Abstract. The evaluation and quantification of Southern Ocean cloud-radiation interactions simulated by climate models is essential in understanding the sources and magnitude of the radiative bias that persists in climate models for this region. To date, most evaluation methods focus on specific synoptic or cloud type conditions and are unable to quantitatively define the impact of cloud properties on the radiative bias whilst considering the system as a whole. In this study, we present a new method of model evaluation, using machine learning, that can at once identify complexities within a system and individual contributions.

To do this, we use an XGBoost model to predict the radiative bias within a nudged version of the Australian Community Climate and Earth System Simulator – Atmosphere-only Model, using cloud property biases as predictive features. We find that the XGBoost model can explain up to 55% of the radiative bias from these cloud properties alone. We then apply SHapley Additive exPlanations feature importance analysis to quantify the role each cloud property bias plays in predicting the radiative bias. We find that biases in liquid water path is the largest contributor to the cloud radiative bias over the Southern Ocean, though important regional and cloud-type dependencies exist. We then test the usefulness of this method in evaluating model perturbations and find that it can clearly identify complex responses, including cloud property and cloud-type compensating errors.

15 1 Introduction

The Southern Ocean (SO) shortwave cloud radiative bias is a well documented problem in global climate models (Bodas-Salcedo et al., 2014; Schuddeboom and McDonald, 2021) as well as some numerical weather prediction models (Protat et al., 2017; McFarquhar et al., 2021). The bias is characterised by too much shortwave radiation reaching the surface of the ocean, and not enough being reflected by clouds back out to space. Significant work has been done to identify the cause of this

20 model bias. Haynes et al. (2011) and Bodas-Salcedo et al. (2016) have shown that a large part of this bias can be attributed to the inability of models to simulate super-cooled liquid water clouds in the SO, in particular in cold sectors of extra-tropical cyclones. A number of observational studies have shown the prevalence of super-cooled liquid water clouds over the SO (Huang et al., 2012; Chubb et al., 2013; Mace and Protat, 2018). The prevalence of super-cooled liquid water clouds is attributed to the pristine conditions found in the region, removed from the sources of terrestrial (eg. dust/biomass burning) and anthropogenic
25 (eg. black carbon) aerosol (although these aerosol can occasionally intrude into the region). The lack of these particular aerosol, which contribute large sources of ice-nucleating particles (INP), limits the ability of cloud droplets to freeze, resulting in liquid clouds at temperatures well below zero. Currently, our climate and weather models do not take into account the pristine composition of the SO atmosphere, assuming, like over much of the world, that INP are available to help freeze cloud droplets, resulting in too many ice-phase clouds, which allow too much shortwave radiation to reach the surface of the ocean.

30 Numerous studies have attempted to address the shortwave cloud radiative bias via cloud phase parameterisations, including, but not limited to, treatment of ice nucleating temperatures (Furtado and Field, 2017; Varma et al., 2020, 2021), ice crystal shapes (Varma et al., 2020) and growth rates (Furtado et al., 2016), ice nucleating particle (INP) number concentrations (Vignon et al., 2021) and sources (Vergara-Temprado et al., 2017, 2018), convective detrainment temperatures (Kay et al., 2016) and more. Invariably, many of these studies find that altering parameters for specific SO conditions results in changes in model
35 performance over other parts of the climate system for better or worse (as explored in Kay et al., 2016; Furtado et al., 2016; Varma et al., 2020, 2021). This outcome is particularly important given the range of recent literature highlighting a latitudinal dependence of cloud properties in the Southern Ocean, which has been attributed by some to differences in aerosol properties (McCoy et al., 2015; Humphries et al., 2021; Mace et al., 2021b, a).

Many model evaluation techniques used to diagnose this problem rely on satellite observations and hence require a satel-
40 lite simulator such as the Cloud Feedback Model Intercomparison Project (CFMIP) Observation Simulator Package (COSIP) described in Bodas-Salcedo et al. (2011). More recently, ground-based lidar simulators are also available for more accurate model evaluation from ceilometers and lidars on the surface (eg. Kuma et al., 2020). In conjunction with such simulators, most studies have separated their data into specific conditions, for example, by isolating particular synoptic situations (eg. Field and Wood, 2007; Bodas-Salcedo et al., 2016) or by cloud regimes (or 'weather states') (eg. Williams and Webb, 2009; Tselioudis
45 et al., 2013; Oreopoulos et al., 2014; Mason et al., 2015; Oreopoulos et al., 2016; McDonald et al., 2016; Leinonen et al., 2016; Schuddeboom et al., 2018; Tselioudis et al., 2021; Fiddes et al., 2022). By isolating particular conditions, the specific microphysical causes of the radiative bias that are relevant to that condition can be diagnosed. However that cause may not perhaps be relevant to other conditions. Additionally, as Fiddes et al. (2022) (a companion paper to this study; herein F22) found, the model being examined in this study rarely simulates cloud regimes correctly, which may reduce the usefulness of
50 the cloud regime approach and calls for a different method of evaluation. Without the use of synoptic typing or cloud regimes, calculating zonal means is a popular way of diagnosing model biases at a macro-scale. However, this method severely limits the microphysical inferences that can be made.

The evaluation techniques presented in the literature are important methods in understanding model biases and have been shown to be useful in testing and tuning new parameterisations. However, these techniques are often limited to using human

55 ability to discern complex physical processes, interactions and patterns to diagnose the drivers of biases. We suggest that
utilising machine learning and associated feature importance metrics can enhance pattern recognition, aid our ability to assess
60 non-linearity and collinearity and shed new light on our understanding of the underlying causes of the biases across multiple
conditions.

Increased computing power as well as increased data availability now means that machine learning techniques are a useful
60 tool to further understand and predict climate and weather problems, especially in relation to clouds (Beucler et al., 2021).
Currently, applications of machine learning in climate science are limited for a number of reasons, including the relatively
recent advances in the field with respect to both methods and accessibility of computing resources, the difficulty in applying
often non-perfect or very limited data sets to a problem and the fact that physical understanding in climate science is often
more important than model accuracy (Beucler et al., 2021). Current applications include (but are not limited to): predicting
65 a particular field, such as low-marine clouds (Fuchs et al., 2018), liquid water path (Zipfel et al., 2022), radiation (Fan et al.,
2018; Mallet et al., 2023); improving retrievals for remote sensing (Yan et al., 2020); downscaling of coarse resolution data
(Vandal et al., 2019); improving subgrid-scale parameterisations (Rasp et al., 2018); or classification problems (Zhang et al.,
2019).

To our knowledge, no study has yet applied machine learning methods to understanding biases in climate models. We now
70 believe that current methods for regression problems combined with feature importance metrics may provide useful insight into
how biases are occurring. Feature importance metrics aim to provide quantification of how each predictive feature in a problem
(regressive or categorical) has contributed to the final outcome. Commonly, feature importance metrics have been considered
misleading due to their inability to take into account dependencies between predictive features (Hooker et al., 2019). However,
the recent advances in this space, including the development of the SHAP (SHapley Additive exPlanations) feature importance,
75 mean that we can better take into account these dependencies.

SHAP analysis builds on Shapley Values, a method originally derived for game theory applications to identify how important
one player in a team was to the outcome of the game (Shapley, 1953; Lundberg and Lee, 2017). SHAP feature importance can
be used to assess individual, accumulative and interacting feature importance, taking into account collinearities. Furthermore,
SHAP analysis is model agnostic and is considered a powerful tool in feature analysis.

80 In this study, we combine SHAP feature analysis with a regression model to evaluate and understand cloud radiative model
biases for the first time. We test if we can perform such an evaluation in a more holistic manner than in previous studies,
considering all conditions at once, rather than specific cloud or synoptic regimes. To do this, rather than isolating a particular
regime and then examining the particular biases in cloud properties associated with it, biases in cloud microphysical properties
are used to predict the bias in the cloud radiative effect. We then apply SHAP feature importance to understand the primary
85 drivers of the cloud radiative bias at any point in space or time. We hypothesise that that this method can provide new insight
into the cloud-radiative bias problem and may be useful tool when it comes to model sensitivity testing.

