**Abstract.** This work defines a new snow metric, snow water storage (SwS), which is the integrated area under the snow water equivalent (SWE) curve [units: length-time, e.g. meter<sup>3</sup>-days]. Other widely-used snow metrics capture snow variables at a single point in time (e.g. maximum SWE) or describe temporal snow qualities (e.g. length of snow season), SwS can be applied at numerous spatial and temporal scales. The flexibility in the SwS metric allows us to characterize the natural reservoir function of snowpacks and quantify how this function has changed in recent decades. In this study, changes in the SwS metric are evaluated at point, gridded and aggregated scales across the conterminous United States (hereafter US). There is special focus on 16 mountainous EPA Level III Ecoregions (ER3s), which ~~play an inordinate role in account for most of the~~ US annual SwS (SwS<sub>A</sub>). ~~An average of 72% of the annual~~ Seventy two percent of the SwS<sub>A</sub> in the US (3.5e13 m<sup>3</sup>d) is held in the 16 ~~mountain mountainous~~ ER3s, despite these ER3s only covering 16% of the US land area. SwS<sub>A</sub> and monthly SwS (SwS<sub>M</sub>) have changed significantly across the US since 1982 at ~~point, gridded and ER3~~ all spatial scales. This change is spatially variable across the US with ~~more spatially widespread significant decreases in SwS<sub>A</sub> than increases~~ notable decreasing SwS<sub>A</sub> trends in the western US and in mountainous regions. The greatest SwS<sub>M</sub> ~~loss occurs in March at stations, grid cells and in mountainous ER3s, though the greatest percent loss of SwS<sub>M</sub>~~ occurs early in the snow ~~snow~~ season, particularly in November. All ~~but two mountainous~~ ER3 ~~mountain ranges (except for the the Northern Highlands in New England)~~ have decreasing trends in SwS<sub>A</sub> and there has been a 22% overall decline in SwS<sub>A</sub> across ~~all mountain the mountainous~~ ER3s. Unsurprisingly, the highest elevations are responsible for the greatest SwS in all mountain ranges, though the relative elevations that have lost or gained SwS over the 39 years of study are variable ~~across between~~ mountain ranges. Comparisons of ~~the percent change in~~ SwS to other snow metrics ~~reveals that change in the SWE curve has not been shape-preserving – instead, the SWE curve has been flattening~~ illuminates the utility of SwS, which can provide information on the natural reservoir function of snowpacks, regardless of SWE curve variability or type (e.g. ephemeral, mountain, permanent). As we move into a future of increased climate variability and increased variability in mountain snowpacks, spatially and temporally flexible snow metrics such as SwS may become more valuable.

## 1 Introduction

Seasonal snow is a ~~keystone-critical~~ resource in mountainous regions and at high latitudes across the United States (US), ~~and many other countries~~, providing an important ecosystem service by functioning as ~~natural reservoirs at river headwaters~~ a natural and spatially-distributed reservoir. These snow reservoirs play a key role in the water cycle by storing water during the cool

season and releasing water gradually throughout the warm season when human and ecological demand is the highest. Given the vulnerability of seasonal snow water storage to climate warming and the importance of snow-derived water to municipalities, agriculture, ecosystems, and hazard forecasters, it is vital to understand how water storage in our natural snow reservoirs is evolving in the context of a changing climate (Immerzeel et al., 2020; Sturm et al., 2017; Barnett et al., 2005; Li et al., 2017; Siirila-Woodburn et al., 2021). As the majority of natural snow water storage in the US occurs in mountainous regions ~~across the United States~~, it is ~~vital-important~~ to understand how the natural reservoir function of snowpack is changing in individual mountain ranges. EPA Level III ecoregions (ER3s) delineate areas of similar abiotic and biotic (including humans) components of terrestrial and aquatic ecosystems that can be used for ecosystem management and to enhance environmental understanding. Numerous ER3s correspond to the major mountain regions in the western and eastern US that serve as the largest natural reservoirs in the country. This work will evaluate how snow water storage is changing in ~~mountain ecoregions to increase the relevance of the findings to ecosystem and human-related impacts~~ mountainous ecoregions in the US.

~~There are many snowpack characteristics of interest. These include snow depth (Hs), snow covered area (SCA), vertical structure or layering of the snowpack, and more. Snow water equivalent (SWE), the is the most relevant snowpack characteristic for many water resources applications. SWE is the~~ depth of water ~~one would get obtained~~ upon melting a column of snow; ~~is the snowpack characteristic that is most relevant for many water resources applications.~~ Having an estimate of SWE across a watershed is analogous to ~~having a reservoir elevation – it allows you to quantify~~ knowing the stage (water elevation) in a surface reservoir; it quantifies the amount of water being stored ~~that will become available as stream flow once the snowpack melts.~~

~~The metrics used to monitor changes in our snowpacks for later use. Other directly measurable snow characteristics~~ largely fall into two categories; they can be temporal snapshots that give us information about snow magnitude at a certain point in time, or they can provide information about snow timing (Nolin et al., 2021). ~~Metrics that fall into the category of temporal snapshots include SWE observed at monitoring stations such as the snow telemetry (SNOTEL) and snow course networks operated by the Natural Resources Conservation Service (NRCS, Serreze et al. (1999)), snowpack volume on April 1st, spring SCA, the approximate date of peak SWE, and others. Previous studies have reported widespread and substantial declines in April 1st SWE across snow course and SNOTEL networks in the western US (Mote et al., 2018; Clow, 2010), declines in the April 1st SWE volume in California (Huning and AghaKouchak, 2018), and declines in spring SCA (Derksen and Brown, 2012) across the Northern Hemisphere.~~

April 1st SWE, snow covered area (SCA), and peak SWE ( $SWE_{max}$ ) are examples of temporal snapshot metrics. Snow metrics that give us information about the timing of snow include snow cover duration (SCD), date of snow onset (DSO) and date of snow disappearance (DSD); ~~among others. Multiple studies have reported widespread declines in SCD from regional to global scales (Bormann et al., 2018; Notarnicola, 2020; Choi et al., 2010) as well as a later DSO (Notarnicola, 2020) and an earlier DSD (Notarnicola, 2020). April 1st SWE has long been used in snow hydrology as an indicator measurement because it is approximately the date of peak snowfall in many locations and because it is relevant to snow course data, which has a very long period of record, but which is usually only collected at the start of each month. Though April 1st SWE has been effectively used as an indicator for the changing character of mountain snowpacks, it is a temporal snapshot that does not~~

provide any information on snow stored during the rest of the season. Conversely, other snow metrics such as SCD, DSO or DSD give us information on snow timing, but do not provide insight on the amount of water held in mountain snowpacks. For example, trends in April 1st SWE could be a result of reduced or increased snow, temporal shifts in the snowpack, or increased variability (repeated accumulation and melt events) in the snowpack. In order to more completely understand how our snow water reservoirs are changing, we need to consider the full time history of the accumulation and loss of the snow over the water year.

Other 'composite' snow metrics, such as the Snow Storage Index (SSI) (Hale et al., 2023) and the Water Tower Index (WTI) (Viviroli et al., 2007), are not directly measurable, but combine information streams in order to relate snowpack to water storage. The SSI indicates the degree to which snowpack delays the timing and magnitude of surface water inputs relative to when it falls as precipitation and the WTI identifies locations where mountain runoff contributes disproportionately to lowland water supplies. Additionally, a global WTI was developed, which ranks all water towers in terms of their water-supplying role and downstream societal and ecological demand (Immerzeel et al., 2020).

A conceptual SWE curve is shown in ~~figure~~ Figure 1(a). Mountain snowpacks generally have a DSO, where ~~the SWE starts~~ the accumulation phase of the snow season SWE accumulation begins and continues up to a peak SWE ( $SWE_{max}$ ), which may or may not occur on Apr ~~1~~ 1 (northern hemisphere). After  $SWE_{max}$ , the ablation phase of the snow season ~~starts~~ begins and the SWE depth declines until it reaches zero at the DSD. The SCD is captured by the width of the SWE curve. Multiple factors can result in systematic changes to the shape of the SWE curve including climate change (Lute et al., 2015), natural land cover change such as wildfire (Gleason et al., 2019) or beetle kill (Pugh and Small, 2012; Boon, 2007; Winkler et al., 2014) and man-made land cover change, such as forest thinning (Krogh et al., 2020; Sun et al., 2022) or logging (Winkler et al., 2005; Troendle and Reuss, 1997).

The shaded regions in ~~figure 1~~ provide the other panels of Figure 1 provide conceptual examples of how the SWE curve may have changed from the past to present day. For example, a current SWE curve could be a scaled (reduced) version of a past SWE curve (~~figure~~ Figure 1(b)). This would result in a later DSO, a lower  $SWE_{max}$ , an earlier DSD and a shorter SCD.

Changes in SWE curves could also result from a temporal shift in the historic curve (~~figure~~ Figure 1(c)). This would not impact  $SWE_{max}$  or SCD, but metrics including April 1 SWE, DSO, and DSD would be affected. Figure 1(d) gives yet another example of a theoretical current scenario, compared to a historic one. In this case, the shape of the conceptual SWE curve is changed by repeated accumulation and melt events during the accumulation season. As shown in this ~~illustration~~ graphic, metrics such as DSO, DSD, SCD,  $SWE_{max}$ , and April 1st SWE ~~are all~~ could all remain unchanged but it is clear that the snowpack is different than in the past. Previous literature has quantified increasing ablation during the accumulation period by defining a 'melt fraction' (Musselman et al., 2021) ~~which is~~ the ratio of the melt that occurs during the accumulation phase to the total melt. Their metric helps to identify snowpacks that have considerable variance and ~~demonstrate~~ vulnerability to warming and rain-on-snow events. Another example of changing snowpack is shown in ~~figure~~ Figure 1(e). Here, the ~~SWE~~ SCD remains constant due to consistent DSO and DSD, but  $SWE_{max}$  could remain constant in magnitude and timing, but the SCD could decrease due to a later DSO and earlier DSD ~~decreases in magnitude, resulting in less snow overall~~. Finally, ~~figure~~ Figure

1(f) shows a theoretical future in which DSO, DSD, SCD, April 1st SWE and SWE<sub>max</sub> all remain constant, but it is clear that there is less snow present throughout the season.

