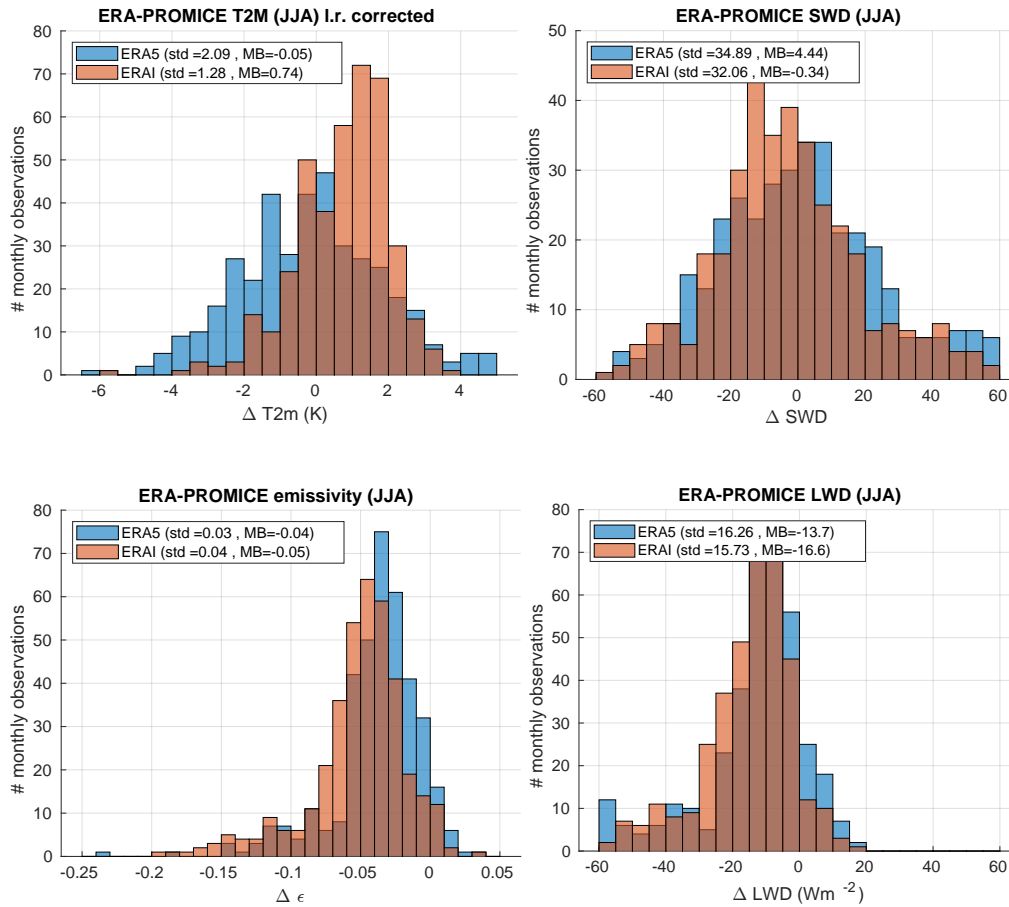

During the summer months, ERA5 and ERAI exhibit pronounced differences in the variables considered (Fig. 1). Over the entire 40-year period, mean summer 2m-air temperatures (~~T2M~~T2m) in ERA5 are more than ~~colder~~1 K lower than in ERAI  
80 over most parts of the ice sheet except the South Eastern margins and the southern dome region. The mean bias exceeds two standard deviations of the interannual variability almost everywhere north of  $66^\circ\text{N}$ . The applied lapse rate correction of  $-5 \text{ K km}^{-1}$  appears to be well chosen as the spatial difference between the two reanalysis products increases when no lapse rate correction is applied, or a higher lapse rate of  $-10 \text{ K km}^{-1}$  is chosen (Fig. S5).