2 Data and methods

2.1 ACCESS-AM2 model and observational products

The Australian Community Climate and Earth System Simulator (ACCESS) - Atmosphere-only Model Version 2 (AM2) model is used in this work (Bodman et al., 2020). ACCESS-AM2 uses the same atmospheric set-up as that of the Coupled Model Intercomparison Project (CMIP) ACCESS-Coupled Model 2 (CM2) (Bi et al., 2020) submission for the AMIP (atmosphere only model intercomparison project) design (Eyring et al., 2016), but with prescribed sea surface temperatures and sea-ice concentrations. While we will provide key details here, a full description of the exact model set-up can be found in F22 (Fiddes et al., 2022). The atmospheric model is the Unified Model (UM) vn10.6, GA7.1 Walters et al. (2019), used in conjunction with the Community Atmosphere Biosphere Land Exchange (CABLE) version 2.5 land surface scheme (also described in Bi et al., 2020) and the GLOMAP-mode (GLObal Model of Aerosol Processes) aerosol microphysical scheme (Mann et al., 2010; Ma et al., 2012). Importantly, for this work we have the COSP simulator switched on (Bodas-Salcedo et al., 2011) to allow for sensible comparison between satellite fields and the model.

We have run the model from 2014-2019, discarding the year 2014 as spin-up. The European Centre for Medium-range Weather Forecasting (ECMWF) Reanalysis 5 (ERA5) product (Hersbach et al., 2020) is used to nudge the model every three hours, using the the horizontal wind and temperature above the boundary layer. The ACCESS model runs at 1.25x1.875 degree horizontal resolution with 85 vertical levels, and for this work we have output daily means.

We use two satellite products in this work: the Moderate Resolution Imaging Spectroradiometer (MODIS) Combined Aqua/Terra, Level 3 daily, 1x1 degree grid, Collection 6.1, COSP product (MCD06COSP_D3_MODIS) derived specifically for CMIP6 (Pincus et al., 2012; Platnick et al., 2017; Hubanks et al., 2020) and the Clouds and the Earth's Radiant Energy System (CERES) Syn1Deg product (Doelling et al., 2013, 2016). Both these products are available at daily mean time-scales and have been regridded to match the ACCESS-AM2 horizontal grid. How these products have been prepared is fully described in F22.

We use the outgoing top of atmosphere (TOA) shortwave (SW) cloud radiative effect (CRE) ($SWCRE_{TOA}$) for this work, derived from the all-sky radiation minus the clear-sky radiation fields (for both the model and satellite products). We have excluded any land regions as significant cloud and radiative biases were found due to non-marine features such as orography. We only consider the summer period for this paper due to the much larger biases found in this season (see F22).

The cloud fields of interest, which are also described in greater detail in F22, include the liquid and ice cloud fractions (CFL and CFI), liquid and ice cloud optical depths (τ_L and τ_I), and cloud top pressure (CTP). As described in F22, the model's COSP liquid water path (LWP) and ice water path (IWP) showed considerable biases when compared to the observed COSP products, and hence the raw model output was used for these fields instead.

In addition to the cloud fields described above, we use the cloud top pressure - cloud optical depth histogram derived cloud types described in F22. These cloud types were developed using k -means clustering, where 12 cloud types were found using the MODIS data set, which were then fitted to the respective ACCESS-AM2 product. After initial analysis the 12 cloud types

120 were merged into 10 cloud types. A full description of how these cloud types were found and an analysis of their patterns and relationships to the cloud-radiation bias can be found in F22.

2.2 XGBoost

XGBoost, or eXtreme Gradient Boosting, is a highly efficient, fast and scalable algorithm that can handle a large variety of problems (Chen and Guestrin, 2016). XGBoost uses decision trees to predict either categorical or quantitative data, eg. 125 classification or regression problems. Instead of randomly bootstrapping data over many decisions trees to minimise variance, as in the random forest technique, boosting takes a staged approach where each decision tree learns from the mistakes of the previous decision trees to minimise errors, while at the same time boosting higher performing trees (Hastie et al., 2009). Gradient boosting, instead of minimising absolute or squared-errors, uses a gradient descent algorithm to minimise the errors of previous trees (Hastie et al., 2009). XGBoost, an ‘extreme’ gradient boosting method, is computationally optimised, reduces 130 the amount of data being considered via tree pruning (i.e. removing parts of the trees that were not useful), or the number of nodes in the trees and can reduce the risk of over-fitting (Chen and Guestrin, 2016).

In this work, we use XGBoost to predict the $SWCRE_{TOA}$ biases using the respective biases in cloud features derived from COSP. To do this, the dataset was split into training and testing datasets, where it was trained on four years of data and tested on one. We have tested the XGBoost model on each of the full summers available at daily resolution: 2015-2016, 2016-2017, 135 2017-2018 and 2018-2019 (where training was performed on the remaining years) to avoid over-fitting.

Model tuning was performed to improve accuracy and efficiency of the XGBoost model. Using a 4-fold cross validation, that splits the training data into four ‘folds’ to train and validate the XGBoost model, we have employed both the SciKit-Learn GridSearchCV function (Pedregosa et al., 2011) and the XGBoost cross validation function (Chen and Guestrin, 2016) to identify the best combination of hyperparameters for our application. We note that the cross validation described here is in 140 addition to testing on different summers. The workflow used for this tuning (and the exact values used for this work) can be found in the available code linked to this study.

Tuning increased the XGBoost model root mean square error (RMSE) by only 0.44 and the explained variance by 0.014%. While this is a small improvement, we recognise that greater XGBoost model improvement could be found by adding more features. We tested this by including the actual MODIS cloud features (ie. not the biases) as predictors, which also resulted 145 in small improvements. However, by adding more features, physical interpretation of the results becomes more difficult. For this reason, a decision was made to reduce the complexity of the XGBoost model (by only using the biases as features) for the benefit of our understanding.

2.3 SHAP Feature Importance

With our predictive XGBoost model, we can now begin to understand what cloud features are most important in driving the 150 radiative bias. SHAP aims to understand what contribution each feature has made, i.e. how important they are, to the prediction of x at any particular point in time or space (known as a local prediction) (Lundberg and Lee, 2017). For the SHAP analysis, two key outputs need to be considered to understand the results. The first one is a singular ‘base’ value for the entire data set

of the target variable. This is equal to the mean prediction, in this case provided by the XGBoost model. Secondly, for each point in time and space, and for each predictor variable, a SHAP value is given, with the same units as that of the base value. A SHAP value quantifies how important a feature is to the total prediction of that point x . It is essential to note that the sum of all SHAP values for a point x do not equal the prediction of x , the base value must also be added. In this sense, we can consider local SHAP values to represent information of the prediction away from the mean (the base value), giving us an indication of how they are contributing to the overall variance. In Section 4, we will provide further description of how to interpret the SHAP values, using the results from this study.

An important strength of SHAP analysis is that the resulting SHAP values are additive with respect to feature attribution, making comparisons across features easy to interpret, even if the features themselves have different units. Similarly, averaging across time or space allows for an in-depth analysis of the results. SHAP analysis further includes the ability to explore the feature dependence and feature interaction, again making interpreting complex models more ‘humanly understandable’. Of specific interest to this work, is the inbuilt function to cluster SHAP values, allowing us to determine if two predictors are providing the same information to the XGBoost model (i.e. a measure of their collinearity).

However, despite the increased ability to interpret how the features are contributing to the prediction, like many statistical methods, strong feature importance does not provide a causal relationship. Physical understanding of the underlying data must also be considered.

2.4 Tools and analysis methods

To produce the results presented in this work, we have applied the XGBoost model and SHAP analysis to the entire data set (2015-2019). For both the bias prediction and feature importance analyses performed in this work we have used the python packages for the Dask (Dask Development Team, 2016) scheduling software, in conjunction with Xarray, SciKit-Learn and other packages specifically mentioned below (Hoyer and Hamman, 2017; Pedregosa et al., 2011). We have run this analysis on the National Computational Infrastructure supercomputer Gadi, using 16 CPUs and 44 GB of memory available via their Open On Demand interface. The workflow for this paper can be found at with our exact methods.

We have defined three regions in this work, following F22, with the boundaries of 30-43°S for the mid-latitudes of the the SO, 43-58°S for the sub-polar region, and a polar region of 58-69°S.

In order to fully evaluate the added value of using a powerful, yet complex and computationally expensive model such as XGBoost, we also used a simple multiple linear regression and Pearson correlation to linearly predict and understand the relationships of the $SWCRE_{TOA}$ bias to the COSP cloud biases (MLR, available from Scikit-Learn, Pedregosa et al., 2011).