~~In order to fully understand the nature by which snow water reservoirs are changing, we need to consider the full SWE curve, both in magnitude and in timing.~~ The conceptual SWE curve and the above discussion is focused on a typical mountain snowpack, with a distinct period of steady accumulation up to a SWE<sub>max</sub>, followed by a similarly steady ablation season. While mountain snowpacks play a key role in natural water storage, other types of snowpacks also have distinct characteristics and are important to the hydrological cycle. For example, ephemeral snowpacks play a role in soil moisture and runoff regimes (Livneh and Badger, 2020; Hamlet and Lettenmaier, 2007) and experience accumulation and ablation processes nearly in tandem (Liston and Elder, 2006). Ephemeral snowpacks tend to have a lower cold content than mountain snowpacks and come and go throughout the winter (Sturm et al., 1995; Hatchett, 2021). Alternatively, Greenland and Antarctic ice sheets primarily experience accumulation processes (Liston and Elder, 2006). The transient nature of ephemeral snowpacks and the lack of an ablation season on ice sheets make metrics such as April 1 SWE, SWE<sub>max</sub> and SCD less useful.

This work aims to characterize the extent to which snowpacks serve as natural reservoirs and evaluate spatial and temporal changes in snow water storage in a new, integrated way. We first formalize the definition of SwS (snow water storage) as the time-integral of SWE over the water year. We note that SwS can be computed over a range of temporal scales (day, month, year). We also note that SwS can be evaluated at a single point (either a measurement station, or a model grid point/cell), or can be spatially aggregated over an area of interest (specific watershed or other). We then look at trends in SwS in mountain snowpacks by addressing the following research questions: (1) ~~Are there significant~~ What are the trends in monthly and annual SwS across the US at discrete point, gridded and aggregated scales? (2) ~~How do SwS aggregate over the~~ What is the role of mountainous ER3s ~~associated with mountain areas~~ in US SwS and how has this changed in recent decades? (3) How ~~do changes in snow water storage vary as a function of elevation between mountainous ecoregions~~ does SwS relate to other common snow metrics?

## 2 Methods

### 2.1 Snow Water Storage Metric (SwS)

~~This work defines a new snow metric, snow water storage (SwS).~~ SwS SwS quantifies the depth of water stored in snow reservoirs over time and is calculated by integrating the area under the SWE curve:

$$SwS = \int SWE(t) dt, \quad (1)$$

where SWE has dimensions of length, and integration occurs over a time period (water year, a given month, etc.) of interest. If daily SWE data are used for this calculation at a given point (~~say a SNOTEL site~~), SwS ~~therefore has~~ SwS will have dimensions of meter-days, or md.

As defined above, SwS is a quantity computed at a single point, e.g. a SNOTEL location, ~~or at the center of a model grid cell~~. However, the SwS metric can also be aggregated across various spatial scales. There are numerous re-analysis products that

provide spatially-distributed SWE information on a regular grid. In this case, SwS can be computed for a horizontal area (say a particular watershed) of interest. In this case, the dimensions of SwS will be  $m^3d$ . ~~Ultimately, this integrated metric helps us to understand how much water is held in our snow reservoirs and for how long.~~

SwS can also be computed for various integration periods. If the integration is done over the entire water year, this yields annual SwS ( $SwS_A$ ). In the integration is for a particular month, this yields monthly SwS ( $SwS_M$ ). Integrating daily SWE data over a single day produces the daily value of SwS ( $SwS_D$ ), but this is simply is the same as daily SWE.

SwS is the integrated area under the SWE curve, indicating the cumulative meter-days of water that was stored as a snowpack. SwS quantifies the degree to which a snowpack functions as a water storage reservoir. Unlike April 1 SWE, or SWE max, SwS can be applied to mountain, ephemeral or permanent snowpacks. Unlike other storage-related metrics such as SSI and WTI, SwS is directly measurable and does not require the combination of multiple data-streams to calculate. Ultimately, this integrated metric helps us to understand how much water is held in our snow reservoirs and for how long.

## 2.2 Data

~~Datasets used for this paper are summarized in Table 1, and briefly reviewed here.~~ Daily observations of SWE were obtained from Natural Resources Conservation Service ~~SNOTEL~~ (NRCS) snow telemetry (SNOTEL) stations (Serreze et al., 1999) and from Cooperator Snow Sensors (COOP). The SNOTEL network provides data at discrete scattered points across the western US and the COOP stations used in this study provide data across California. We used the 465 stations that have a period of record from at least water year 1982 to water year 2020 with less than 10% of days missing during that period.

This study also uses the University of Arizona SWE (UASWE) dataset (Zeng et al., 2018; Broxton et al., 2019) a daily 4-km gridded dataset that spans the US. The UASWE dataset assimilates SWE and snow depth observations into an empirical temperature index snow model that is forced with PRISM temperature and precipitation data (Daly et al., 2008). The primary value of this dataset is that it provides SWE estimates at locations other than the SNOTEL stations. This allows for the aggregation of SWE information over areas of interest (Zeng et al., 2018). ~~While we recognize the potential limitations of using a modeled SWE product, the~~ The UASWE product has been shown to outperform (Dawson et al., 2018) other gridded SWE products such as the SWE estimates from the Snow Data Assimilation System (SNODAS, ~~Center. (2004)~~ Center. 2004). Additionally, a spatially-continuous, gridded product allows us to build a more complete picture of spatial changes in SwS and how changes in SwS are occurring at aggregated scales. Despite the good performance of the UASWE product, there are limitations to using any modeled SWE product. Factors such as imperfect physics, inaccurate boundary conditions and re-scaling errors can contribute to inaccuracies in the modeled field, SWE, in this case (Sturm, 2015; Zhang et al., 2007).

The EPA Level III Ecoregions (ER3s) (McMAHON et al., 2001; Omernik and Griffith, 2014), which are regions with similar ecosystems and environmental resources, were used to identify mountainous regions and to delineate the grid cells in the UASWE dataset that were associated with each ER3 (~~figure~~ Figure 2). Mountainous ER3s were included in this study if at least half of their area resided in the snow covered mask (described in section 2.3 below). Since each ER3 has similarities in biotic, abiotic, terrestrial and aquatic ecosystem components, examining SwS change in any given ecoregion may help us understand ecosystem impacts that are related to changes in SwS.

Finally, NASA SRTM Digital Elevation data (Farr et al., 2007) were re-gridded to create a digital elevation model (DEM) matching the grid of the UASWE product. Elevation data were used to calculate watershed hypsometry in each ER3. The procedure used to calculate a hypsometry grid is described in section 2.4.2.

165 Though the station and ER3 datasets extend beyond the conterminous US, the UASWE dataset does not. All datasets were spatially constrained to the conterminous US in order to facilitate the comparison of results between spacial scales. [A summary of all of these datasets is provided in Table 1.](#)

## 2.3 Study Area

As noted above, this study considers both discrete station data that focus on the western US, and spatially-continuous gridded data that cover the conterminous US. Regarding the gridded data, many locations have little to no snow. Therefore, we restrict analysis of the gridded product to locations that have a mean of at least 30 snow covered days per year based on [a the 39-year climatology \(1982-2021\) \(figure of the UASWE dataset \(Figure 3\)\)](#). As expected, snow cover duration increases with latitude and elevation, with the longest snow cover duration found along mountain tops in the western US. In the ER3 SwS change analysis, all ER3s are considered that contain grid cells that meet the 30-day snow cover threshold, though we more closely examine the mountainous ecoregions across the country since they store the bulk of our winter water.

## 2.4 Analysis

### 2.4.1 SwS Trends

To ~~answer the first research question, are there~~ [evaluate](#) significant trends in  $SwS_A$  and  $SwS_M$  across the US, these quantities were computed over a 39-year period of ~~reecord~~ [study](#) (water years 1982-2020) at stations and at UASWE grid cells, [which have an area of 16 km<sup>2</sup>](#). The grid cell-based SWE from the UASWE product was additionally aggregated for each ER3 in order to assess trends at larger scales. [To compute SwS at aggregated ER3 scales, the gridded SWE data within an individual ER3 were simply integrated spatially, resulting in SwS with units of meter<sup>3</sup>-days.](#)

[This study used the Hamed and Rao Modified MK test from the pyMannKendall python package to compute trends in SwS \(Hussain and Mahmud, 2019\).](#) The Mann-Kendall test is a rank-based non-parametric test that is used to evaluate monotonic (increasing or decreasing) trends in temporally-varying data (Hirsch et al., 1982). Thus, the null hypothesis is that the data are randomly and independently ordered and the alternative hypothesis is that a monotonic trend exists in the data. Though the Mann-Kendall test is widely used in hydrological studies, it does not account for positive autocorrelation, which increases the probability of detecting trends when no trends exist. Because of this, many studies have turned to a modified Mann-Kendall test that does account for autocorrelation (Hamed and Rao, 1998). ~~This study used the Hamed and Rao Modified MK test from the pyMannKendall python package to compute trends in SwS (Hussain and Mahmud, 2019).~~

### 2.4.2 SwS Trends by Elevation in ~~Mountain~~ [Mountainous](#) Ecoregions

~~Our analysis is~~ This analysis focused on 16 ER3s ~~that corresponding to~~ corresponding to the mountain ranges that receive substantial snowfall relative to surrounding ecoregions. 12 of these ecoregions are located in the western US, and 4 ER3s are located in the ~~Eastern~~ eastern US. The relative elevation of SwS<sub>A</sub> change in each ER3 is examined in this study. In order to  
195 make trends in SwS<sub>A</sub> comparable over the wide range of elevations across the US, the elevations of each ER3 are converted to hypsometry scores. Each ER3 boundary is used to select co-located elevation data from the regrided NASA SRTM Digital Elevation Dataset. ER3 hypsometry is calculated by determining the percentage of the ER3 area that falls below a given elevation within that ER3. Thus, there is 0% of the ER3 at the lowest elevation of the ER3 and 100% of the ER3 is below the highest elevation. ~~In this work, each~~ Each elevation grid cell in the DEM is turned into a value between 0 and 1 based on where  
200 that grid cell lies relative to other elevation grid cells within the same ER3. ~~This procedure yields a gridded dataset of ER3 hypsometry scores for the US.~~ Hypsometry scores in each ~~mountain~~ mountainous ER3 are then binned into 10% increments, from 0% of an ER3 below to 100% of an ER3 below, in order to compute the mean SwS<sub>A</sub> and the percent change in each hypsometry band from 1982-2020. The percent change in the interquartile range (IQR) of ~~SwS<sub>D</sub>~~ SWE was also computed for each hypsometry band from 1982-2020. To calculate the percent change in IQR, the IQR in each ER3 is calculated for each  
205 year in the study by subtracting the 25th ~~percenetile from the 7th percentile of SwS<sub>D</sub>~~ percentile from the 75th percentile of SWE. The trend is evaluated in each hypsometry band following the trend analysis described in section 2.4.1.