The summer shortwave downward radiation at the surface (SWD) is ~~stronger~~larger in ERA5 than in ERAI over the main  
85 ice sheet. The mean bias exceeds two standard deviations on the lower parts of the ice sheet where SWD in ERA5 exceeds SWD in ERAI by approximately  $15 \text{ W m}^{-2}$ . Only isolated ice caps and the outermost margins of the main ice sheet show

**Figure 1.** Mean bias between ERA5 and ERAI for the summer mean (i.e., June, July, and August, JJA) 1979–2018 period of the lapse rate corrected 2m-air temperature (top left), downward shortwave radiation (top right), emissivity (bottom left) and cloud-cover-downward longwave radiation (bottom right). Stippling indicates regions where the mean bias is smaller than two respective standard deviations. The solid gray line depicts the elevation of 2000 m.

a distortion of the opposite sign in some places. In-contrast, the emissivity-Downward longwave radiation over lower parts of the ice sheet is lower in ERA5 deviates only slightly from ERA-Interim which, in most parts of the ice sheets except for, seems to be related to the lower temperature while atmospheric emissivity shows no significant change. An exception is the central-eastern margin where lower LWD is related to a pronounced negative bias at the central-eastern margins in effective atmospheric emissivity and points to a qualitatively different climate regime (here the mean bias in emissivity and LWD exceeds

**Figure 2.** Distribution of ERA5 and ERAI biases with respect to monthly PROMICE observations for the summer months (June, July, August) in 2007–2016: 2m-air temperature (top upper left), downward shortwave radiation (center upper right), and emissivity (bottom lower left) and downward longwave radiation (lower right). The text box insets provide standard deviation (std) and mean biases (MB) for the respective distributions.

two standard deviations between 66 °N and 70 °N). The lower parts of the ice sheet have mostly lower emissivity values in ERA5, which is consistent with the pronounced positive shortwave radiation bias in ERA5. However, these features are not accompanied by a correspondingly lower Finally, neither difference in longwave nor in shortwave radiation are associated with a correspondingly different cloud cover in ERA5 (Fig. S8 in the Supplement).

A comparison with automatic weather station (AWS) measurements from the PROMICE network (Fausto et al., 2021; Ahlstrom et al., 2008) (Fig. 2) shows no significant bias in the ERA5 summer temperatures while the ERAI summer temperatures are significantly warmer higher than the observations with a mean bias of 0.74 K (according to t-tests with a 0.05 significance level). Applying the Here again a lapse rate correction of 5 K km<sup>-1</sup>, for example, was applied to correct for elevation differences between the interpolated reanalysis data and the elevation of the AWS. A comparison with uncorrected

**Figure 3.** 1979–2016 yearly summer means of [interpolated](#) (a) [lapse rate corrected](#) 2m-air temperature, (b) downward surface shortwave radiation, (c) emissivity, and (d) ~~cloud-cover~~ [downward longwave radiation](#) for ERA5 (blue) and ERAI (red) averaged over the 0 m to 2000 m elevation range of the GrIS.

[temperatures reveals that the lapse rate correction](#) reduces the spread of the reanalysis data around the observational data considerably but also reinforces the warm bias in ERAI (Fig. S7). ~~This comparison~~ [Fig. 2](#)) also shows a larger scatter in SWD around observed station data, a significant positive bias in SWD for ERA5, and a significant negative bias in emissivity [and](#) [LWD](#) for both reanalyses. There is no significant bias in the ERAI SWD data. [In case of LWD both bias and spread can be reduced by recalculating LWD from emissivity and lapse rate corrected T2m \(Supplement Fig. S9\).](#)

105

Over the lower parts of the ice sheet (< 2000 m), differences are pronounced, as shown by the temporal evolution of the fields considered (Fig. 3). ~~This~~ [In Fig. 3](#) height range covers the ablation zone which is generally limited to altitudes below

2000 m above sea level, analysis in (1000 m) intervals from 0 to (4000 m) is provided in the supplement Figs S10-S13. The averaged lapse rate corrected ERA5-ERA1 2m-air temperature difference here varies around a mean of  $-1.0$  K with a standard deviation of  $0.24$  K (Fig. 3). This bias is enhanced by 25 % during the period between 2002–2009 when it is consistently above  $-1.25$  K. This colder period in ERA5 may be partly related to a known cold bias of ERA5 in the lower stratosphere between 2002 and 2006 (one reason why ECMWF released ERA5.1, a rerun of this period Simmons et al. (2020)). The SWD bias-mean bias for SWD varies around  $16.7$ ,  $\text{W m}^{-1}$  with a standard deviation of  $1.6$ ,  $\text{W m}^{-1}$ .

