Abstract

Coastal wetlands are fundamental for climate-change mitigation thanks to their ability to store large amounts of organic carbon in the soil. They also represent the first natural emitter of methane (CH₄). Salinity is known to inhibit CH₄ production, but its effect in brackish ecosystems is still poorly understood. Our study aims to understand how environmental variables may affect greenhouse gas emissions (GHGs) in coastal temperate wetlands. We present the results of over one year of measurements performed in four wetlands located along a salinity gradient on the northeast Adriatic coast near Ravenna, Italy. Soil properties were determined by collecting soil samples, while carbon dioxide (CO₂) and methane (CH₄) fluxes from soils and standing waters, water levels, surface, and groundwater physical-chemical parameters (temperature, pH, electrical conductivity, and sulphate concentrations of water) were monthly monitored by a portable gas flux-meter and multiparametric probes, respectively. Principal component analysis (PCA) was used to investigate emergent relationships between GHGs fluxes and environmental variables. Our results suggest that, among all variables, temperature and irradiance play a significant role in CH₄ emissions from water and soil whereas water column depth and salinity are limiting factors of GHGs emissions.

Keywords: coastal temperate wetlands, GHGs; CO₂; CH₄; PCA; portable gas flux-meter; salinity

1. Introduction

Wetlands store large amounts of carbon (C) in sediments and soils for long periods and in a more effective way than other environments (Whalen, 2005; Saunio et al., 2016), and this capability puts them among the largest C pools of the world. Even though the majority of C tends to remain in wetland soils, some of it is recombined producing carbon dioxide (CO₂) and methane (CH₄), two greenhouse gases (GHGs) released into the atmosphere. CH₄ is the second most important GHGs after CO₂, responsible for 20% of the direct radiative forcing since 1750 (Mar et al., 2022). Increased CH₄ emissions in wetlands could trigger a positive feedback loop that further increases temperatures, potentially making wetlands the first natural emitters of CH₄ in nature and worsening climate changes effects (Gedney et al., 2019; Saunio et al., 2016).

Over the last three decades, variations in wetland emissions have dominated the year-to-year variability in surface emissions, and it is estimated that just in the 2000s natural wetlands have accounted globally for the production of 175-217 Tg CH₄ yr⁻¹ (Kirschke et al., 2013); among them, if only temperate wetlands are considered, they have been reported to emit an average of 0.109 g/m²/day of methane (Turetsky et al., 2014). In a recent study by Peng et al. (2022), it is estimated that between 2019-2020 the emissions from wetlands have increased by 6.0 ± 2.3 Tg CH₄ yr⁻¹. Nevertheless, large uncertainties still affect estimates of the total contribution of wetlands at different scale (Abdul-Aziz et al., 2018). Therefore, understanding C cycle in wetlands is a key factor in fighting climate change and achieving climate targets by compensating anthropogenic carbon emissions (Erwin, 2009; Howard et al., 2017).

Water table level, temperature, and salinity are only some of the environmental factors that have an impact on air-water CH₄ fluxes, especially in wetlands (Huertas et al., 2019). Salinity has an inhibitory effect on the organic carbon mineralization and CH₄ production especially in coastal systems due to the presence of sulphate (SO₄²⁻) (Poffenbarger et al. 2011). This ion, at certain concentrations, allows sulphate-reducing bacteria to outcompete methanogens for energy sources, consequently inhibiting CH₄ production. No consensus has been reached for salinity threshold under which the system becomes a CH₄ source. This process can be complicated by site-specific conditions that can allow CH₄ production to continue in coastal environments despite the inhibitory effect of SO₄²⁻ (Megonigal et al., 2004; Poffenbarger et al., 2011).

The water table level has a direct effect on CH₄ production by affecting vegetation productivity, redox potential, and oxidation process in the rhizosphere (Bhullar et al., 2013), but its overall function is still unclear, posing a significant source of uncertainty for estimating its contribution to the global budget of CH₄ (Whalen, 2005; Calabrese et al., 2021).

Site-specific conditions highly affect CH₄ production, resulting in an high spatial-temporal heterogeneity in these ecosystems (Poffenbarger, et al. 2011). Each type of coastal wetland ecosystems must be taken into account separately because of the differences in CH₄ release and regulatory mechanisms in order to properly estimate global wetland methane emissions and to evaluate possible changes as a result of environmental stressors (Turetsky et al., 2014).

To our knowledge no previous studies have been conducted on GHGs emissions in coastal wetlands in the Po River Delta, and just an exiguous number of studies has been carried out in the overall Mediterranean Basin (Huertas et al., 2019; Venturi et al., 2021). Temperate Mediterranean coastal wetlands are unique ecosystems that are subject to Mediterranean climate forcing and therefore subjected to a strong seasonality (Alvarez Cobelas et al., 2005). Although some earlier studies have been conducted from both global perspective and within regional context of coastal wetlands, few are known on temperate wetlands and specifically on temperate coastal systems (de Vicente, 2021).

In this work, we explore the relationships between CH₄ and CO₂ fluxes and environmental variables from a group of four different coastal wetlands located in the province of Ravenna, an area in the Northern Adriatic coastal zone (Italy). The

selected four different ecosystems are located along a salinity gradient, ranging from fresh- to strong-brackish water and, being near to each other, belonging to the same climate zone. This set-up offers the opportunity to closely investigate physical-chemical environmental drivers and their relationships with CH₄ and CO₂ production. Our findings can be useful for modelling the C cycle accounting in temperate coastal wetlands models and for improving environmental management strategies and evaluate climate change future trends (increase in temperature, sea level rise, change in precipitation patterns).