### 2.4.3 SwS<sub>A</sub> Compared to Other Snow Metrics

SwS<sub>A</sub> trends are compared to other commonly used snow metrics including April 1st SWE, SWE<sub>max</sub>, day of SWE<sub>max</sub>, and SCD in order to evaluate what type of information the SwS<sub>A</sub> metric provides that other metrics do not. This is done in ~~3~~ four  
210 ways using the station data. First, the percent of stations with positive, positive significant, negative and negative significant trends in each metric are computed. Second, ~~a~~ we calculate the trend in the annual number of snow-free periods at each station from 1982 to 2020 to evaluate whether snowpacks are becoming more ephemeral using the Hamed and Rao Modified MK test described in section 2.4.1. The annual number of snow-free periods is defined as the number of times in a water year there is no snow following a period of snow. Next, the utility of the SwS metric compared to other snow metrics is shown using a  
215 case study of SNOTEL station 706 (Quartz Mountain, Oregon), a station that has transitioned from a mountain snowpack to an ephemeral snowpack. Third, a regression is computed between the percent change in SwS<sub>A</sub> and each other metric above using empirical data from the stations. ~~Third~~ Finally, the relationship between the percent changes in the empirical data is compared to what we would expect the relationship to be in a few conceptual SWE curve change scenarios presented in ~~figure~~ Figure 1. For example, the empirical relationship between the percent change in SwS<sub>A</sub> and the percent change in SWE<sub>max</sub> is compared  
220 to what ~~we would expect the percent change to it would~~ be if there ~~has been~~ was a uniform scaling in the ~~conceptualized~~ conceptual SWE curve as ~~is depicted in~~ shown in Figure 1(b).

### 3 Results

#### 3.1 SwS Change Trends

##### 3.1.1 SwS<sub>A</sub> Change Trends

225 The average SwS<sub>A</sub> across all stations in this analysis is 60 md. The lowest SwS<sub>A</sub> found at a single station was 0 md and the  
maximum SwS<sub>A</sub> observed was 510 md. Changes in SwS<sub>A</sub> range from a decrease of 122 md to an increase of 69 md over the  
period of study (Figure 4). Of the 97 SNOTEL and COOP stations with increasing trends in SwS<sub>A</sub>, only 10 had significant  
(p<0.1) increases (~~figure-Figure 4~~). ~~One hundred twenty three Significant decreasing SwS<sub>A</sub> trends were found at 123 of the~~  
~~stations of the 367 stations with decreasing SwS<sub>A</sub> trends, had significant decreases. Losses in SwS<sub>A</sub> ranged from 2 md to 122~~  
230 ~~md.~~ Spatially, there are widespread decreasing SwS<sub>A</sub> trends across most of the 11 western states that contain snow stations:  
~~The is a mean decline of 39.8% across the stations with significant declines in SwS<sub>A</sub>, though these values range from a 17.3%~~  
~~decline to a 86.5% decline, with declines ranging from 17% to 87%.~~ The 10 stations with significant increases in SwS<sub>A</sub> range  
from a ~~6.26%~~ increase to a ~~78.4% increase, with a mean increase of 37.4%~~ 78% increase. The stations with increasing SwS<sub>A</sub>  
235 trends are mostly located in the Northern and Middle Rockies and also includes a few station in the Southern Rockies and in  
the Cascades.

As we move from discrete station data to the the spatially-continuous gridded UASWE data, we find a mean SwS<sub>A</sub> of 1.8e8  
m<sup>3</sup>d across grid cells. Mountainous ER3s in the western US have an average SwS<sub>A</sub> of over 1.4e9 m<sup>3</sup>d and the maximum SwS<sub>A</sub>  
is 2.6e10 m<sup>3</sup>d. The average SwS<sub>A</sub> in much of New England and the Upper Peninsula of Michigan ranges from 3.2e8 to 6.4e8  
m<sup>3</sup>d.

240 The grid cell-scale change analysis yields similar geographic patterns of significant changes in SwS<sub>A</sub> in the western US  
~~(figure as the station-scale analysis (Figure 5)).~~ This is not surprising given that the UASWE product assimilates SNOTEL (and  
other) station data. The benefit of including a spatially distributed product such as UASWE in this analysis is that it adds detail  
and insight as to where changes in SwS<sub>A</sub> are occurring beyond the western US and in-between the locations where discrete  
stations are located. ~~Remember that the station network only includes the western portion of the US.~~ Significant increases  
245 in grid cell SwS<sub>A</sub> are primarily found in the north-central and north-eastern US. Only 5% of US grid cells have significant  
increasing trends ~~;~~ and have a mean percent increase of ~~84.484%~~ 84.484%. From 1986-2015, ~~these regions have the north-central and~~  
north-eastern US experienced an increase in annual precipitation, particularly in spring and fall, though these regions also  
show spatially-variable increases in precipitation during the winter (Easterling et al., 2017). These precipitation changes may  
partially explain the increases in SwS<sub>A</sub>, though these regions have also experienced increases in winter temperatures over the  
250 same time period. Significant decreases in SwS<sub>A</sub> are more widespread and are found across the western US, the Appalachian  
Mountains, the Blue Ridge Mountains and in the Ozarks. ~~There is a mean decline of 43.5% across the 11~~ Of the 54% of US  
grid cells that have decreasing trends in SwS<sub>A</sub>, 11% have significant decreasing trends. The mean percent decline in SwS<sub>A</sub> for  
the grid cells with significant trends is 44%.

Figure 6 indicates the percent change in  $SwS_A$  across ER3s. Aggregating UASWE  $SwS_A$  at ER3 scales spatially-filters (and thus mutes) some of the grid cell-scale trends in  $SwS_A$  as can be seen when comparing figures Figures 4 and 5. Of the 51 ER3s that are evaluated in this study, 37%–19 have increasing trends and 63%–32 have decreasing trends. Only one ER3, the non-mountainous Lake Agassiz Plain, has a significant positive  $SwS_A$  trend of 85.8% increase while four trend in  $SwS_A$  (86% increase). Five ER3s, the Cascades, the Eastern Cascade Slopes and Foothills, the Southern Rockies, the Idaho Batholith and the Arizona/New Mexico Mountains, have significant decreasing  $SwS_A$  trends, with a mean percent decrease of 47.438%. All four-five of the ER3 that have significant decreasing  $SwS_A$  trends are mountain-mountainous ER3s. Of the 16 mountainous ecoregions-ER3s (outlined in red), only one shows (insignificant) increases in  $SwS_A$ , while the Northeastern Highlands has a (non-significant) increasing  $SwS_A$  trend, while the other 15 mountainous ER3s show decreases in  $SwS_A$  have decreasing  $SwS_A$  trends. This means that 93.8% of mountain-ER3s that play a role in the snow water storage have in 94% of mountainous ER3s has declined from 1982-2020.

### 265 3.1.2 $SwS_M$ Change Trends

The highest monthly mean  $SwS_M$  occurs in March at stations (12.8 md), grid cells ( $2.7e7 m^3d$ ) and in mountainous ER3s ( $7.4 m^3d$ ). Figures 7, 8, and 9 summarize trends in  $SwS_M$  change evaluated at stations, UASWE grid cells and ER3s, respectively. There are predominantly significant Significant decreases in  $SwS_M$  occurring-occur across all months at all spatial scales examined. November has the greatest-experienced the highest number of stations, grid cells and ER3s with significant  $SwS_M$  loss at stations and grid cells and ER3 scales. November also has the losses compared to any other month. The greatest monthly median percent loss of  $SwS_M$  per decade occurred in November at stations (14.156%) and grid cell (14 cells (44%), though the greatest monthly median percent loss of  $SwS_M$  per decade in ER3s was in March (15.3 and in March at mountainous ER3s (61%). The greatest number of stations with significant  $SwS_M$  increase occur in October, February, March and April at the station scale, and in February and March at the grid cell spatial scales, though there was Looking at raw change values, we find that the months with the greatest decrease in  $SwS_M$  are not the same as the months with the largest percent changes. March, December and January are the months with largest decrease in median  $SwS_M$  at stations (4.6 md), grid cells ( $6.4e6 m^3d$ ) and mountainous ER3s ( $1.1e11 m^3d$ ), respectively.

Though there is an overall negative median percent change in  $SwS_M$  per decade during these months. At the in all winter months at the station and grid-cell scale, February and March have higher occurrences of significant  $SwS_M$  increase than any other months. At the grid cell-scale, October, March-May and July-August all have a 0% median percent change in  $SwS_M$  per decade because most grid cells within the snow-cover mask are snow-free during these times. At the ER3 scale, April stands out as being the only month with a significant positive the median percent change in  $SwS_M$  per decade (51.5%), though if you consider the mountain-ER3s (where there is the highest  $SwS$ ), there is a significant negative median percent change of 15% per decade. This indicates that the large significant increases in April  $SwS_M$  are not occurring in mountainous parts of the country. Looking at only mountain-ER3s, there are no months with a significant positive median percent change. ER3s have the greatest number of significant increase in  $SwS_M$  in October. October is also the only month that mountain-ER3s had any

~~significant increases. is negative in all months.~~ Most data points that indicate significant positive increases in monthly storage are considered outliers at all spatial scales.

### 3.2 SwS<sub>A</sub> ~~Change Trends on the Landscape -- Mountain in Mountainous~~ ER3s

290 Analysis of ~~mountain-mountainous~~ ERs illuminates the ~~out-sized-large~~ role mountains play in storing winter snow water resources as snowpack, ~~particularly in the western US~~. An average of 72% of the annual SwS<sub>A</sub> in the US (~~3.5e13 m<sup>3</sup>d~~) is held in the 16 ~~mountain-mountainous~~ ER3s, despite these ER3s only covering 16% of the US land area. ~~Further, (figure 6). Western mountainous ERs cover 12% of the US land surface and store~~ an average of 65% of the annual SwS<sub>A</sub> ~~in the US is held in western mountain ERs, which cover 12% of the US land surface~~. Across all ~~mountain-mountainous~~ ER3s, there has been a  
295 22% decline (~~6.1e12 m<sup>3</sup>d~~) in SwS<sub>A</sub> over the 39 year period of study. Over the same time span, there has been a 24% decline in SwS<sub>A</sub> in western ~~mountain-mountainous~~ ER3s, indicating that western snow reservoirs are shrinking faster than ~~Eastern eastern~~ snow reservoirs.