3 Predicting the $SWCRE_{TOA}$ biases

Figure 1a shows the difference in DJF $SWCRE_{TOA}$ between the satellite product (CERES-Syn1D) and ACCESS-AM2. As discussed in F22 (Fiddes et al., 2022), a strong bias in the polar region of the SO is found, corresponding to too little shortwave solar radiation being reflected back out to space by clouds, and too much reaching the surface of the ocean. In the sub-polar

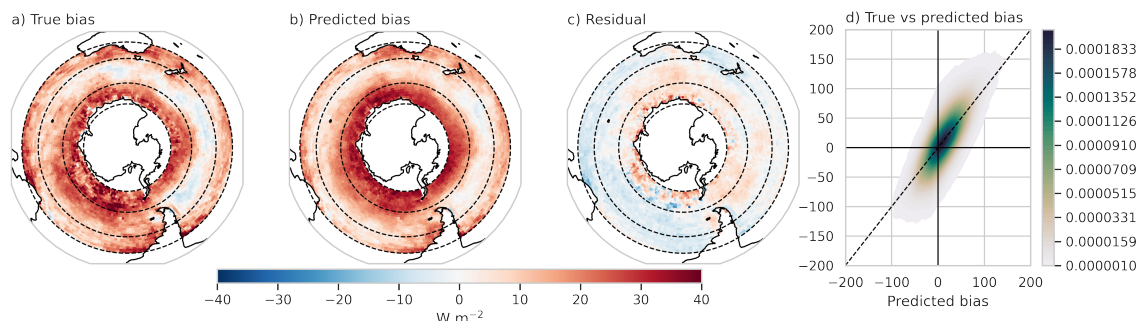

Figure 1. The true (a) and XGBoost predicted (b) DJF SWCRE_{TOA} bias (CERES-Syn1D minus ACCESS-AM2) averaged over time; c) shows the residual difference between the predicted and true biases. The dashed lines represent the three regions of interest, mid-latitudes (30-43°S), sub-polar (43-58°S) and the polar (58-69°S) regions. In d): the associated distributions of the true bias (y-axis) and XGBoost predicted bias (x-axis), with a scatter plot under laid showing the extremes. The one-to-one line is shown by the dashed line. All units are in W m⁻².

185 region, a zonally asymmetric bias is found with positive biases are shown in the eastern Indian Ocean and Pacific Ocean sectors, while negative biases are found throughout the rest of that region, as well as in the mid-latitude region. Examination of the model and satellite fields separately (not shown) shows that the asymmetrical bias appears to be due to ACCESS-AM2 failing to capture the observed spatial variability. F22 noted that ACCESS-AM2 lacked the diversity of cloud regimes found in the satellite observations, and hence it is unsurprising that this is also reflected in the SWCRE_{TOA} bias.

190 The spatial variability of this bias suggests that cloud/radiative regimes strongly vary across the Southern Ocean. The asymmetry of this bias makes it difficult to evaluate and understand without splitting the region up into specific synoptic or cloud regimes, as done in studies such as Bodas-Salcedo et al. (2016) or Fiddes et al. (2022). Building on knowledge from previous work, where we understand that particular cloud characteristics (or lack of) are responsible for driving the SWCRE_{TOA} bias in parts of the Southern Ocean, in this study we use biases in such cloud characteristics to predict the SWCRE_{TOA} bias. We
 195 hypothesise that if we can satisfactorily predict a bias, we can then use the derived XGBoost model to better understand the sources contributing to the bias. Firstly however, we want to understand more about the individual relationships of each cloud feature bias and the SWCRE_{TOA} bias.

Correlations have been calculated for each cloud feature with respect to the SWCRE_{TOA} bias, as well as to each other to test for both linearity of the cloud-radiative bias relationship and collinearities between the cloud features. We find that the LWP
 200 bias has the strongest relationship with the SWCRE_{TOA} bias, but can only linearly explain 30% of the variance. The other cloud features explain very little of the SWCRE_{TOA} bias under a linear assumption. Similarly, correlations between cloud features do not exceed 31%, indicating weak collinearity. Analysis of scatter plots comparing the respective biases (not shown) confirms that these relationships are in some cases highly non-linear, and in other cases, very weak.

In reality, how clouds interact with radiation is a complex system that depends on many variables. Hence, analysis comparing
 205 singular features should not be expected to provide strong indications of how this system works. For this reason, we also wanted

to test whether a simple technique such as multiple linear regression could predict the $SWCRE_{TOA}$ bias more satisfactorily. The benefit of such a technique is the low computational requirements and easy interpretation. However, the multiple linear regression was only able to predict between 42-43% of the variance (when tested on different summers, in the same way as described for the XGBoost training and testing data sets). This result again shows that linear assumptions are not suitable for a problem such as this, and that weak-moderate multi-collinearity must be taken into account. However, the improvement from the individual cloud features does give us an expectation we can improve upon this problem with a more sophisticated tool that can account for the inherent characteristics of the data.

The tool we have chosen to address these issues is XGBoost because it can handle non-linear applications and its performance isn't significantly impacted by collinearity among predictor variables, although as we discuss shortly, these must be still considered when we interpret the importance of these predictors. Using XGBoost, we model the DJF $SWCRE_{TOA}$ biases using the biases in the cloud features discussed above. The results for each period of training and testing were similar, predicting between 54-55% of the $SWCRE_{TOA}$ bias (the R^2) and a root mean squared error of between 29.45-30.12. For the subsequent results and analysis, we use the full data set, where 58% of the $SWCRE_{TOA}$ bias is explained.

Figure 1 shows the XGBoost predicted bias (b), the residual between the true and predicted bias (c) and a distribution scatter plot of the true bias and predicted bias (d). If we were to consider just the median values of the entire region, the XGBoost model predicts a $SWCRE_{TOA}$ bias of 11.4 W m^{-2} compared to 11.7 W m^{-2} (the means are 12.4 W m^{-2} and 12.4 W m^{-2} respectively), implying that the XGBoost model performs quite well, albeit with a lower standard deviation (32.9 W m^{-2}) than that of the true bias values (44.4 W m^{-2}).

We get a much clearer picture of the XGBoost model's performance in different spatial regions in Figure 1a, b and c. Here we can see that the XGBoost model appears to capture the SO negative bias in the polar region reasonably well, with the predicted median of 23.2 W m^{-2} and a true value of 19.4 W m^{-2} . The residual is fairly uniform except in the Weddell Sea region, which could reflect the influence of sea ice. In the sub-polar region, there are small differences between the predicted and true $SWCRE_{TOA}$ biases, with the median for the predicted bias is 6.9 W m^{-2} compared to the true bias of 7.3 W m^{-2} . Interestingly, these small residuals are not zonally symmetrical, with positive values in the Australian and Pacific Sectors and negative biases in the Atlantic and most of the Indian Ocean sectors. In the mid-latitude region, the positive $SWCRE_{TOA}$ bias is slightly underestimated in the XGBoost model (median of 8.6 W m^{-2} for the predicted bias compared to 12.6 W m^{-2}). The residuals, however, are more zonally symmetric than the sub-polar and polar latitude bands.

As stated previously, our XGBoost model can explain just over half of the variance in the $SWCRE_{TOA}$ bias ($R^2 = 0.55$). The remainder of this variance, as well as some of the spatial differences observed in Figure 1d suggests that the biases in the cloud fields used in this work may not be the only contributors towards this particular feature of the radiative bias. Alternatively, it could also imply that the robustness of the data that we consider truth are not the same for all regions. The study that the current work follows on from, F22, showed little zonal asymmetry in the LWP, IWP, CFL and CFI biases and similarly, little asymmetry in the relative frequency of occurrence biases of different cloud types, suggesting the need to account for additional physical properties and relationships in these regions.

240 The missing component could be a range of things, for example, another micro-physical cloud field, dynamical field or
environmental factor, i.e: the presence of ice nucleating particles, sea surface temperatures or thermodynamical properties of
the atmosphere. For example, the influence of dust derived ice nucleating particles may be greater in particular sectors of the SO,
in certain seasons, which may change cloud properties in those regions. Alternatively, Zipfel et al. (2022), in predicting LWP
over marine boundary layer clouds in the Southeast Atlantic, found that dynamical characteristics and sea surface temperature
245 were important environmental factors, along with other cloud property predictors.

Although the XGBoost model is able to explain a larger amount of the $SWCRE_{TOA}$ bias than any individual or linearly
associated cloud feature could, we must keep two things in mind. Firstly, by adding more (and in particular, not internally
consistent) data we make interpretation more difficult and secondly, that the relationships shown here do not prove a causal
relationship. We must understand what the model is inferring physically for us to make such association. In this work, we
250 anticipate that even with only 54-55% of the variance explained by these cloud biases we can derive valuable information in
how they contribute or do not contribute to the radiative bias. For these reasons, we will continue with our described method,
and explore how each of these cloud features contribute to predicted $SWCRE_{TOA}$ bias using SHAP analysis.