In the paper, after the characterization of the study area (Section 2), we examine the physical and chemical variables that affect CH₄ and CO₂ production (Section 3) and provide detailed analysis on the relationships between the environmental variables and the measured gases (Section 4). We close by discussing the meaning of the findings for future environmental management.

2. Materials and methods

2.1 Study Area

The study site is located along the Northern Adriatic Coast, in the province of Ravenna (Italy) (Fig. 1) and includes four natural wetlands in pristine conditions named *Punte Alberete*, *Pirottolo*, *Cavedone* and *Cerba*, delimited to the North by the Lamone River and to the South by the Cerba channel. The entire area is part of the Po River Delta Natural Park, protected by the European Union legislation (Punte Alberete SCI/SPA IT4070001 and San Vitale pine forest IT4070003; EEC 1979; 1992). The site is characterized by a temperate climate with annual rainfall of about 643 mm (data from Dext3r website (<https://simc.arpae.it/dext3r/>), mainly concentrated in autumn and spring. Temperatures range from 24 °C in summer to 3 °C in winter (Zannoni, 2008), with mean annual temperature of 13.3°C. Precipitations, temperature and evapotranspiration greatly influence the water table, saltwater intrusion (Laghi et al., 2010; Giambastiani et al. 2021) and soil salinity (Buscaroli and Zannoni, 2017)

The topography of this area lies below mean sea level and the coastal area is prone to saltwater intrusion for both natural (subsidence and high hydraulic conductivity) and anthropogenic stressors (Antonellini et al. 2010; Giambastiani et al. 2021); river banks, palaeodunes in the forest and current coastal dunes, constitute the highest areas with elevation of 1-3 m a.s.l. The alternation of highs and lows in the topography, which correspond to different past coastlines and the different stage in the Po Delta evolution (Amorosi et al., 1999) affects vegetation distribution.

The water table is around 0 m a.s.l. or below sea level, and the coastal phreatic aquifer is salinized with the occasional presence of shallow freshwater lenses floating on brackish-salty water and shallow freshwater-saltwater interface (Antonellini et al. 2008a; Giambastiani et al. 2021). During the dry and warm season, water table decreases (Giambastiani et al., 2021) and groundwater salinity increases in most of the area, as shown in Fig. 1b. Salinization of surface and ground waters is especially significant in, and along, canals and rivers, and close to the Piailassa Baiona lagoon, which is directly connected to the Adriatic sea (Fig. 1; Antonellini et al. 2008a).

The entire study area is subjected to mechanical drainage that is necessary to manage floodwater and allow nearby farmland activities by maintaining constant water table depth in the range of 1.5-2 m below ground level during the year (Soboyejo et al., 2021). The complex system of drain canals and water pumping stations avoids flooding but creates a general inland-directed hydraulic gradient with consequent saltwater intrusion from the lagoon and sea (Giambastiani et al., 2021). Water level is also controlled in large areas of the wetlands, some of which are kept constantly flooded thanks to a system of ditches

and sluices. Given the naturalistic and ecological importance of these wetlands, water quality and water table management are crucial for preserving these environments against the ongoing salinization process.