Table 2 summarizes the fraction of US SwS<sub>A</sub> in each ~~mountain-mountainous~~ ER3, the percent change in SwS<sub>A</sub> from water years 1982 to 2020, and the p-value associated with the percent change. ~~Snowpack plays an important role in climate, ecological processes and recreation in both eastern and western mountains, but is essential to warm-season water resources in the western US. Snowpack is not essential to warm-season water resources in the Eastern US since there is adequate warm-season precipitation.~~ In the western US, the Middle Rockies are responsible for the greatest fraction (~~11.612%~~) of SwS<sub>A</sub> in the country, followed by the Southern Rockies (~~9.810%~~) and the Idaho Batholith (~~8.38%~~). ~~All mountain SwS<sub>A</sub> has declined in all mountainous~~ ER3s in the western US ~~have declines in SwS<sub>A</sub>~~ over the last 39 years ~~with the exception of the North~~  
305 ~~Cascades, where SwS<sub>A</sub> increased by 13%~~. The greatest declines in western SwS were in the Arizona/New Mexico Mountains (56% decline), the Eastern Cascade Slopes (40% decline) and Foothills and the Cascades (39% decline). ~~Similar to the west, all eastern mountain~~ ~~All eastern mountainous~~ ER3s showed declines in SwS<sub>A</sub> over the last 39 years with the exception of one, ~~the Northeastern Highlands~~. The Northeastern Highlands are responsible for the greatest fraction (~~3.54%~~) of SwS<sub>A</sub> in the ~~in the Eastern US and had a SwS<sub>A</sub> increase of 13.15%~~ ~~eastern US where SwS<sub>A</sub> increases 13%~~ over the last 39 years. The greatest  
310 decline in SwS<sub>A</sub> in the ~~Eastern-eastern~~ US was in the Ridge and Valley (11% decline), which holds an average of 0.2% ~~)~~ of US SwS<sub>A</sub>.

~~All mountain ER3s have the~~ ~~The~~ greatest SwS<sub>A</sub> ~~is found~~ in the highest 10% of ~~the-mountainous~~ ER3s ~~that fall within their boundaries (figure elevations (Figure 10))~~. Most ~~mountain-mountainous~~ ER3s have decreasing trends in SwS<sub>A</sub> across all hypsometry bins, though the Sierra Nevada (~~5~~), the Wasatch and Uinta Mountains (~~19~~), the Southern Rockies (~~21~~), the North  
315 Central Appalachians (~~62~~) and the North Cascades (~~77~~) show increasing trends in SwS<sub>A</sub> at low elevations with decreasing trends at higher elevations. The Northern Highlands is the only ER3 that shows increasing trends in SwS<sub>A</sub> at all elevations. Increasing trends in SwS<sub>A</sub> at low elevations in some ER3s may partially be a result of very low SwS<sub>A</sub> to begin with, thus small changes in SwS<sub>A</sub> may suggest large percent changes. ~~Looking across all mountain ER3s, there are only significant declining SwS<sub>A</sub> trends and no significant increasing trends.~~

320 By looking at the percent change trends in the IQR of  $SwS_D$ SWE, we are able to get an idea of how interannual SWE variability has changed from 1982-2020 (Figure 10). Several ER3s have increases in the  $SwS_D$ SWE IQR of the lowest hypsometry bands, which correspond to the lowest parts of ER3s. This could be a result of increasing snow variability as freezing levels move to higher elevations, resulting in increased irregularity in precipitation form. In the middle and upper hypsometry bands of most ER3s, there is largely a decrease in the IQR. This may be a result of declining snowpacks, which would allow for less  
325 variability in the range of  $SwS_D$ SWE values overall. The Northern Highlands, Rige Ridge and Valley, Central Appalachians and North Cascades stand out somewhat in that they have increasing trends in IQRs across most hypsometry bands.

### 3.3 $SwS_A$ Compared to Other Snow Metrics

~~The  $SwS_A$  metric was compared to other commonly used snow metrics including the annual number of snow covered days~~ Figure 11 demonstrates how the conceptual SWE curve is changing in each of the ER3s based on the trend analysis of four common  
330 ~~snow metrics; DSO,  $SWE_{max}$ , day-of- $SWE_{max}$  day of water year ( $SWE_{max}$  DOWY), and DSD. Trends in DSO,  $SWE_{max}$  and April,  $SWE_{max}$  DOWY, and DSD were evaluated because these metrics serve as anchor points that define the boundaries of the conceptual SWE curve. These conceptual SWE curves are superimposed on the observed mean SWE curves for each ER3. With the exception of the Northern Highlands, the 2020 SWE curve (solid red line) delineates a smaller conceptual SWE curve than in 1982 (dotted red line). The specific anchor points that cause the shrinkage of the conceptual SWE curve are variable  
335 across ER3s. Of the ER3s that experienced significant ( $p < 0.1$ ) decreases in  $SwS_A$ , the Southern Rockies and the Arizona/New Mexico mountains also had significant changes in the DSO, DSD and  $SWE_{max}$ . The Cascades, the Eastern Cascade Slopes and Foothills and the Idaho Batholith also experienced significant declines in  $SwS_A$ . These three ER3s had significantly earlier DSDs. Although evaluating change at the anchor points tells us how the conceptual SWE curve is changing, the actual SWE curve is not a triangle and is subject to complex patterns of change. The SwS metric accounts for these complex patterns and  
340 is able to quantify natural reservoir storage and change.~~

~~Trends in snow metrics ( $SwS_A$ , April 1st SWE. The fraction of increasing, decreasing and no trends in each of these metrics is summarized in Table ??). The percent of stations with negative trends was greater than SWE,  $SWE_{max}$  and SCD) are not changing in the same direction at all stations (figure 12). SNOTEL and COOP stations were placed to capture mountain snowpack regimes where snow increases up to a maximum value throughout the accumulation season and then disappears  
345 across the ablation season. April 1st SWE,  $SWE_{max}$ , SwS and SCD are snow metrics that are useful for characterizing and monitoring change in mountain snowpack regimes and describe points relevant to a conceptual SWE curve. While trends in these metrics have changed in the same direction at 286 of the percent of stations with positive and positive significant trends in all metrics considered. Across all metrics, there was a relatively small (14%) range in the percent of stations with positive trends and only 1-2% of stations had significant positive trends across all metrics. The was an 18% range in the percent of  
350 stations with negative trends and a 14% range in the number of stations with significant positive trends across all metrics. 465 SNOTEL and COOP stations, 38.5% of stations have non-uniform inter-metric trend directions. This means that if trends in only one snow metric were to be examined, it could paint an incomplete picture of change.~~

Figure 14 provides the results of regressing the percent change in April 1st SWE onto the percent change in SwS<sub>A</sub> and the percent change of SCD onto SWE<sub>max</sub> using empirical station data. In all cases, the slope is less than 1 (although only slightly less in the case of SwS<sub>A</sub> vs SCD), illustrating how the SwS metric is able to capture complex change, such as is associated with an ephemeral snowpack. At the Quartz Mountain station, there are significant negative trends in SwS and SCD, no trend in April 1st SWE and a positive trend in SWE<sub>max</sub>. The regression analysis between the percent change in SwS<sub>A</sub> and April 1st SWE yields a slope of 0.94. This nearly 1:1 relationship suggests that SwS<sub>A</sub> is largely not relevant as a snow monitoring metric because the majority of years are snow-free on April 1st at this location. This station is interesting because it has opposite significant trends in SWE<sub>max</sub>, which is decreasing, and SCDs, which are increasing. Since SwS<sub>A</sub> and April 1st SWE have experienced a similar percent change over the 39-year period of record, the regression between SwS<sub>A</sub> and April 1st SWE is the integral of the SWE curve, both magnitude and duration of snow cover are incorporated into its calculation. This allows the SwS metric to provide a robust picture of the degree to which the snowpack is serving as a reservoir for water storage and how that reservoir function may be changing.

There are other ways to demonstrate the utility of SwS as an additional tool for gaining insight into our changing snowpack. April 1st SWE is overwhelmingly the metric cited by water resource managers as the singular measure of the season's snow. But, how do changes in that measure correspond to changes in others? First, Figure 14 shows the relationships between percent changes in various snow metrics of interest. It can next be useful to return to the idea of a conceptual SWE curve (Figure 1(a)). Based on this simple geometry, the SwS<sub>A</sub> is given by

$$SwS_A = \frac{1}{2} SWE_{max} SCD. \quad (2)$$

If the geometry of the conceptual SWE curve were to be preserved over time, the SWE curve would be uniformly scaled (Figure 1(b)). In this scenario, we would expect the percent change in SWE<sub>max</sub> and SCD to each be half the percent change in SwS. However, the regression plots in Figure 14 reveal that the percent change in SwS<sub>A</sub> and SCD is roughly 26% that of the percent change in SwS. And it is found that the percent change in SWE<sub>max</sub> yields a slope of 0.86, suggesting that the changes in SWE<sub>max</sub> have been slower than the changes in SwS<sub>A</sub>. With a slope of 0.26 in the SwS<sub>A</sub> versus SCD regression, we find that SwS<sub>A</sub> has changed about 4 times faster than SCDs. The regression analysis between SwS<sub>A</sub> and SCD yields a slope of 0.26. The percent change in April 1st SWE was nearly identical to the percent change in SWE<sub>max</sub>, with a slope of 1.03 when April 1st SWE was regressed onto SWE<sub>max</sub> (not pictured). SwS. What this means is that the conceptual SWE curve has been flattening over the period of study of the data. So, relying on a single metric like April 1st

SWE gives an incomplete assessment of the storage of snow throughout a full season, and a more holistic metric like SwS may be more informative.

#### 4 Discussion

390 SwS is a unique snow metric because it essentially has unlimited degrees of freedom - any change in the SWE curve (e.g. changes in SWE magnitude, timing, variability, etc.) will be captured in its calculation. Thus, regardless of how the SWE curve changes, the SwS metric is able to provide information about water storage in natural reservoirs at a given location. SwS is different from the other common snow metrics discussed in this paper (April 1 SWE, SCD, SWE<sub>max</sub>) because the other metrics have 1 degree of freedom - they provide data on one dimension of the SWE curve. The flexibility of the SwS  
395 metric is particularly useful when attempting to quantify storage in snowpacks that have fundamental shifts in their SWE curve. As demonstrated above, the SwS metric can still quantify natural reservoir storage when a snowpack has transitioned from a mountain-type snowpack to an ephemeral type. If a snowpack were to transition from a permanent snowpack to a mountain-type snowpack, the SwS metric would also be able to provide information on the storage.