4 Understanding the $SWCRE_{TOA}$ biases

SHAP feature importance analysis allows us to quantify the contribution (or importance) of each cloud feature made to the
255 predicted result, in this case the XGBoost radiative bias. This is demonstrated in Figure 2a, where a so-called force plot is
shown. Here, we can see how, for this singular prediction of x , each cloud feature has contributed to the total prediction $f(x)$,
but shifting the values away from the base value (12.4 W m^{-2}). We note that for the cloud features, their actual values, not the
SHAP values are shown in text for the top predictors, while the magnitude and sign of the SHAP value is indicated by the bar.
The base value can be considered as the starting point of any prediction, i.e. if we had no information about the cloud state, a
260 good prediction to start with is the base value. Each cloud feature then adds subsequent information to the prediction, which
all together sum (with the base value) to the total prediction. This also means that when summed together for any individual
point, or subsection of points, the SHAP values do not represent the total prediction for that point or subsection, but rather the
difference from the base value. This is demonstrated by Figure 2b, which shows the mean sum of all SHAP values spatially,
which is equivalent to the difference between the predicted bias (shown in Figure 1b) minus the base value. This characteristic
265 of the SHAP analysis must be kept in mind when considering the SHAP values.

4.1 The mean importance of cloud features to the $SWCRE_{TOA}$ bias

With this functionality of SHAP features in mind, we can now start to analyse our results both globally (ie. the mean across all
points) and locally (using subsections, either spatially, temporally or other groupings). Figure 2c shows the global importance
values, which is simply the absolute mean (|MI|) of all SHAP values for each cloud feature. These values give us the first
270 indication of how important each cloud feature is comparatively, with the higher the |MI| value, the more important that feature
is to the overall prediction. Here we can clearly see that the biases in liquid water path contribute most to the predicted

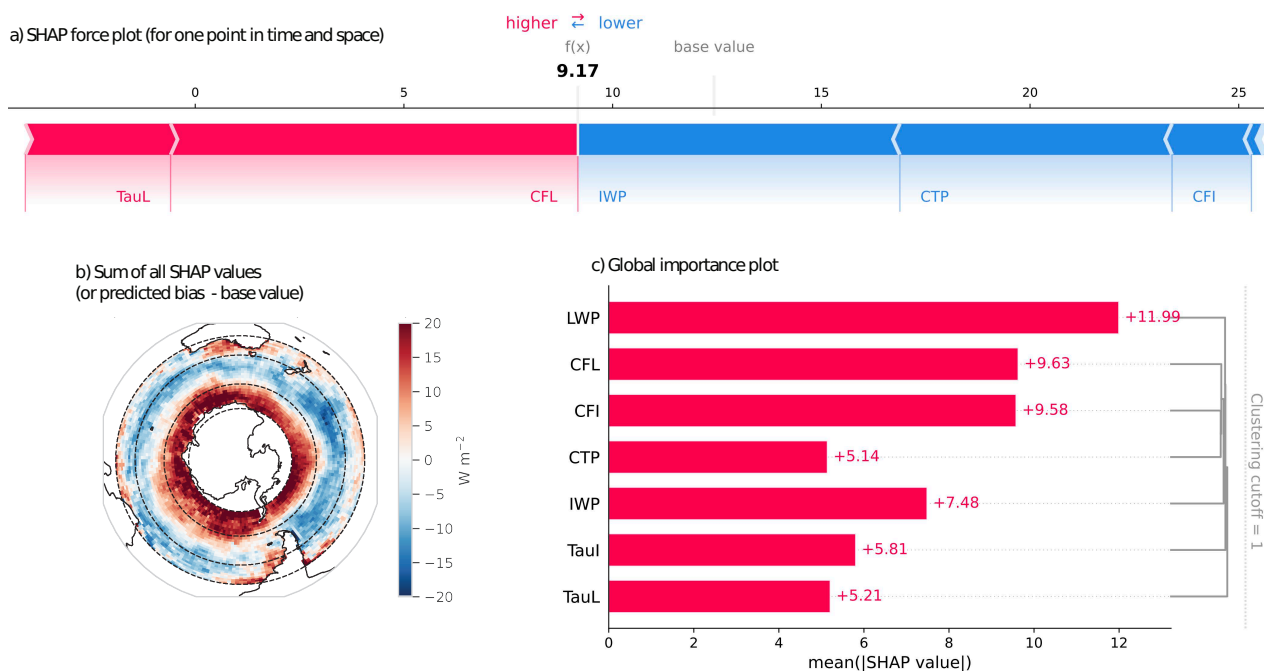

Figure 2. (a) a SHAP force plot showing the SHAP values for each predictor for a single example prediction. The sum of these values is the difference between the 'base' value (i.e. mean prediction) of $12.4 W m^{-2}$ and the individual prediction of $9.17 W m^{-2}$. (b) the sum of all SHAP values for each spatial point. (c) the global importance plot showing the mean of the absolute SHAP values (in $W m^{-2}$) for each predictor across all predictions, with the dendrogram indicating the degree to which these predictors are clustered.

SWCRE_{TOA} bias, with $|m|$ equal to $11.99 W m^{-2}$. This is followed by the liquid cloud fraction ($9.63 W m^{-2}$), ice cloud fraction ($9.58 W m^{-2}$) and ice water path ($7.48 W m^{-2}$), ice optical depth ($5.81 W m^{-2}$), liquid optical depth ($5.21 W m^{-2}$) and cloud top pressure ($5.14 W m^{-2}$) biases.

275 Figure 2c has not been arranged in order of most to least important, but has instead been clustered, using the in-built SHAP clustering function. This is shown by the dendrogram on the right of the plot, where features are hierarchically merged into clusters. Clustering the SHAP features together can give us an indication of which cloud features are providing similar information to our XGBoost model. If two features provide the same information, the XGBoost model will only use one of them for efficiency, which, while maintaining statistical robustness (eg. avoiding the effects of collinearity), can impact our

280 interpretation of the results. For this plot, we have used a clustering distance cut-off of 1, allowing us to see that our features merge at a distance closer to one. A distance of one would imply feature independence, while zero would imply complete redundancy.

Here we see that the least important cloud feature (CTP) is the first to be merged into clusters with the most important cloud features (eg. CFI). However, the merge is occurring only slightly before other features are merged into the other clusters,