100

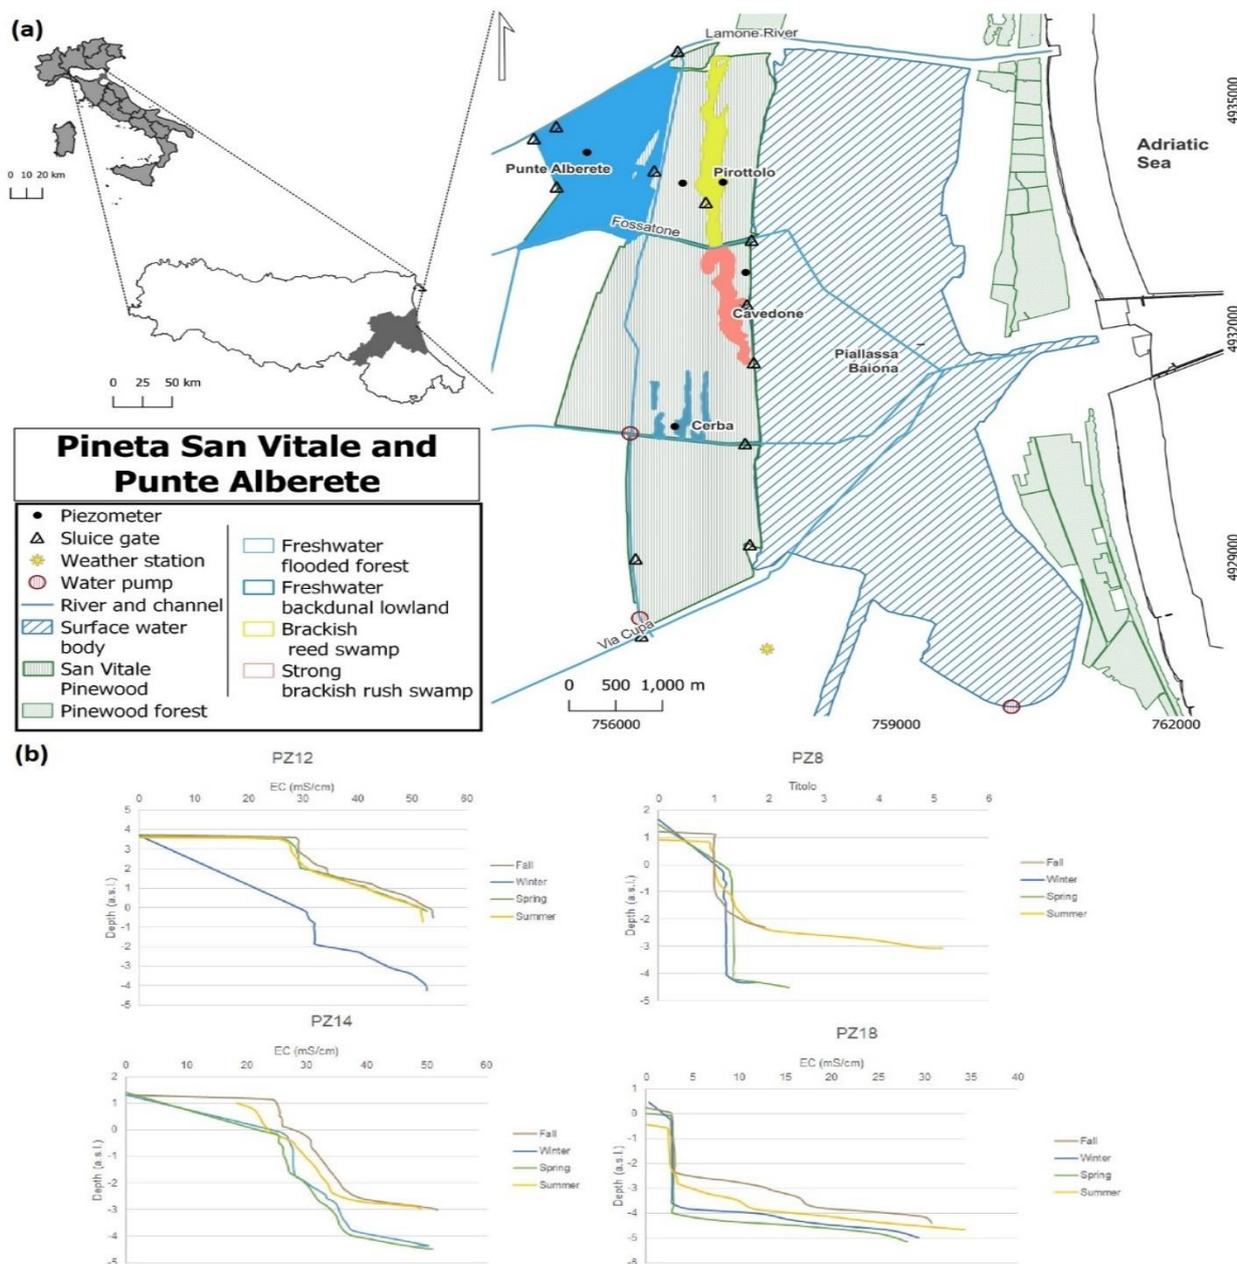

Fig. 1 – (a) Study area (EPSG: 32632 – WGS 84 UTM zone 32N) and (b) vertical distribution of groundwater electrical conductivity (EC in mS/cm) measured in four piezometers located in the four selected wetlands during the sampling period.

105 2.1.1 Punte Alberete

The site of *Punte Alberete* (PA) (Fig.1), about 190 ha, is a predominantly hygrophilous forest dominated by *Fraxinus oxycarpa*, *Ulmus minor*, *Populus alba*, and *Salix alba* (Merloni and Piccoli, 2001). The area is almost permanently flooded, and sediment grain size is typically fine (<64 µm). The sediments are calcareous and moderately alkaline. It alternates microenvironments and plant formations depending on the depth and seasonal variation in water levels. A predominance of common reeds patches of hygrophilous and flooded forest is observed (RER, 2018b). The sedimentary substrate is calcareous and characterized by fine-grain size (<64 µm) in western part and coarser in eastern part. Soils have different texture depending of the substrate, are calcareous, moderately alkaline and with superficial organic horizons (RER, 2021). *Punte Alberete* is classified as “wetlands of international importance” under the Ramsar Convention and falls entirely within a protected oasis (EEC, 1979; 1992; RER, 2018b). The local municipality is in charge of the management of the area, and specifically of vegetation, and water levels. The water inflow is through a sluice located on the right bank of the Lamone River. This area is characterized by the presence of superficial inflow: water flows westward along the west perimetral canal till the *Fossatone Canal*, and from here it feeds the entire forest through sub-lagoonal canals. This area is characterized by the presence of surface freshwater, and a slightly saline deep groundwater (Fig. 1b) (Giambastiani, 2007). Part of the Lamone water comes from the *Canale Emiliano Romagnolo* (CER), which is the channel that brings the Po River water to the Romagna region for drinking, agricultural, and industrial uses. The water recharge of the area is often stopped in summer (June-August) when the mowing of the helophytic vegetation is often performed.

2.1.2 Cerba

The monitored site belonging to the *Cerba* area (CE) is an elongated wetland located between palaeodunes deposited between the 10th and 15th century at the mouth of the Po River delta (Lazzari et al., 2010; Regione Emilia Romagna 2018a). At a larger scale, the site is part of the *San Vitale* pine forest, the northernmost of the coastal forests that historically separated the city of Ravenna from the sea. The forest is characterized by a succession of ancient dune belts and interdunal wetland, with sandy and calcareous soils forming on sand bar deposit consolidated by old forestations (Zannoni, 2008; Vittori Antisari et al., 2013; Ferronato et al., 2016; RER 2018a). Here, soils with thinner vadose zone may accumulate salts in the surface horizons during summer season (Buscaroli and Zannoni, 2017). In this area surface water is fresh, whereas groundwater becomes increasingly saline with depth (Fig. 1b) (Giambastiani, 2007).