Of the snow metrics discussed in this paper, SwS is uniquely positioned to capture storage change at aggregated scales, across the full SWE curve. Metrics such as DSO, SWE<sub>max</sub>, DSD, SCD, etc. are essentially anchor points for the conceptual SWE curve. Though it can be beneficial to note changes at any of these points, change can also happen in-between these anchor points, such as an increase in accumulation season ablation or an increase in ablation season accumulation. This type of change has already been documented as changing melt fractions (Musselman et al., 2021). At aggregated scales, such as across a watershed, snowpack variability (due to landscape features such as aspect or elevation) influences the SWE curve between the  
400 anchor-point metrics. Change that occurs between the anchor-point metrics is not inherently captured by these metrics. Since the SwS metric can accommodate various spatial scales, it is able to capture natural reservoir storage regardless of variability in snow change or snowpack fluctuations that occur in-between anchor point metrics.  
405

The widespread losses of SwS<sub>A</sub> over the last 39 years reported in this study are consistent with the broader narrative of snowpack change literature, which has established declines in snow covered area, snow cover duration, April 1st SWE, SWE<sub>max</sub>, etc  
410 (Rupp et al., 2013; Mote et al., 2018; Notarnicola, 2020; Marshall et al., 2019; Bormann et al., 2018; Choi et al., 2010; Huning and Agha)  
. Losses of winter snowpack are largely attributed to increasing global temperatures (Hamlet et al., 2005), which have resulted from a combination of natural variability and anthropogenic-caused climate warming (Rupp et al., 2013; Pederson et al., 2013). Though the majority of SwS trends are declining, there is notable temporal and spatial variability in this change. The declining trends in SwS<sub>A</sub> are a reflection of declining trends in SwS<sub>M</sub> in nearly every month, at every scale. The greatest SwS<sub>M</sub> losses  
415 percent losses in SwS<sub>M</sub> occur early in the snow season, particularly in November. The loss of early season SwS is consistent with previous work that used satellite imagery and reported that that first snow DSO is occurring later (Notarnicola, 2020). Although decreasing trends in SwS<sub>A</sub> dominate the US spatially, the north central plains and New-England-the Northeastern Highlands show increasing SwS<sub>A</sub> trends. Snowmelt and rain-on-snow are know-known to be flood generating mechanisms in

New England, Minnesota and along the Mississippi and Missouri Rivers (Collins, 2009; Novotny and Stefan, 2007; Wiel et al.,  
420 2018; Olsen et al., 1999). The increasing SwS trends in these regions may therefore have implications for flood hazards.

Spatial scale ~~had~~ has long been a topic of conversation in snow hydrology as certain processes that occur at very small scales contribute to considerable within-grid cell heterogeneity as one scales up from point to grid cell to regional scales (Blöschl and Sivapalan, 1995; Molotch and Bales, 2005). In this work, we find differences in the magnitude and timing of significant changes in SwS<sub>A</sub> and SwS<sub>M</sub> when we compare different spatial scales. For example, less of the US landscape shows significant  
425 changes in SwS<sub>A</sub> in the ER3 analysis compared to the grid cell analysis. Thus, the aggregation of SwS<sub>A</sub> into ER3s ~~negates~~ filters some of the grid cell-scale spatial SwS<sub>A</sub> trends. Temporally, there is a higher fraction of sites with a significant positive increase in SwS<sub>M</sub> from October - March in the grid cell analysis compared to the ER3 analysis. This indicates that local significant increases in SwS<sub>M</sub> at grid ~~cell scales are negated~~ cell scales are offset by smaller magnitude increases in SwS<sub>M</sub> or decreases in SwS<sub>M</sub> at many locations once the SwS<sub>M</sub> is aggregated to ER3 scales. From a water resources perspective, these  
430 findings underscore the importance of choosing an appropriate aggregation scale in order to accomplish management goals.

~~Mountains play an out-sized role in natural reservoir storage on the US landscape. Across all mountain ER3s, there has been a 22% decline in SwS<sub>A</sub> over the 39 year period of study.~~ In the western US, where snowmelt is vital to supplementing warm-season water supplies, about 70% of runoff in mountainous regions originates as snow (Li et al., 2017). Snowpacks also play an important role in climate, ecological processes and recreation in both eastern and western mountains. Across all mountainous  
435 ER3s, there has been a 22% decline in SwS<sub>A</sub> over the 39 year period of study. The ER3 mountain ranges considered in this work include the headwaters to 13 of the 18 water basins located in the US, underscoring the importance of these natural reservoirs to water resources. The loss of SwS in these regions is of further concern as the warm season is projected to increase in length due to anthropogenic climate warming (~~Mallakpour et al., 2018; Padrón et al., 2020~~). ~~Furthermore, it is possible that natural variability has in fact~~ (Mallakpour et al., 2018; Padrón et al., 2020; Siler et al., 2019). Siler et al. (2019) also suggests  
440 that declining snow trends may accelerate once the current natural climate mode changes because natural variability has slowed the decline of western snowpacks since the 1980s, ~~suggesting that snow declines may accelerate once the current natural climate mode changes~~ (Siler et al., 2019). ~~Overall, the~~ The capacity of natural snow reservoirs is declining in most of the western US and across most mountain ranges in the US. ~~Because of this~~ Since declining trends are expected to continue into the future, monitoring our natural snow reservoirs is essential. Metrics ~~like SwS that~~ are highly flexible in space and time ~~and~~ (like SwS)  
445 can be used in monitoring change and evaluating future projections.

SwS<sub>A</sub>, the changes in SwS<sub>A</sub>, and the variability in ~~SwS<sub>D</sub>~~ SWE are all influenced by elevation. The greatest amount of snow water storage occurs on a disproportionately small fraction of our landscape - at the highest elevations of ~~mountain~~ mountainous ER3s. Almost all mountainous ER3s are losing SwS<sub>A</sub> at all elevations. In the majority of ~~mountain~~ mountainous ER3s, the highest elevations have experienced the greatest losses SwS<sub>A</sub> over the last ~~49~~ 39 years. The elevation-dependent  
450 changes in our natural snow reservoirs are likely associated to documented elevation-dependant changes in temperature and precipitation (Wang et al., 2014; Harpold et al., 2012; Pepin et al., 2015, 2022; Qixiang et al., 2018). Winter ~~temperature~~ temperatures have increased significantly in the recent past (Vose et al., 2017), which increases the vapor pressure deficit in the atmosphere and may enhance sublimation and vapor fluxes ~~Harpold et al. (2012)~~ (Harpold et al., 2012). Higher elevations

have also warmed at faster rates than their low elevation counterparts, where there have been increasing trends in precipitation  
 455 (Wang et al., 2014; Pepin et al., 2022). Wang et al. (2014) suggests that elevational warming amplification is likely associated  
 with effective moisture convection. These mechanistic ~~driver~~ drivers are a plausible explanation for finding the greatest SwS<sub>A</sub>  
 loss at the highest elevations.

This work also finds elevation-dependant changes in ~~SwS<sub>D</sub> variability. Assuming there have not been systematic changes~~  
~~in synoptic weather patterns, SwS<sub>D</sub>-SWE variability.~~ SWE variability has likely increased as a result of winter freezing levels  
 460 moving to higher elevations (Catalano et al., 2019), an increased fraction of precipitation falling as rain instead of snow and  
 more rain falling on snow (McCabe et al., 2007) ~~→~~ all of which are related to increasing winter temperatures. Decreases in  
~~SwS<sub>D</sub>-SWE~~ SWE variability at higher elevations, where there are declining trends in SwS<sub>A</sub>, may be a result of shallower snowpacks  
 overall.

~~Comparison of the various snow metrics provides insight as to how the SWE curve is changing. Since April 1st SWE is~~  
 465 ~~largely used as standard time to capture an estimate of SWE<sub>max</sub> in a way that is uniform across stations, and since the percent~~  
~~change in April 1st SWE nearly identical to the percent change in SWE<sub>max</sub>, this discussion will focus on the relationship~~  
~~between SWE<sub>max</sub>, SCD and SwS. Starting with the conceptual SWE curve illustrated in figure 1a, the area of the SwS<sub>A</sub> triangle~~  
~~is;~~

$$\underline{SwS_A = \frac{1}{2} SWE_{max} SCD.}$$

470 ~~If the geometry of the conceptual SWE were to be preserved over time, the SWE curve would be uniformly scaled and we~~  
~~would expect the percent change in SWE<sub>max</sub> and the percent change in SCD to be equal, i.e.,~~

$$\underline{\frac{d(SWE_{max})}{SWE_{max}} = \frac{d(SCD)}{SCD} .}$$

~~Additionally, the percent change in SwS would equal the sum of these~~

$$\underline{\frac{d(SWS)}{SWS} = \frac{d(SWE_{max})}{SWE_{max}} + \frac{d(SCD)}{SCD} .}$$

475 ~~In this scenario, we would expect the percent change in SWE<sub>max</sub> or SCD to be half the percent change in SwS. However, the~~  
~~regression plots in figure 14 reveal that~~

$$\underline{\frac{d(SCD)}{SCD} = 0.26 \frac{d(SWS)}{SWS}}$$

~~and~~

$$\underline{\frac{d(SWE_{max})}{SWE_{max}} = 0.85 \frac{d(SWS)}{SWS} .}$$

480 ~~This means that the SWE<sub>max</sub> is decreasing faster than SCD. Thus, we find that the conceptual SWE curve has been flattening~~  
~~over the 39-year period of record.~~

The conceptual SWE curve and the above discussion is focused on a typical mountain snow pack, with a distinct period of steady accumulation up to a  $SWE_{max}$ , followed by a similarly steady ablation season. While mountain snowpacks play a key role in natural water storage, other types of snowpacks also have distinct characteristics and are important to the hydrological cycle. For example, ephemeral snowpacks play a role in soil moisture and runoff regimes (Livneh and Badger, 2020; Hamlet and Lettenmaier, 2000) and experience accumulation and ablation processes nearly in tandem (Liston and Elder, 2006). Ephemeral snowpacks tend to have a lower cold content than mountain snowpacks and come and go throughout the winter (Sturm et al., 1995; Hatchett, 2021). Alternatively, Greenland and Antarctic ice sheets generally only experience accumulation processes (Liston and Elder, 2006). Because of the transient nature of ephemeral snowpacks or the lack of an ablation season on ice sheets, metrics such as April 1 SWE,  $SWE_{max}$  and SCD may not be relevant. These scenarios are examples of where a more flexible metric, such as SwS, could be employed to characterize the annual (or other timescale) storage across a variety of snowpack types, which could be beneficial for universal monitoring of snow.