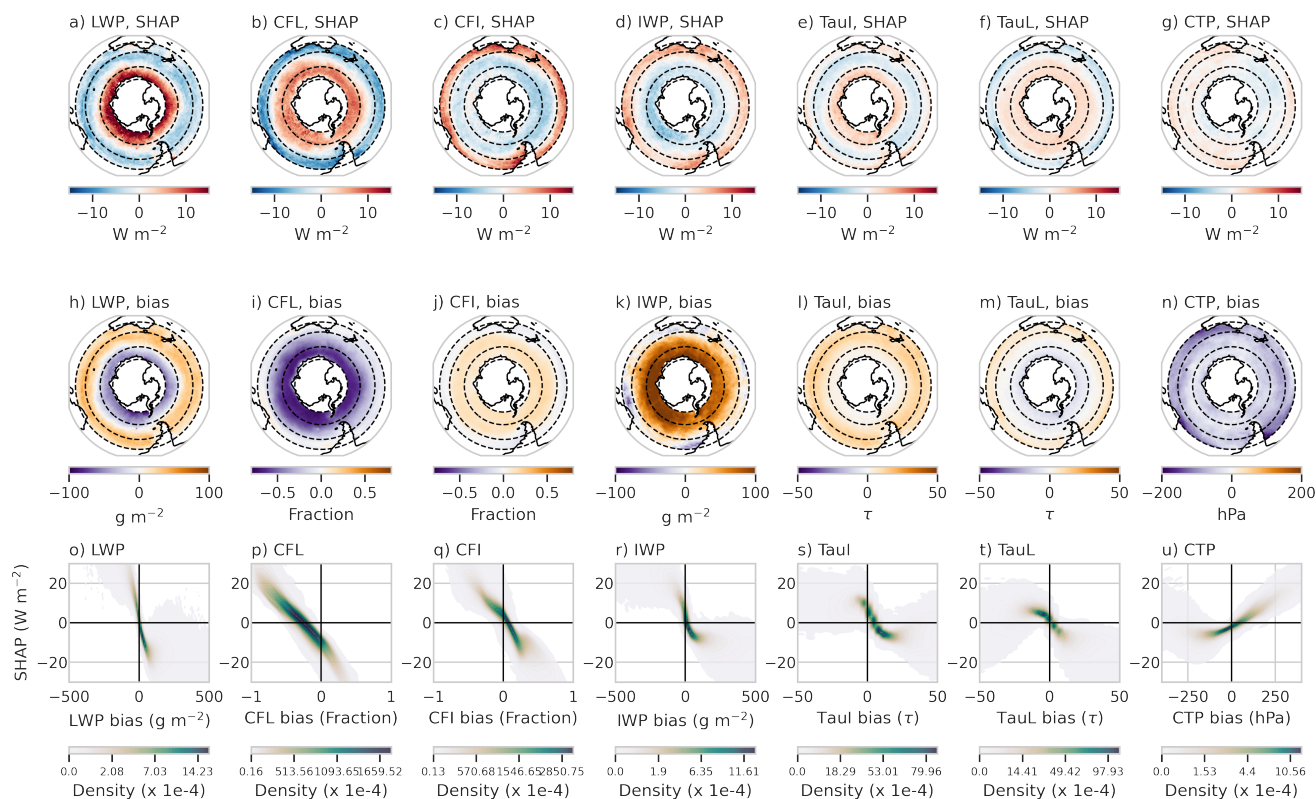

Figure 3. Top row (a-g): the time-averaged SHAP values for each cloud feature over the SO domain. Middle row (h-n): the time-mean biases (ACCESS-AM2 - MODIS) for each of the cloud features. Bottom row (o-u): Scatter plot distributions (darker colours indicate greater density) showing the relationship between the bias in each cloud feature and respective the SHAP values. Note that the scatter plots have been limited along the x and y axis to better show the behaviour of the majority of the distribution.

285 indicating that even the weakest cloud features are providing important information to the XGBoost model. This supports our earlier finding of only weak-moderate collinearity between cloud features and means that we are able to make inferences about how each cloud feature is impacting the radiative bias physically.

4.2 Drawing physical conclusions from our SHAP values

290 While these global importance values are useful to summarise results, they limit the information needed to be able to physically explain why a particular feature may or may not be important. A strength of the SHAP analysis is that an individual SHAP value can be calculated for each feature for every point in time and space. Thus, we can use them to understand how these cloud features contribute to the radiative bias spatially (i.e. their ‘local’ values), and use the relationships of the SHAP values to their respective cloud feature to try to understand their contribution physically. Figure 3 summarises the outcome of the SHAP analysis.

295 The scatter plots of Figure 3 (bottom row) help us understand the spatial means that are presented along the top two rows. Here we find that most of the relationships shown are non-linear, especially with respect to the outliers, with at least one case being parabolic (CTP in Figure 3u). Interestingly, the ice and liquid counterparts for each field (bar cloud top pressure), are similar in shape, giving us confidence that this method is able to capture the role cloud phase plays in the $SWCRE_{TOA}$ bias.

Examining Figure 3 field by field, for LWP, we can see that the spatial SHAP values and the bias patterns line up closely (plots a and h), indicating that increasingly large and positive values of the LWP bias do contribute to an increasingly negative radiative bias (and vice versa). Figure 3o indicates that this behaviour should be expected, with the distribution diagonally centred on zero. In the mid-latitudes, positive LWP biases are associated with negative SHAP values, which transition to negative LWP biases and positive SHAP values in the polar region. Both of these outcomes make sense with our physical knowledge of how LWP interacts with radiation, where clouds with high LWP would reduce the amount of sunlight reaching the surface.

For the CFL, SHAP values are negative in the mid-latitudes while positive in the sub-polar and polar regions. The change in sign of the biases in CFL does not coincide spatially with the SHAP values, which are strongly negative in the polar and sub-polar region, and weakly negative in the mid-latitudes. Examining Figure 3p shows that the relationship between the biases and SHAP values is offset from zero so that weakly negative CFI biases can produce negative SHAP values. These weakly negative CFL biases are occurring predominantly in the northern boundary of the sub-polar region. If we consider making a prediction of the radiative bias, starting from our base value (12.4 W m^{-2}), and only knowing about the CFL properties, we can say that in instances where the CFL bias is weakly negative, the radiative bias will be less positive than if the CFL bias is much larger. While this makes sense when considered together with the base value, this result still demonstrates that the radiative influence of clouds is not as simple as "less cloud (even marginally) equals more sunlight passing through".

315 Unlike the CFL, the CFI SHAP values and bias patterns are easier to interpret, with the spatial patterns of Figure 3c and j lining up neatly. Weakly negative biases in CFI correspond to moderately strong positive SHAP values in the mid-latitudes, while positive CFI biases contribute to moderately negative SHAP values, having a compensating effect to the overall $SWCRE_{TOA}$ bias of the region. Similarly, the IWP SHAP values are negative in the polar and sub-polar regions and positive in the mid-latitudes. The IWP biases are strongly positive in the polar region, positive in the sub-polar region and are a mixture of positive and negative values for the mid-latitude, depending on proximity to land masses.

325 The association of negative SHAP values with positive IWP and CFI values is not an immediately intuitive one, given that the literature suggests that too much ice, in place of liquid, results in too much radiation reaching the surface. However, too much ice can still physically result in too much $SWCRE_{TOA}$ being reflected out to space. The broad similarity in SHAP patterns between the LWP and CFL, as well as the IWP and CFI implies that the underestimation of liquid clouds is a key driver of the $SWCRE$ bias, while the underestimation of ice clouds is actually having a compensating effect. These results suggest that modelling efforts to simply shift water mass from the liquid to the ice phase (eg. by changing ice nucleation temperatures or slowing crystal growth rates) may not entirely solve the problems in radiative properties. Instead we suggest that these two phase types may need to be tackled independently, with consideration of the ice nucleating particle availability explicitly included in future model development.

330 The TauI SHAP values presents an almost cubic function compared to the TauI bias in Figure 3s, which is, on average, positive. The weaker the positive TauI bias (ie. the thinner the cloud), the more positive the SHAP values (more sunlight reaching the surface). Interestingly, the weakest TauI biases occur in the polar region (Figure 3l), despite strongly overestimated IWP (and to some degree CFI). We suggest that the ice water may be dispersed through the overestimated cloud fraction, resulting in lower biases in optical thickness. However, the positive SHAP value (rather than a simply weak negative value) indicates the non-linearity of this system and possibly a process that we are yet to understand. For TauL, we see a similar relationship, where the thinner the cloud (eg. negative biases), the more sunlight is allowed to pass through the cloud (positive SHAP values). Positive SHAP values are found in the polar and sub-polar regions, while this transitions to negative in the mid-latitude region (Figure 3f).

Finally, the CTP presents the only zonally asymmetric cloud SHAP values in the sub-polar and polar region, with negative SHAP values in the Pacific sector and West Antarctic region. The relationship between SHAP values and CTP bias is non-linear (Figure 3n), where positive and negative CTP values can correspond to both positive and negative SHAP values. What is causing the difference in SHAP values is difficult to discern at this broad scale, as meridional differences such as this have not been previously identified in this study. As discussed earlier (Section 3), the XGBoost model does a poor job of capturing the asymmetry of the $SWCRE_{TOA}$ bias. While the CTP does contribute a small amount, it is, tellingly, the weakest predictor of all the fields examined. However, these findings indicates that vertical cloud structure should not be neglected when trying to reduce the region's overall $SWCRE_{TOA}$ bias.

The results presented in this section have provided us with an overall understanding of what the relationships of the SHAP values are with the respective biases. In most cases, the relationships presented make physical sense, aligning with our understanding of how cloud biases may influence radiative biases. For CFL and TauI, where the relationship was offset from zero along the y-axis, the relationships require consideration of the broader environment (eg. the base value) and demonstrate non-linearity and possibly a threshold dependence too. In the next section we will further break down the SHAP/bias relationships into cloud specific contexts to examine this further.