2.1.3 Bassa del Pirottolo

The northern part of *San Vitale* pine forest is crossed from north to south by the *Bassa del Pirottolo* (PIR), a reed swamp of fresh and brackish water located in an interdunal zone. The swamp originates from the southern bank of the *Lamone* river and is crossed in the east-west direction by numerous feeder canals ((Vittori Antisari et al. 2013; RER 2016; 2018a). The water here is superficially slightly saline till becoming brackish along the depth (Fig. 1b) (Giambastiani, 2007) The soils have a medium-grain sandy, sandy-loam texture and hydromorphic or subaqueous features (Vittori Antisari et al., 2013; Ferronato et al., 2016).

2.1.4 Buca del Cavedone

140 The *Buca del Cavedone* (CAV) wetland is located south of the *Bassa del Pirottolo* and has slightly brackish water. This strip of
interdunal lowlands extends until the adjacent *Pialassa Baiona* (Vittori Antisari et al. 2013; RER 2018a) and has sandy,
calcareous soils with subaqueous features (Ferronato et al., 2016). Shallow water is medium saline, with salinity increasing
along the depth, till reaching very saline concentrations (Fig. 1b) (Giambastiani, 2007). The area is permanently flooded. The
145 progressive water freshening due to freshwater inflow from the *Fossatone* canal and isolation from the *Pialassa Baiona* basin
is causing the disappearance of the halophilic vegetation. This habitat is of considerable naturalistic and ecological value,
with rushes and large open water pools harbouring submerged hydrophyte communities, typical of still water (RER 2018a).

2.2 Data collection

2.2.1 Gas fluxes

150 Field observations were collected once a month from April 2021 to June 2022 for a total of 748 point fluxes observations.
Direct measurements of gas fluxes from soils and standing water were performed by a portable CH₄-CO₂ flux-meter (West
Systems srl, Pontedera, Italy) equipped with two infrared spectrophotometer detectors: (i) Licor 8002 for CO₂ and (ii) tunable
laser diode with multipass cell for CH₄. All measurements were retrieved using a dark chamber, equipped with a floating
155 device for measurements on standing water (Fig. S1 in Supplement), recording a measurement approximately every 15-20
m along a transect or the wet border of the wetland. Spacing depended on environmental conditions and settings. (Fig.S2 in
Supplement). Every point was georeferenced by GPS included in the portable fluxmeter.

Gas flux measurements were based on the accumulation chamber “time 0” method (Cardellini et al., 2003; Capaccioni et al.,
2015). Based on the linear regression of increased CH₄ and CO₂ concentration values over time inside the dark chamber,
fluxes from single point source were estimated, using the Flux Revision Software produced by West System s.r.l. (Giovenali
160 et al., 2013). All measurements have been recorded after a minimum of 90 seconds analysis. Based on the lowest sensitivity
limit of the instrument, a value of 0.05 mol/m²/day was assigned to all fluxes larger than zero and lower than this value to
avoid over estimation. The 21 negative measurements and the 55 zero measurements were considered incorrect and thus
removed from the dataset, resulting in 671 single observations used for data analysis.

Soil samples were collected using a soil corer and extracting a 40 cm long core. The samples were weighted and later dried
165 in the oven for 24 hours at 105°. The dry weight was used to obtain bulk density (Al-Shammary et al., 2018). Later the sample
was homogenized in a mortar to perform Loss on Ignition analysis: 2-3 gr of sample were then dried in crucibles in furnace
for 8 hours, gradually increasing the temperature from 100°C to 450°C (Roner et al., 2016). After cooling, all samples were
reweighted and organic carbon contents calculated (Roner et al., 2016).

170 2.2.2 Environmental variables

Monthly physical-chemical parameters such as EC, pH, Eh and T of surface water were retrieve using Eutech probes
connected to a data logger in all four sites. All measurements were repeatedly performed in the same spot for every location.
Moreover, four piezometers at 6 m depth were monitored to retrieve monthly physical-chemical parameters for
groundwater in every location. Phreatimeter and level logger were used to measure water table level, EC, T and pressure,
175 respectively (Fig. 1a).

Irradiance was retrieved monthly from both in-situ measurements and the nearby ARPae weather station of Ravenna (Fig. 1a), whose data are available from the Dext3r website (<https://simc.arpae.it/dext3r/>). The local weather station also provided atmospheric pressure measurements to calibrate the calculation of the gas fluxes.

180 Finally, water samples were collected monthly at each station and in the same spot to measure SO_4^{2-} concentrations by using a HACH DR/2010 spectrophotometer.

2.5 Statistical Analysis

All data were tested for normality distribution using the Shapiro-Wilk Normality Test (Package *stats* version 4.2.1) and, for homoscedasticity with the Fligner-Killeen Test (Package *stats* version 3.6.2) in R (version 4.2.2).

185 Principal Component Analysis (PCA) is a multivariate statistical technique used to analyse the linear components of the considered variables. PCA was used to summarize and visualize the relationships between CH_4 and CO_2 fluxes with environmental variables by using the “FactoMineR” (Lê et al., 2008) and “factoextra” (Komlan Mawuli Afiademanyo et al., 2020) R packages. The first principal component PC1 captures the maximum variance in the dataset, whereas the second principal component captures the remaining variance in data and is uncorrelated with PC1. In a Cartesian plain with the first and the second PCs as principal axes, the point measurements of the several variables considered in this study were plotted
190 and a vector was calculated for each variable. Variable vectors which are close to each other are positively related, while opposing variables are negatively related.