## 5 Conclusions

In this paper, SwS is a new snow metric. SwS is defined and used to identify where and to what extent water storage in natural snow reservoirs has already changed in the observational record. Mountains, especially western mountains, play an inordinate disproportionate role in natural water storage relative to the surrounding landscape. These high-elevation High-elevation natural snow reservoirs are responsible for the greatest  $SwS_A$ , and have generally experienced the greatest declines in  $SwS_A$ . Declines in  $SwS_A$  are associated with a fundamental shift in the shape of the SWE curve SWE curve as it appears to be flattening. As we move into a future of increased snow variability, diminished snowpacks and as more of the winter snow landscape transitions to ephemeral regimes, temporally static metrics such as April 1 SWE and  $SWE_{max}$  may become less representative of our snowpacks and. Concurrently, it may be valuable to have metrics such as SwS that can adapt to a wide range of circumstances. Spatially Spatially and temporally flexible metrics such as SwS may become increasingly valuable particularly when it comes to monitoring change.

Declining storage in our natural snow reservoirs has broad implications for human and ecological systems. Natural snow reservoirs help to increase water storage far beyond the capacity of man-made reservoirs in the western US, supporting their roll in linking cool-season precipitation to warm-season water demand. As one of the most robust projected impacts of climate change is a continued increase in air temperatures, it is likely that declining trends in  $SwS_A$  will continue. Water managers, planners and decision makers will need to account for these declines in natural snow water storage as they relate to streamflows for fish migration and recreation, municipal and agricultural water supplies and flood hazards. Though this paper does not focus on future predictions of snowpack, SwS could be a useful tool for understanding how our natural snow reservoirs change in the future. Change in our natural snow reservoirs is multidimensional and already happening. We need metrics that can capture this complexity of change.

*Data availability.* Below is an enumerated list providing links to the publicly available datasets used in this study.

**Figure 1.** Theoretical Conceptual illustration of a SWE curves. Blue curves illustrate the past characteristic SWE curve and green curves demonstrate a range of various ways the historic SWE curve may have changed that it could change from past to present.

**Table 1.** Summary of data used in this work.

Data set	Hosting agency	Data Type	Temporal resolution	Spatial resolution
Snow Telemetry (SnoTel)	Natural Resources Conservation Service (NRCS)	Point observations	Stations were selected with a period of record starting in water year 1982 and less than 10 percent of days missing	N/A
Cooperator Snow Sensors (COOP)	Natural Resources Conservation Service (NRCS)	Point observations	Stations were selected with a period of record starting in water year 1982 and less than 10 percent of days missing	N/A
University of Arizona SWE (UASWE)	National Snow and Ice Data Center (NSIDC)	Gridded product	water year 1982-present	4km x 4km
NASA SRTM Digital Elevation	Google Earth Engine (GEE)	Gridded product	N/A	30m x 30m
EPA Level III Ecoregions	Google Earth Engine (GEE)	Vector data	N/A	N/A

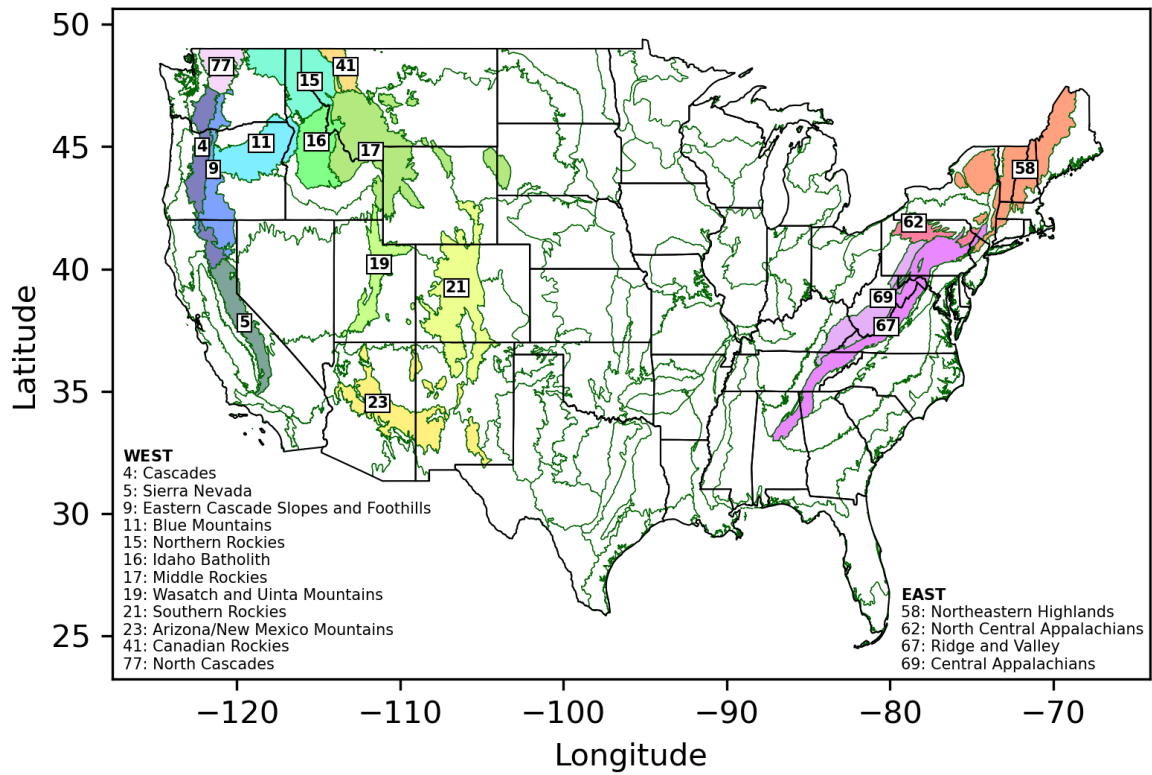

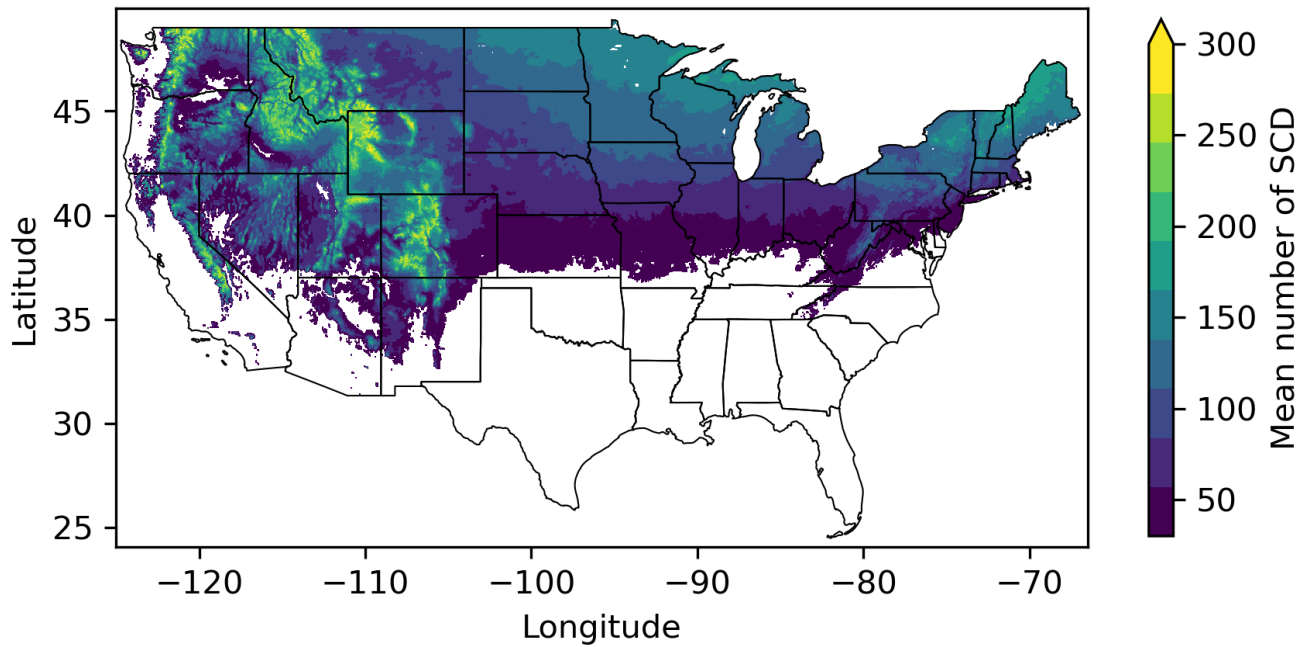

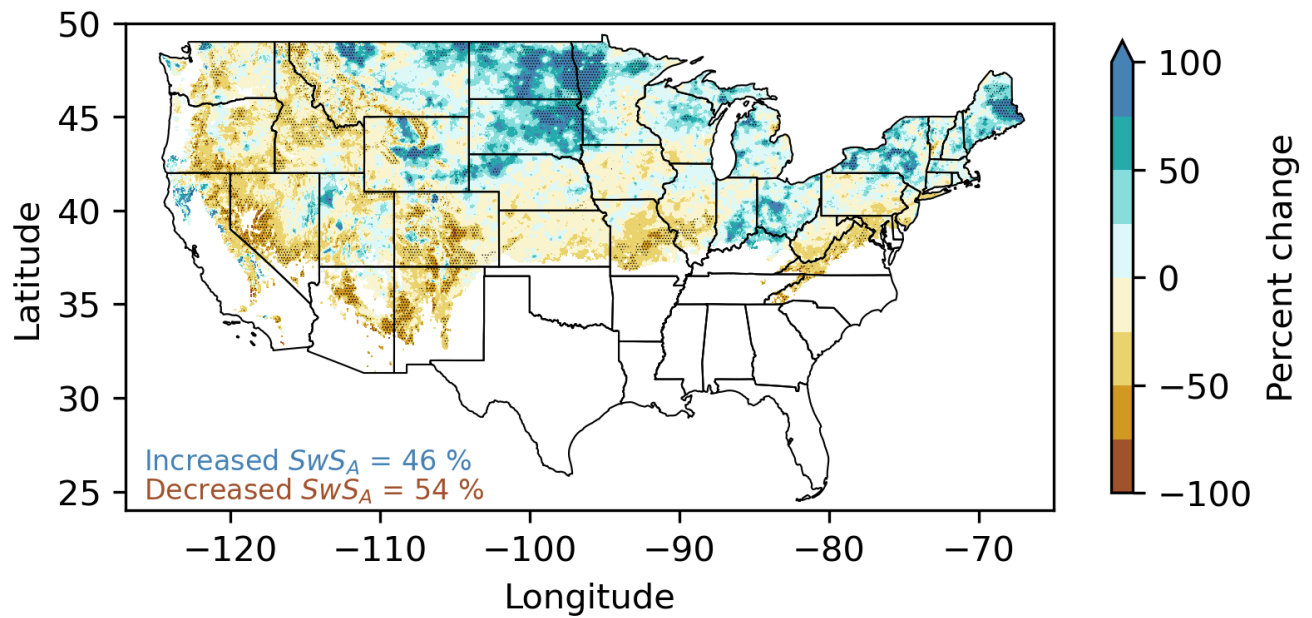

Figure 2. Map of ER3s in the US. Mountain-Mountainous ER3s are colorshaded and labeled.