4.3 Cloud-scale dependence

The majority of the Southern Ocean cloud-radiation bias literature performs some form of conditional grouping to evaluate model performance (as discussed in the introduction). In this work, we use the cloud types developed in F22, where ten cloud types are defined based on their CTP-optical depth profiles. In the remaining analysis, we use the MODIS derived cloud types to summarise the SHAP values and biases to determine if a cloud-type dependent relationship exists. Figure 4 shows a scatter plot of SHAP values versus the cloud feature bias, similar to the bottom row of Figure 3. However, in Figure 4, the points represent the mean SHAP versus bias value relationship for each of the MODIS derived cloud types, shown by the colours, with the shapes representing the three regions of interest and sized by their frequency of occurrence. The cloud types are arranged from the highest, thinnest clouds (thin cirrus, TC; cirrus, Ci), to optically thick mid-high clouds (convective, Cv; frontal, Fr), optically thick mid-low level clouds (mid-level, ML; stratocumulus, StC) through to optically thick low level clouds (marine stratiform, MS; cloud decks, CD) and less optically thick low clouds (shallow cumulus, ShC). Finally the Antarctic (Ant)

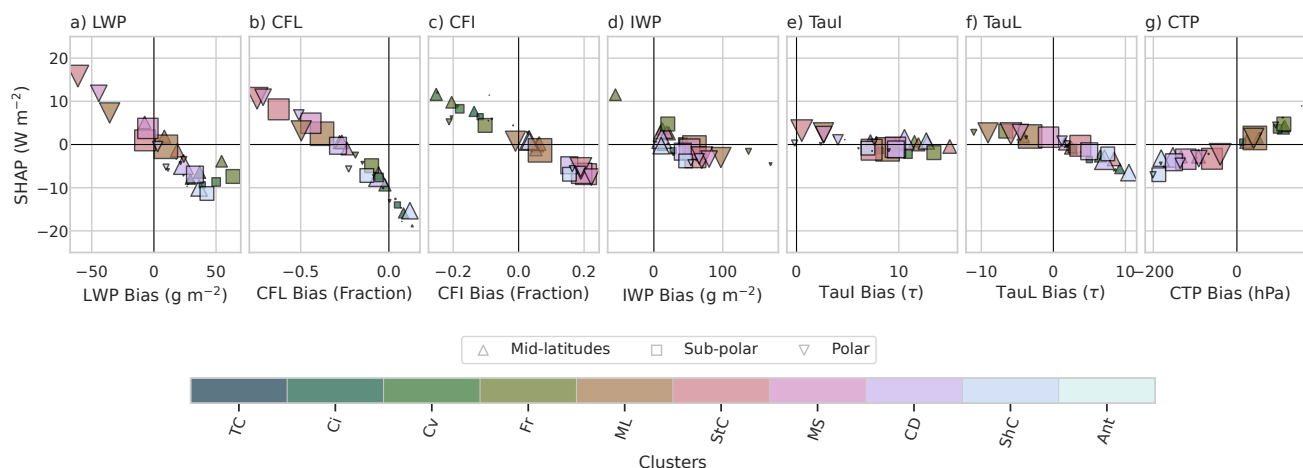

Figure 4. The mean SHAP values (y-axis) versus bias (x-axis) for each cloud feature (a-g) averaged by MODIS cloud type (colours) for the three regions of interest indicated by: upwards triangle - mid-latitudes; square - sub-polar; downwards triangle - polar. The size of the shape indicates the frequency of occurrence of each cloud type; a larger shape indicates a more dominant cloud type. The cloud types are as follows: thin cirrus, TC; cirrus, Ci; convective, Cv; frontal, Fr; mid-level, ML; stratocumulus, StC; marine stratiform, MS; cloud decks, CD; shallow cumulus ShC; Antarctic, Ant

clouds represent mid-level very optically thin clouds. More details about the properties, frequencies and distribution of these clouds can be found in F22.

Figure 4 offers a new, quantitative insight as to how the biases for each cloud type are contributing to the overall $SWCRE_{TOA}$ bias. Firstly, it is clear that there is a dependence on cloud type for the role played by the cloud biases on the radiative bias. For most cloud features shown, the cloud types are grouped by height/thickness. For example, Figure 4a, the LWP, shows that the mid-level, stratocumulus and marine stratiform clouds in the polar region contribute most to the $SWCRE_{TOA}$ bias, with SHAP values of up to $15.8 W m^{-2}$ associated with large negative LWP biases. For the sub-polar and mid-latitude regions, lower LWP biases correspond to lower SHAP values for these same cloud types, despite their continued dominance (indicated by size), indicating that for these regions, these optically thick, mid-low level clouds are not driving the $SWCRE_{TOA}$ bias. The remainder of the cloud types exhibit the opposite trend, where both the higher clouds (eg. convective, frontal) and the lower, less optically thick clouds (cloud decks, shallow cumulus) are characterised by positive LWP biases and negative SHAP values. These cloud types are much more dominant in the sub-polar and mid-latitude regions, indicating a regional dependence with respect to the role that LWP path plays in radiative bias.

The CFL, shown in Figure 4b, shows a similar trend to that of the LWP, where the polar mid-low level, optically thick clouds demonstrate the largest SHAP values and biases. With this figure, we can also begin to understand the conditions where negative CFL biases result in negative SHAP values, where the optically thinner shallow cumulus, frontal and convective cloud types of the sub-polar region, and interestingly, cloud decks of the mid-latitudes are the major contributors.

For the CFI, Figure 4c, clear groupings of cloud types are found with less dependence on region. Higher clouds, including cirrus, convective and frontal clouds are primarily responsible for driving positive SHAP values, associated with negative biases. Most other mid-latitude clouds, in addition to the mid-level polar and sub-polar clouds show little bias/SHAP value, while the majority of low-level polar and sub-polar clouds are associated with too much CFI, resulting in negative SHAP values. Interestingly, less clear trends are found for the IWP.

The two optical depth cloud features show a larger regional dependence, where points are grouped more so by region than by cloud type. The SHAP values of all cloud types for the optical depths are small (regardless of bias) compared to the other cloud features. This may indicate that how the optical depth biases interact with radiation biases is much less dependant on the cloud type than other physical characteristics (eg. latitude).

Finally, the CTP shows the clearest separation of SHAP/bias relationship by cloud type of all the cloud features. The cloud types are clearly grouped together, with the lowest clouds having negative CTP biases/SHAP values and the higher clouds having positive CTP biases/SHAP values. CTP, in earlier analysis, was characterised as the weakest contributor of the radiative bias, but these results show that if appropriately grouped, it has a similar importance as that of the CFI. This finding indicates that CTP (or cloud vertical structure) may be of greater importance for the radiative bias than currently acknowledged in the literature.

These results offer a new perspective of how different cloud properties, for different clouds and regions may affect the radiative bias. The SHAP analysis allows us to consider many properties at once, in a meaningful and quantitatively comparable way. Previous work, including the work preceding this analysis, F22(presented in Fiddes et al., 2022), has been unable to provide such a holistic, and yet quantitative analysis of the cloud-radiative bias to date. For example, while F22 was able to highlight the importance of stratocumulus and mid-level clouds for the SO cloud-radiative bias, as well as the compensating effects of lower, thinner clouds such as shallow cumulus clouds, the analysis was far more qualitative than what has been presented in this work.

5 Using SHAP analysis to understand model perturbations

We have demonstrated the usefulness of the SHAP method in quantitatively understating drivers of biases. This method has provided useful insights into the mean drivers of the SWCRE_{TOA} bias as well as into cloud-specific influences. We now want to test if this method is useful in understanding how perturbations applied to a model may change the results. To do this, we have performed a second nudged simulation, where we have altered the ice-crystal capacitance, following the work of (Varma et al., 2020). We refer to the new simulation as the ‘ice’ simulation (compared to the ‘control’). In the ice simulation, we have changed the capacitance from 1 in the control, which assumes a spherical crystal, to 0.5, which assumes an oblate ice crystal. The effect of this change is to slow down ice crystal growth rates. Overall, reducing the ice crystal growth rates reduces the radiative bias by -1.0 W m^{-2} for the entire region (-1.2 W m^{-2} for polar region, -1.0 W m^{-2} for sub-polar region and -0.8 W m^{-2} for mid-latitudes) in our simulations. This difference is smaller on average and noisier than that found in Varma et al. (2020) (and not statistically significant), which we expect is a result of the nudging of the model. Similar constraints on

meteorology was found in Fiddes et al. (2021) when nudging was applied during model perturbation experiments. Regardless, this small perturbation experiment provides an opportunity to test the usefulness of the SHAP method, even if the changes are very small.

With this second simulation, we have re-trained (and re-tuned) our XGBoost model. The performance of the XGBoost-ice model is very comparable to that of the control, explaining between 54-55% of the variance. The mean difference in the predicted bias from the control is similar to that of the true bias, of 0.9 W m^{-2} . Once again, LWP is the most important cloud feature, and the order of importance for each cloud feature has not changed.