We also investigated the sample structure through the score plot. The position of observations along the components indicates similarities between the samples that are positioned close to each other. Observations particularly influenced by a specific variable will be positioned along its vector.

195 Autocorrelations between CH_4 emissions and environmental variables were calculated using the Pearson correlation matrix in the R “ggplot2” package (Wickham, 2016). The same package was used to compute the probability density function (PDF) of CH_4 and CO_2 fluxes. The effect of different environmental variables was statistically proven by the Mann Whitney test function performed with the “ggstatsplot” package in R (version 0.10.0).

3. Results

200 3.1 GHGs fluxes and environmental variables

3.1.2 Environmental variables

For a general overview, data are divided in two groups, i.e. those collected in the Fall/Winter (FW) period and those collected in the Summer/Spring (SS) period (Tab.1).

205 PA is always the site with the coldest water temperature (9.4 °C in FW and 18.7 in SS), and the lowest water EC value (0.67 mS/cm both FW and SS) of the whole study area for both seasons. This site also always has the second highest water column levels (51 cm in FW and 58 cm for SS) of the overall study area, and the lowest irradiance values (139.7 W/m^2 in FW and 532.2 W/m^2 in SS).

CE, while still being a freshwater site, has higher salinity than PA during both seasons (1.49 mS/cm in FW and 2.24 mS/cm in SS) and records the highest mean water temperature in SS (22.3 °C). In the same period, also air temperature has one of the
210 highest values recorded during the field campaign (25.1°C). CE is also the site where the mean water column is the lowest

(14 cm in FW and 19 cm in SS), and the mean irradiance is the highest (486.4 W/m² in FW and 650.5 W/m² in SS) during both SS and FW. CE has the lowest mean soil content of organic matter (1.4%) of the four sites.

PIR has the second highest value of EC (7.06 mS/cm in FW and 6.79 mS/cm in SS) of all four sites during both seasons and it has the second highest concentration of SO₄²⁻ during SS (640.8 mg/l). PIR is also the site with the highest water column level during both seasons (80 cm in FW and 72 cm in SS), and the highest mean content of organic matter in the sediments (2.2%) but the lowest bulk density (1 g/cm³).

CAV is the site with the highest EC of all studied areas during both seasons (38.85 mS/cm in FW and 21.97 mS/cm in SS), and the highest concentration of SO₄²⁻ during SS (875.1 mg/l). Here, the mean air temperature is the lowest of all sites during FW (13°C). For this site no record on the water column level is collected, due to fluxes being always under the detection limit of the instrument.

Tab. 1 a) Mean seasonal values for recorded environmental parameters. No values for water column in CAV were collected. B) Mean values of bulk density and organic matter content measured on soil cores.

(a)	Parameters	Punte Alberete (PA)	Cerba (CE)	Bassa del Pirottole (PIR)	Buca del Cavedone (CAV)
Fall-Winter (FW) (Oct-Feb)	T air (°C)	15.4	16.2	14.6	13.0

225 3.1.2 GHGs fluxes

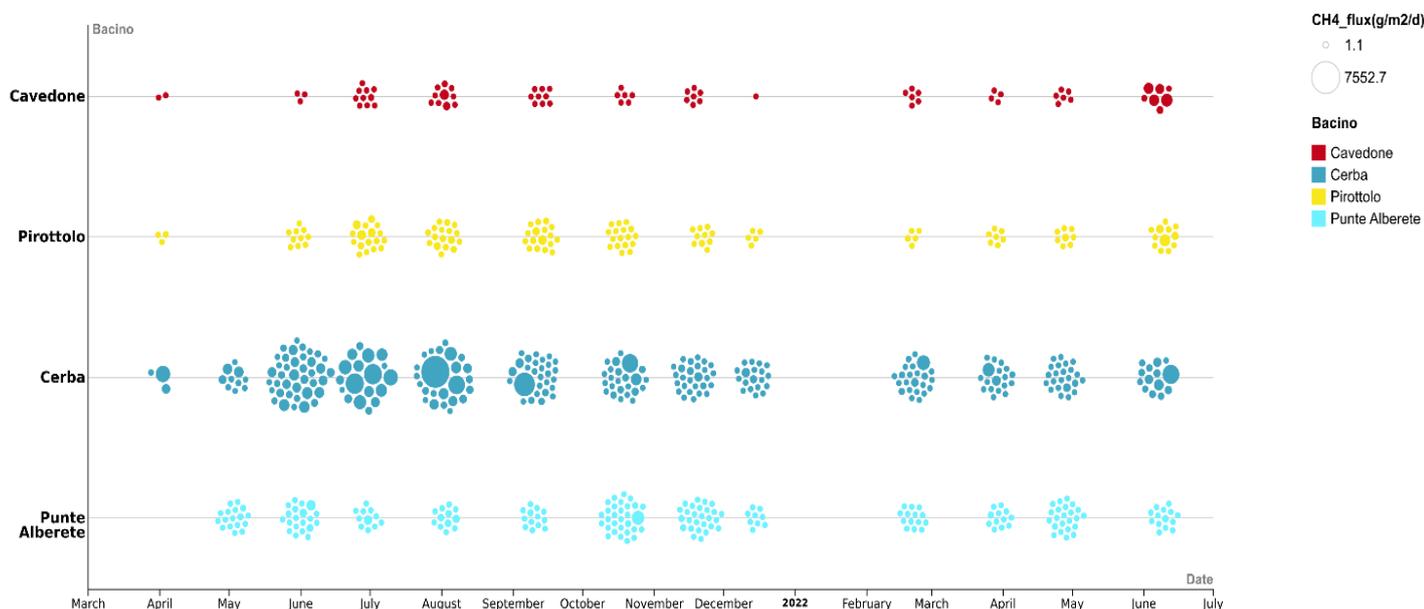

Fig. 2 shows the seasonal pattern in the CH₄ emissions recorded through the sampling campaign. Higher fluxes are recorded throughout the spring and summer months, declining in winter and fall. Also, fluxes in freshwater environments (PA and CE) are often higher than those recorded in brackish environments (PIR and CAV).