~~Bias in cloud cover appears to be about throughout the period 1979–2018, with the remarkable exception of the year 2017. In 2017, both, ERA5 and ERA1 show similar mean cloud cover values over the lower ice sheet and for LWD varies around  $6.9$ ,  $\text{W m}^{-1}$  with a standard deviation of  $1.1$ ,  $\text{W m}^{-1}$ . Differences in effective emissivity also remain largely stable over time, with a mean bias of  $-0.0063$  and a standard deviation of  $0.0017$ .~~

These biases in the ablation zone imply that using either ERA1 or ERA5 climate to drive the same energy balance model will result in different surface melt rate distributions in GrIS. We use the simplified formulation of the surface energy balance for a melting snow surface as given in Krebs-Kanzow et al. (2018) to estimate the resulting melt rate difference as about

$$\Delta M = \left( (1 - A) \Delta SWD + k_1 \Delta T_{2M} T_{2m} \right) \frac{1}{\rho L_f}, \quad (3)$$

where  $A$  is the albedo of the surface,  $\rho = 1000 \text{ kg m}^{-3}$  is density of water,  $L_f = 3.34 \times 10^5 \text{ J kg}^{-1}$  is latent heat of fusion, and the parameter  $k_1$  is chosen to be  $10 \text{ W K}^{-1} \text{ m}^{-2}$ . The differences between ERA5 and ERA1 of  $\Delta SWD = 15 \text{ W m}^{-2}$  and  ~~$\Delta T_{2M} = -1 \text{ K}$~~   $\Delta T_{2m} = -1 \text{ K}$  yield a range from  $\Delta M = -0.25 \text{ mm day}^{-1}$  for a low albedo of  $A = 0.4$  in the dark bare ice zone to  $-2 \text{ mm day}^{-1}$  for a fresh snow albedo of  $A = 0.9$ . Therefore, melt rates from ERA5 are expected to remain mostly lower than the respective estimates based on ERA1, especially at higher altitudes where albedo is generally high. This would result in a lower equilibrium line and stronger melt gradients between the equilibrium line and the ice sheet's margin. However, stronger SWD differences may overcompensate for the colder-lower temperatures in the darker parts of the ablation zone and consequently lead to stronger melt estimates under ERA5 forcing.

#### 130 4 Conclusion

Our comparison reveals substantial, spatially and temporally coherent differences between ERA5 and ERA-Interim, resulting in a modified surface energy balance over the GrIS. ERA5 is characterized by systematically colder-lower near-surface air temperatures and more intense insolation in summer. To some degree differences can be related to the higher spatial resolution of ERA5. In case of near surface air temperature small scale, resolution dependent differences can be removed largely by a uniform lapse rate correction while large scale differences of the order of  $\Delta T_{2m} = -1 \text{ K}$  remain and appear unrelated to resolution differences. The difference in shortwave radiation downward-downward shortwave radiation (SWD) is particularly pronounced along the lower parts of the ice sheets where ice sheet's margins and may in part be related to the higher spatial resolution of ERA5 better represents the steep orography and a sharper transition of cloud properties from the coastal zone

140 to the interior ice sheet. However, differences in downward shortwave radiation do not generally correspond to differences in atmospheric emissivity which indicates differences between the two reanalyses in cloud parameterization or radiation scheme.

Correcting the near-surface air temperatures with a lapse rate of  $-5 \text{ K km}^{-1}$  not only reduces the differences between the two reanalysis products and but also improves the comparison with monthly observations from PROMICE weather stations for both data sets too. This result is consistent with slope lapse rates diagnosed from both data sets and stresses the benefit of this simple downscaling method when dealing with coarse-resolution temperature fields.

145 In contrast to Delhasse et al. (2020), we find a significant warm bias of ERAI relative to weather station data, but this is only fully evident when a lapse rate correction is applied, while SWD appears to be slightly overestimated in ERA5.

The observed differences between ERA5 and ERAI have implications for the estimation of surface melt and ultimately the release of runoff. Replacing ERAI with ERA5 forcing in an energy balance model of the GrIS may therefore require some re-calibration to reproduce existing observations (e.g., Shepherd et al., 2020).

150 *Code and data availability.* The reanalysis data sets are provided by the European Centre for Medium-Range Weather Forecasts (ECMWF). Information about ERA-Interim and ERA5 are given at <https://www.ecmwf.int/en/forecasts/dataset/ecmwf-reanalysis-interim> [accessed 2021-11-12] and <https://www.ecmwf.int/en/forecasts/dataset/ecmwf-reanalysis-v5> [accessed 2021-11-12]

155 *Author contributions.* UKK performed the analysis and lead the manuscript writing. All authors contributed to the interpretation of the results and proofreading of the manuscript.