Figure 5 shows the changes in SHAP values (ice-control) for each cloud field along the top row, and the changes in the fields themselves along the middle row (also ice-control). The noisiness introduced by the nudging is clear in these plots and we note that none of the changes are statistically significant. Nevertheless, some interesting features can be seen in these results.

Firstly, we can see that changing the ice crystal shape, which slows ice growth and increases LWP in the polar and sub-polar regions (Figure 5h). This change reduces the overall bias in the polar region (which is negative - see Figure 3h). In the mid-latitudes the change is much less coherent. The resulting change in SHAP values indicates that in the polar region, the increased LWP has overall reduced the SHAP values, although results are quite noisy. Figure 5o demonstrates that polar and sub-polar stratocumulus clouds are associated with the largest increase in LWP and reduction in SHAP values. Interestingly, shallow cumulus clouds, despite showing only small increases in LWP, are also associated with larger SHAP values for all regions.

CFL (Figure 5i) shows a varied and very small response to the change in ice crystal growth. CFI on the other hand (Figure 5j) shows a clear and consistent increase in fraction. This increase in CFI may be caused by an increase in cloud lifetime as the ice crystal growth rate slows down, which is supported by a small decrease in snowfall rates over the polar region (not shown). The change in SHAP values for CFL is predominantly negative in the polar regions and positive in the sup-polar to mid-latitudes. For the CFI, the changes in SHAP values are harder to differentiate.

Considering these changes grouped by cloud type, some interesting patterns are apparent, though we note the magnitude of these values in cloud fraction are again very small. For CFL, higher clouds (cirrus, convective, frontal) are found to be associated with a reduction in CFL and an increase in SHAP values. Polar marine stratiform and cloud decks exhibit a stronger positive change in CFL, associated with a decrease in SHAP values, while the remaining cloud types (for all regions) show a much more neutral response. For CFI, all cloud types, for all regions, experience on average an increase in fraction, but this increase results in positive change in SHAP values for the lower, thicker clouds and a negative change in SHAP values for the higher, thinner clouds. The varying behaviour of higher/thinner clouds compared to lower/thicker clouds for CFI and CFL, both with respect to the cloud properties themselves, and their resulting SHAP values, highlights that a 'one solution fits all' approach to reducing cloud-radiative biases in models is not appropriate.

We will not discuss the changes in optical depth or IWP for brevity, however, will touch on CTP in Figure 5g, n, and u. Consistent reductions in CTP are found for the entire regions, which acts to increase in magnitude the already negative bias (Figure 3n). The changes to SHAP values on average are small. However, if we consider these values separated by cloud type/region, we can see a strong separation in behaviour between cloud types. Thinner, higher clouds, which were on average

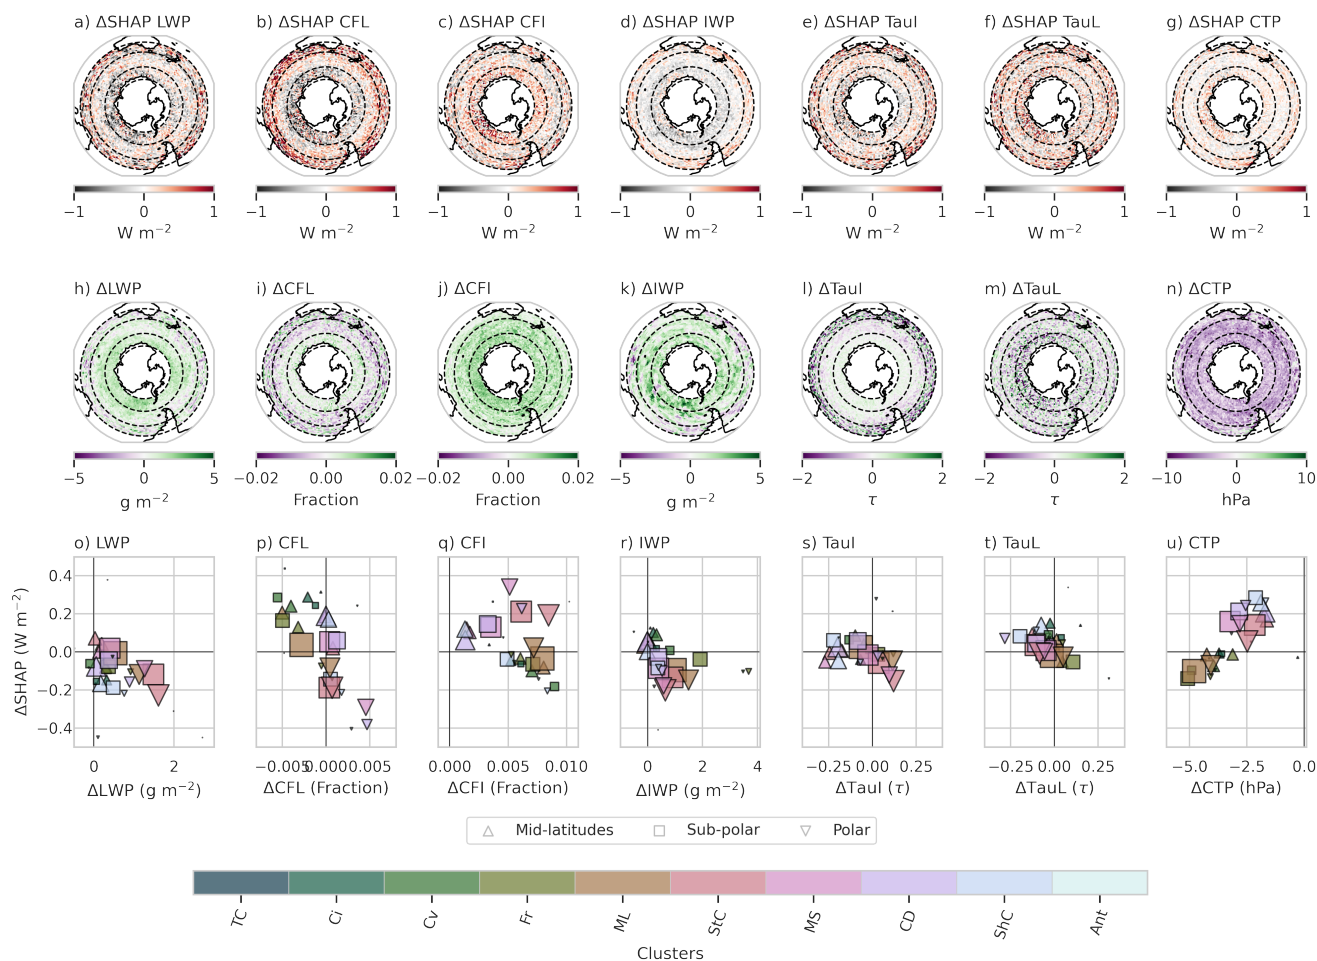

Figure 5. Top row (a-g): the time-averaged difference in SHAP values (ice-control) for each cloud feature over the SO domain. Middle row (h-n): the time-mean changes (ice-control) for each of the cloud features

overestimating CTP, are found to have larger decreases in the CTP. The lower, thicker cloud types exhibit a smaller magnitude decrease, only minimally exacerbating the CTP bias (see Figure 3u). These two groups of clouds types are also associated with different SHAP values, where the lower/thicker clouds, decreases in CTP (increases in cloud height) results in more positive SHAP values. The higher/thinner clouds, despite also decreasing in CTP, are found to have negative changes in SHAP values.

The results presented in this section indicate very small, insignificant changes to cloud properties when ice crystal growth rates are slowed within a nudged model framework. Nevertheless, these changes have resulted in the expected decrease in radiation bias and are of use to us within the context of this analysis: can we use SHAP values to examine changes in model parameterizations? Here, the behaviours of cloud types/regions, with respect to changes in cloud properties/SHAP values, are of greater interest to this work for a number of reasons. Firstly, these results highlight that despite the averages presented in

the top two rows of Figure 3, cloud-radiative interactions are much more complex. Importantly, this analysis has been able to condense and analyse a large amount of information in a more succinct way than previously possible, with many prior studies only concentrating on one region and/or one cloud type (typically low-level stratiform). Secondly, this analysis clearly demonstrates instances of compensating radiative errors between different cloud properties, types and regions. While spatial compensating errors have previously been identified, few prior studies have examined them with respect to cloud type. To our knowledge, no other study has been able to directly associate changes in cloud properties to changes in the radiative bias (though we stress that the results here do not present a casual relationship).