230 CH₄ and CO₂ fluxes in PA are always lower than those recorded in CE, while being both sites characterized by the presence of freshwater. During SS in particular, PA has the lowest mean flux of CH₄ of the whole study area (6.04 g/m²/day) (Tab.2). The highest mean values of CH₄ and CO₂ for both seasons is recorded in CE (Tab.2). Mean CH₄ fluxes account for 61.83 g/m²/day during the FW and 254.09 g/m²/day during the SS, and CO₂ fluxes for 20.34 g/m²/day during the FW and 100.62 g/m²/day during the SS (Tab. 2).

In PIR, CH₄ are 1.99 g/m²/day in FW and 15.80 g/m²/day in SS, among the lowest during SS, with exception of PA. CO₂ fluxes are 16.02 g/m²/day in FW, the lowest record for the season, and 19.37 g/m²/day in SS (Tab. 2). CAV is the site with both the highest salinity and the lowest emissions. CH₄ and CO₂ fluxes are the lowest during the FW with a recorded mean value of 1.10 g/m²/day and 2.16 g/m²/day, respectively.

240 **Fig. 2 -Bubblegraph representing CH₄ fluxes from June 2021 to July 2022 in the four studied wetlands. During January 2022 it was not possible to perform measurements due to frosting.**

Tab. 2 Seasonal values for CO₂ and CH₄ fluxes.

Season	GHGs fluxes (g/m ² /day)	Punte Alberete (PA)		Cerba (CE)		Bassa del Pirottolo (PIR)		Buca del Cavedone (CAV)

3.2 Principal component analysis

245 3.2.1 PCA results

PCAs analysis is performed considering separately CO₂ and CH₄ fluxes to better investigate their correlation with the environmental variables and the two Principal Components that better explained the most variance percentages.

In this section PCA analysis on fluxes from soils and water are presented jointly. Fig. 3 shows the plots of PC1 and PC2 for CH₄ (Fig. 3a) and CO₂ (Fig. 3b) and all measured environmental variables. In the first case the two components explain 63.9% of the total variance, and specifically PC1 explains 38.5% and PC2 25.4% of variance (Fig. 3). Water temperature, air temperature and irradiance are clustered in one group to the right, indicating close relation among each other. They all increase as the PC1 increases, while they are barely affected by PC2. CH₄ emissions also increase as the PC1 increases, but they increase as PC2 decreases. On the contrary, both salinity and SO₄²⁻ increase as PC2 increases, showing a limited contribution of PC1 (Fig. 3a). This result shows a positive correlation between CH₄ production, water and air temperature, and irradiance, whereas CH₄ production is negatively correlated to salinity (Fig. S7 in Supplement).

Points in biplot represents the field measurements. Plotted in Fig. 2a, points in red represent data collected at CAV, and have in general higher PC2 values than those collected in the other three study sites. Their distribution goes accordingly the strong positive correlation between PC2 and salinity, and CAV presenting higher salinity values than the other sites. Similarly, CAV appears to be the site with the lowest CH₄ emissions in FW period (Tab.2), given that CH₄ emissions increase as salinity decreases. We conclude that measurements performed in brackish environments such as CAV are characterized by generally lower emissions if we compare them to those measured in freshwater sites.

When the PCA is performed on CO₂ and the observed environmental variables, PC1 explains 38.6 % and PC2 24% of total variance, accounting together for 62.6% of the total variance (Fig. 3). The results are shown in Fig. 2b. Similarly, to the results obtained for CH₄, water and air temperature and irradiance cluster together, highly contributing to PC1. These variables also show a positive correlation with CO₂ production and are highly correlated within themselves (Fig.S8 Supplement). On the contrary, salinity is displayed along PC2 and shows a negative correlation with CO₂ emissions.