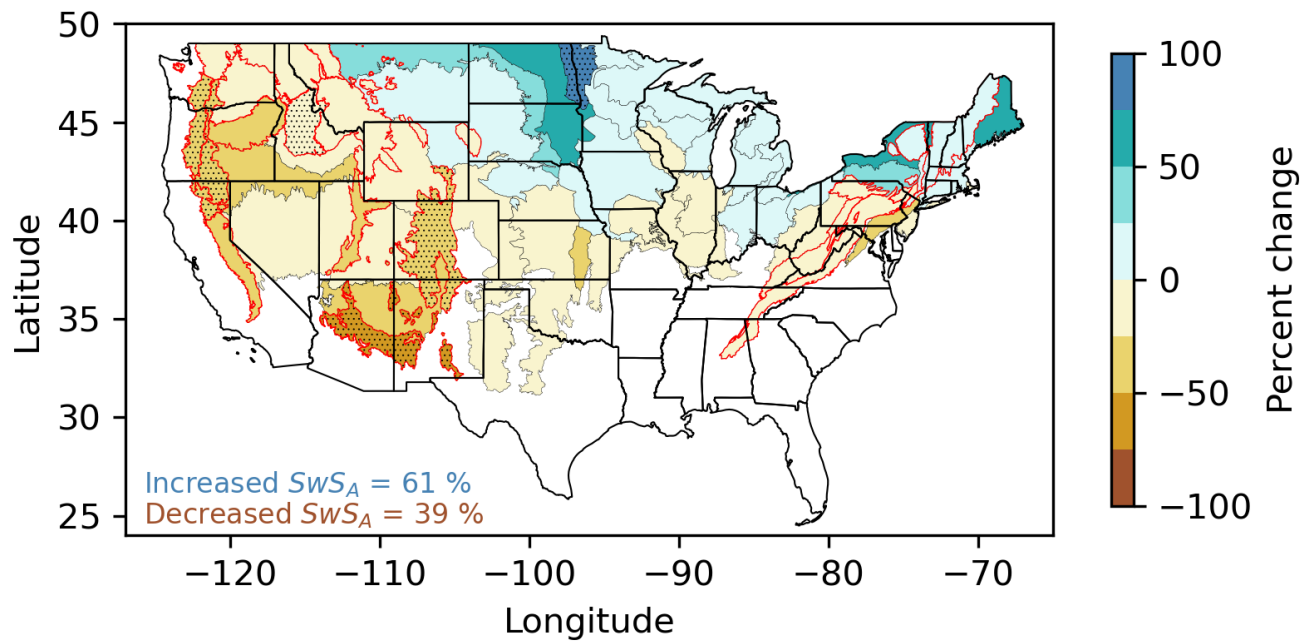

**Figure 3.** Study area [for the UASWE dataset](#) indicated by color shading showing the mean number of [annual-SWE-days-SCDs](#) across the contiguous US in locations that have a minimum average of 30 snow covered days/year over the period of [recordstudy](#).

**Figure 4.** Percent Change in  $SwS_A$  [md] (a) and percent change in  $SwS_A$  (b) across US stations from water years 1982-2020 (left). Large outlined circles indicate stations with  $p < 0.1$ .

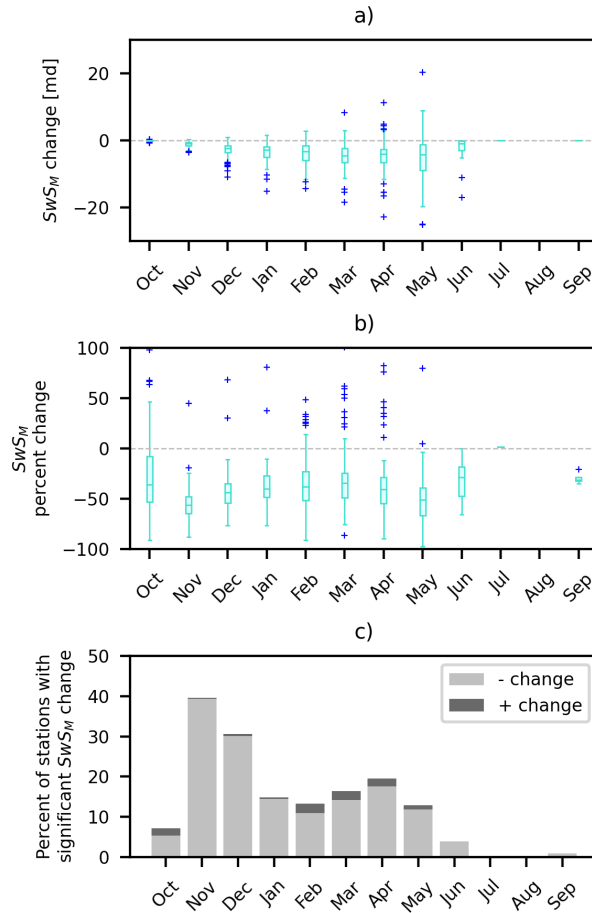

**Figure 5.** Grid-cell-scale changes in  $SwS_A$  from over water years 1982-2020 across for the UASWE data set. Stippling indicates locations with  $p < 0.1$ .

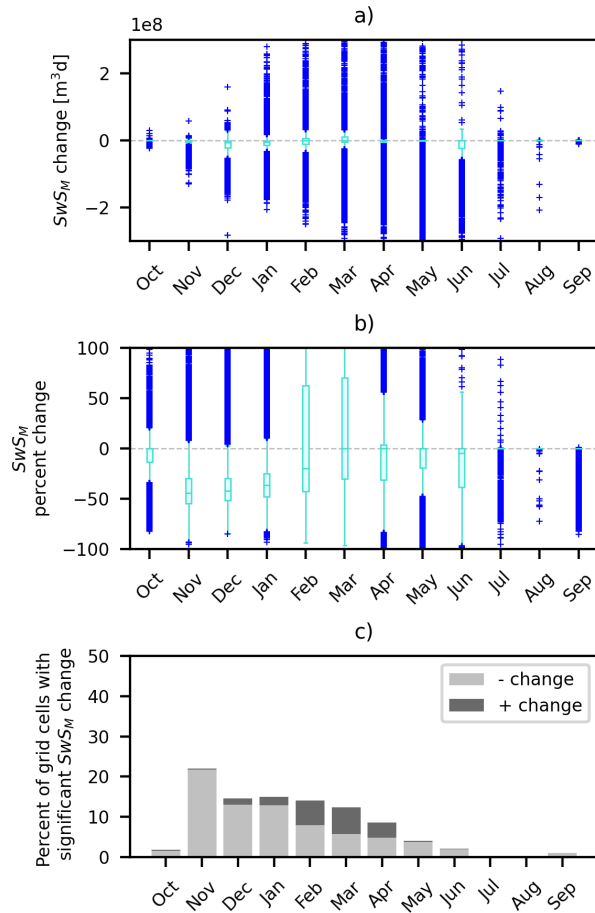

**Figure 6.** Grid-cell-scale changes Changes in  $SwS_A$  aggregated across ER3s from over water years 1982-2020. Stippling indicates ER3s with  $p < 0.1$ .

**Figure 7.** Percent change Changes (significance  $p < 0.1$ ) in SwSM across US stations. The top boxplot shows monthly, in dimensional (a) units and in terms of percent change in snow-water storage per decade (b). The rectangle indicates the interquartile range, with the middle bar indicating the median. The blue pluses are outlier points. The bottom bar chart Panel (c) shows the fraction of stations that had significant increases or decreases in SwS.

**Figure 8.** As in [figure Figure 7](#), but for the [Grid cell-scale changes in SwS from water years 1982-2020 across the gridded UASWE data setdataset](#).