We believe that this last point is where the power of SHAP analysis lies. In this work we can see that, for example, for low/thick clouds in the polar region, the resulting changes in LWP, CFL and IWP caused by the model perturbation work to decrease the prediction of the radiative bias, while CFI and CTP have the opposite effect. No other analysis method is able to consider a system as a 'whole' (within the confines of the data provided that is), and subsequently isolate the effect of individual components.

6 Discussion and Conclusions

The SO radiation bias has been a topic of considerable research over the last decade, motivating a number of innovative methods and studies to understand its controls. While methods such as cloud regime clustering or cyclone tracking have become standard ways to evaluate the SO radiative bias (eg. as in Bodas-Salcedo et al., 2016), they do not account for the entirety of the SO and the range of biases found across it. This narrower view has proven detrimental to some model development studies, where some aspects of cloud microphysics, such as ice nucleation temperatures, have been altered to target the worst of the radiative bias, but have led to unwanted changes in other regions (eg. as in Varma et al., 2020; Furtado et al., 2016).

In this study, we have proposed a new method for model bias evaluation, employing modern machine learning and taking advantage of the large amount of cloud and radiation data available to us and facilitated by enhanced computing resources. This method, where we use biases in cloud properties to predict the $SWCRE_{TOA}$ bias, considers the entire SO, from the mid-latitudes to the polar regions, at a daily timescale. This study has been made possible due to our ability to perform a nudged climate model simulation, an underutilised method in climate research without which like-for-like comparisons to satellite fields are not possible. This work provides a new perspective on the downwelling shortwave radiation bias, which will help guide our future model developments. Furthermore, we expect that this method could be applied to a range of complex model biases throughout the climate system beyond radiation.

Specifically, in this work we have continued our evaluation of the ACCESS-AM2 models SO cloud and radiative biases (from Fiddes et al., 2022). The ACCESS-AM2 SO $SWCRE_{TOA}$ bias is shown to be the largest in magnitude over the polar region, while it weakens in the sub-polar and mid-latitude regions. Of interest to this work in particular is that the ACCESS-AM2 model lacks the zonal asymmetry of the CERES-Syn1D $SWCRE_{TOA}$, with positive biases in the Australian and Pacific sectors. This asymmetry has not previously been considered and indicates that the SO radiative balance is a complex system that cannot be solved with one 'fix'.

Importantly, the ACCESS-AM2 SWCRE_{TOA} bias cannot be completely explained by the biases in several key cloud properties, including LWP, IWP, CFL, CFI, TauL, TauI, and CTP from the MODIS COSP product. Many of these cloud biases have a non-linear relationship with the radiative bias, as well as weak collinearities amongst them, demonstrating the complexity of the system and the need for a method that can take such complexities into account. For this purpose, we have used a tuned and tested XGBoost model to predict the SWCRE_{TOA} bias, using the biases from these cloud fields as predictors. The XGBoost model can explain up to 55% of the SWCRE_{TOA} bias; more than any one of the cloud fields alone or a linear combination could. While the general pattern of the radiative bias is captured, the zonal asymmetry is not, with the XGBoost prediction lacking the positive values found in the sub-polar region. This finding suggests that the asymmetry may not be a function of the cloud properties explored in this work, but possibly some other environmental factor, such as a dynamical or thermodynamical property, aerosol sources and interaction or proximity to the polar front. Other studies have found that environmental factors, such as SSTs or dynamical predictors are important for predicting cloud characteristics or radiation (Zipfel et al., 2022; Mallet et al., 2023). Such factors may contribute to the missing 45% of predictability, though this has not been tested in this work. For this analysis, we have chosen not to explore additional parameters for three reasons: 1) to maintain interpretability - the more parameters you have the less interpretable your model becomes; 2) to maintain some level of data homogeneity - we try to limit the number of sources (eg. different satellite products) our predictors are coming from to limit inconsistencies in assumptions; and 3) to keep our focus on the cloud-radiative relationship, without compounding it with other external factors. However, we suggest that future work should explore how environmental factors may influence the SWCRE_{TOA} bias, including looking at cloud condensation nuclei availability, cloud droplet number concentration, ice nucleating particle concentration, sea surface temperature, and vertical cloud overlap.

One of the benefits of using the XGBoost model is that it can efficiently be interpreted and analysed with the SHAP feature importance method. Our SHAP analysis has shown that the biases in LWP are the main drivers of the SWCRE_{TOA} bias (with CFL, CFI and IWP following). Further exploration of the SHAP feature importance and the cloud biases indicates that the relationships are still non-linear, but for the most part, we can make physical sense of them. In addition, we have shown that there are cloud-type specific behaviours that can be easily captured using this type of analysis. This method allows us to evaluate cloud-radiative biases in a much more holistic way, compared to isolating just one, often pre-designated, 'important' cloud type. Furthermore, we find distinct cloud-type behaviours in the SHAP/bias relationship, which we expect can be leveraged in future model development.

We have tested this by exploring a simple model perturbation, previously described in Varma et al. (2020), where we reduce the ice shape capacitance from 1.0 to 0.5, thereby reducing the ice crystal growth rates, increasing LWP and reducing the radiative bias by approximately 1 W m⁻². We note that (Varma et al., 2020) saw much larger radiative changes in response to this perturbation, which we suggest is due to the free-running nature of their experiments. Although the changes between this test run and our control were small (and insignificant), we believe that results demonstrate the power of SHAP analysis, where complex changes within a system can be evaluated and their impact quantified.

In this work, we find that the SHAP values for opposite cloud phases do not balance out. Total liquid phase values outweigh the total ice phase values. This finding, plus the non-linearities and cloud-type dependencies of the system suggest that changing

our cloud parameterisations to simply move mass from one phase to another in order to balance the liquid and ice phases may not remove the $SWCRE_{TOA}$ bias entirely. We suggest that concerted effort is required to improve the individual representation of each phase, in a more physical way, which can take into consideration different environmental conditions. We suggest that the parameterisations of CCN and INP is a good place to start as, unlike other changes to the model (eg. changing the freezing temperatures, detrainment temperatures, ice crystal shape or growth rates: Varma et al., 2020; Furtado and Field, 2017; Kay et al., 2016), they are derived independently, and do not simply change phase partitioning. Note we are not suggesting that improvements to microphysical representations are futile (in fact the opposite); we do suggest that they may have a lesser impact, or in some cases, undesirable impacts, if not done with strong physical backing.

Vignon et al. (2021) has shown that empirically forcing a model's INP concentrations can result in significant improvements in super cooled liquid water fraction. Such work has begun for the UM model family: (Vergara-Temprado et al., 2017) have explored the importance of marine organics and dust to INP concentrations in the SO and their subsequent control on cloud reflectivity, but a more concerted effort is needed. Specifically, we need to ensure the chemical and aerosol pathways responsible for both INP and CCN are a) accurate and b) coupled to the cloud scheme satisfactorily (two-way coupling preferred). In ACCESS-AM2, analysis has shown that CCN concentrations are significantly underestimated in the SO (manuscript in preparation), while INP concentrations are not resolved by the aerosol scheme, but rather parameterised without consideration of the compositional environment. This is a key area for development, a process that has been started by Varma et al. (2021), though still requires considerable work with a stronger connection to the aerosol scheme. We hope that future work in this space can make use of the methods presented in this study, to holistically quantify how their changes to the model affect the cloud-radiative system.

To summarise, we have provided a new method for understanding model biases, using a nudged climate simulation and machine learning. We hope that this method can be applied to other fields to gain new insight into the complexity and the drivers of modelling biases, and how model perturbations may improve or worsen such biases. When considered as a whole, the SO $SWCRE_{TOA}$ bias is shown to be complex, with large non-linearities, cloud-type and regional dependencies and compensating errors. Our results suggest that the liquid phase of clouds is the most important contributor to the $SWCRE_{TOA}$ bias, more so than the ice phase, and that different higher/thinner clouds often behave in an opposing manner to that of the lower/thicker cloud types, in some cases having compensating effects on the radiative bias. We propose that we need to address the biases in the liquid and ice phase of SO cloud properties individually (i.e. more physically) in order to reduce the $SWCRE_{TOA}$ bias and we expect that the best way to do this is to ensure the nucleating particles (CCN and INP) are resolved by an aerosol scheme and fully coupled to the microphysics.

Code and data availability. Processed model and observational data and the relevant code for this project is available at <https://doi.org/10.5281/zenodo.7196622>.