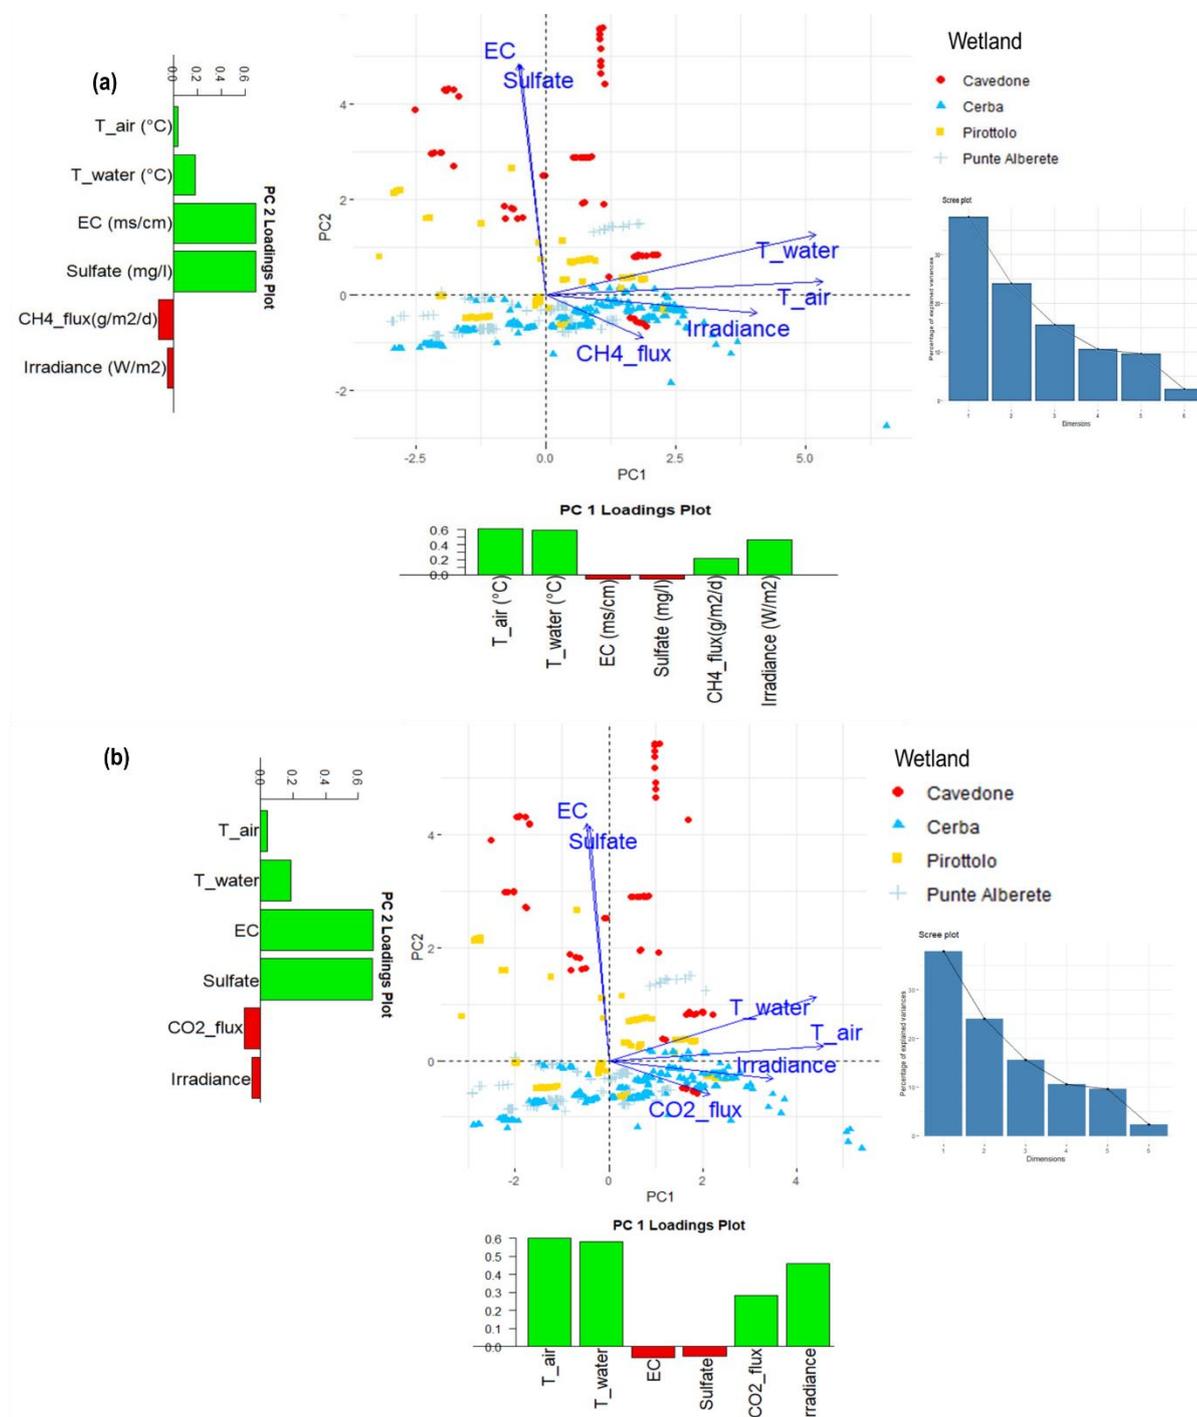

Fig. 3 – Biplot representing PC1 and PC2 for (a) CH₄ fluxes and the observed environmental variables, and (b) CO₂ fluxes and the observed environmental variables. Along the axis of the biplot, the histograms report the loadings values for the respective component. On the right the scree plot shows the percentage of explained variance of each component.