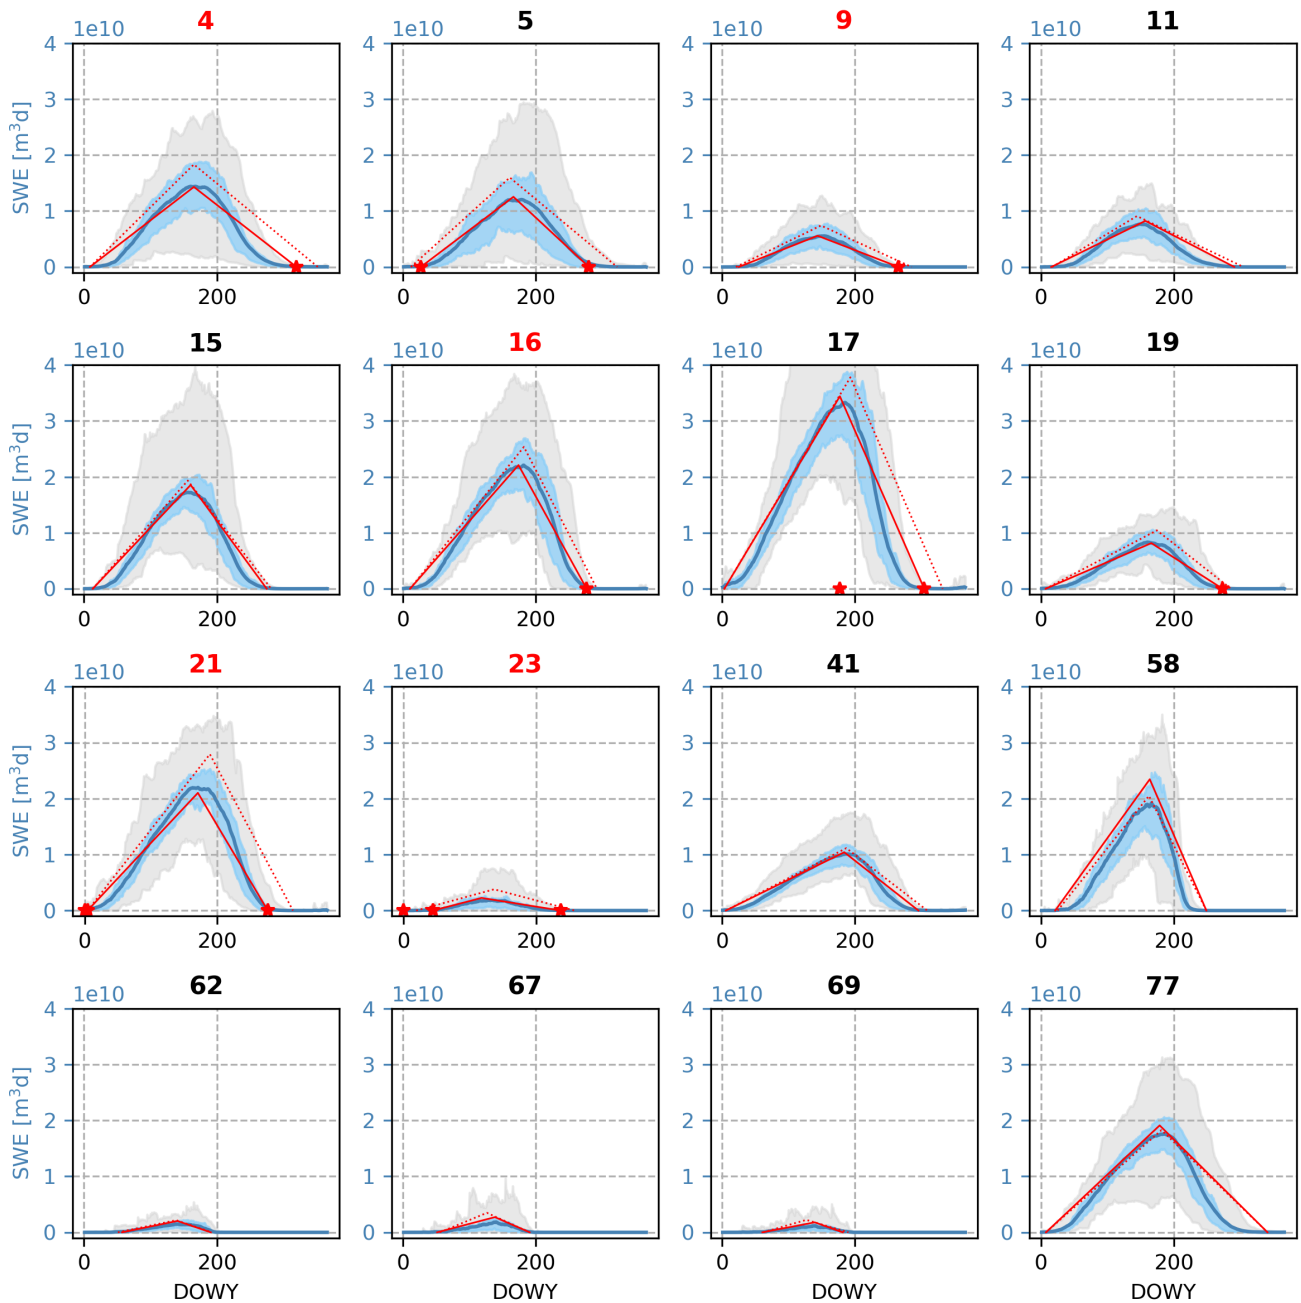

**Figure 9.** As in [figure Figure 7](#), but for changes in  $SwS_M$  aggregated across ER3s from water years 1982-2020. Red components of this [figure Figure](#) indicate the results only considering [mountain-mountainous](#) ER3s.

**Table 2.** Overview of SwS<sub>A</sub> in ~~mountanous~~-mountainous ER3s. ~~Red-Bold~~ p-values are ~~signifeat~~-significant at  $p < 0.1$ .

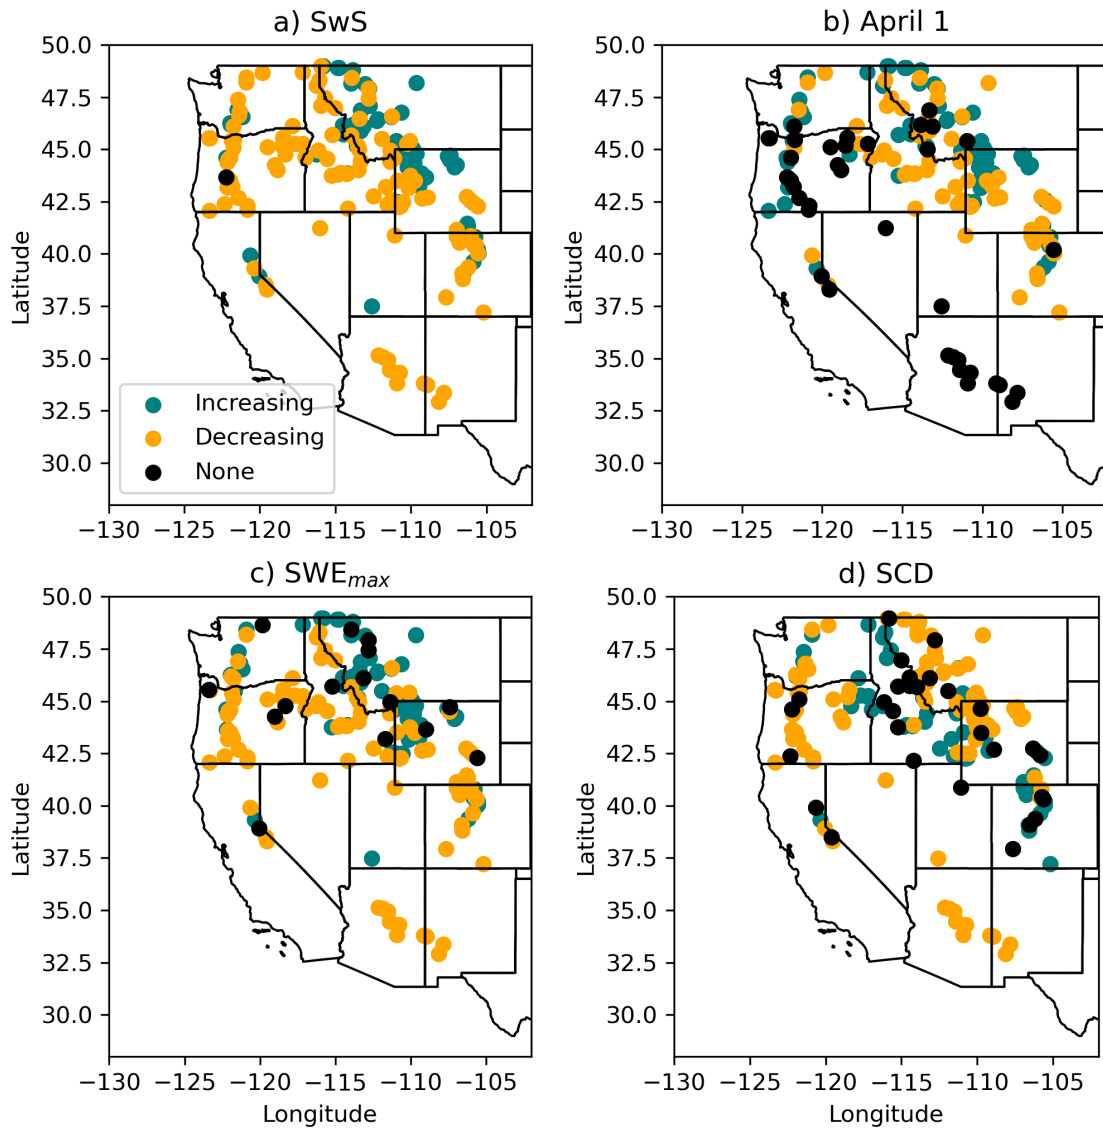

ER3 code and name	Average fraction of US SwS <sub>A</sub>	Percent change from 1982 to 2020	p-value

**Figure 10.** SwS<sub>A</sub> in each mountainous ER3 as a function of ER3 hypsometry. Teal line indicates the average SwS<sub>A</sub> in each hypsometry bin from water years 1982-2020 (left axis). Solid red line indicates the percent change in SwS<sub>A</sub> as a function of hypsometry for each mountainous ER3 over the time period of interest-study (right axis). Black × symbols indicate where the percent change in SwS<sub>A</sub> is significant ( $p < 0.1$ ). Dashed red line indicates the percent change in the IQR of daily SwS (aka daily-SWE) as a function of hypsometry in each mountainous ER3 over the time period of interest-study (right axis). Black +o symbols indicate where the percent change in the IQR is significant ( $p < 0.1$ ).

**Figure 11.** Summary of snow metric trends—Observed SWE curves for water years 1982–2020 mountainous ER3s shown with historic and current conceptual SWE curves. Metric Percent of stations with positive trend Percent of stations with significant positive trend Percent of stations with negative trend Percent of stations with significant negative trend The blue line indicates the observed mean SWE curve for each ER3. Light blue shading indicates the interquartile range of observed daily SWE and grey shading indicates the minimum and maximum range of observed daily SWE. Red ER3 labels signify ER3s that had a significant change in the SwS21-2-79-21-SCD-14-1-79-29<sub>A</sub> over the period of study. The red dotted line indicates the conceptual SWE curve for each ER3 at the start of our study period (1982) based on the trend analysis of DSO,  $SWE_{max}$  23-2-74-23-Day of SWE,  $SWE_{max}$  28-2-61-15-April 1-DOWY, and DSD. The red line indicates the conceptual SWE 24-2-68-22-curve for each ER3 at the end of our study period (2020). Red stars on the x-axis indicate significant changes in DSO,  $SWE_{max}$ , DOWY, and DSD. Red stars on the y-axis indicate significant changes in  $SWE_{max}$ .

**Figure 12.** Regression of percent change Trend directions in  $SwS_A$  with percent change in April 1 SWE (top left), April 1st  $SWE_{max}$  (top right) and SCD,  $SWE_{max}$  (bottom left). Regression of  $SWE_{max}$  with and SCD (bottom right) across stations that do not have the same trend directions across all metrics.

**Figure 13.** SWE curves from every second water year from 1982-2020 at the Quartz Mountain SNOTEL station.

**Figure 14.** Regression of percent change in  $SwS_A$  with percent change in April 1 SWE (a),  $SWE_{max}$  (b) and SCD (c). Regression of  $SWE_{max}$  with SCD (d).