3.3 GHGs fluxes from flooded areas

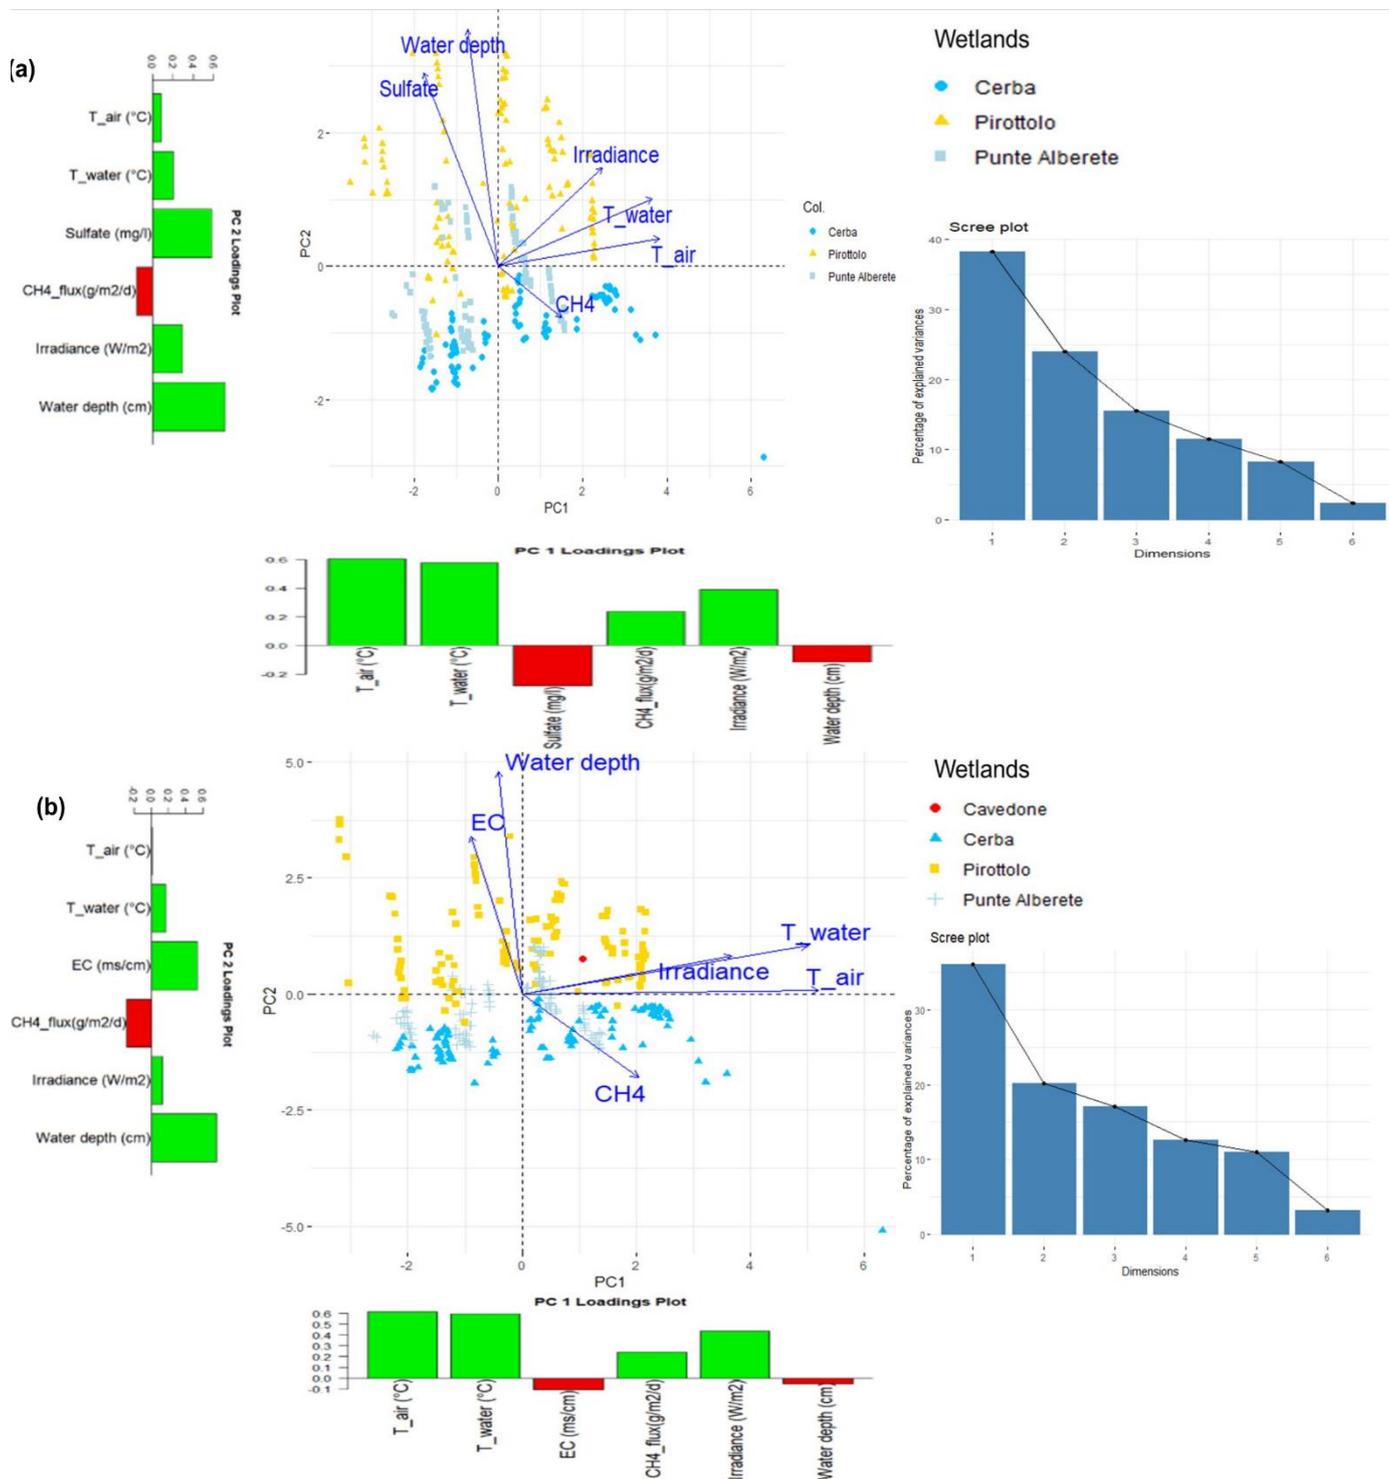

3.3.1 PCA results

275 Considering that in our study sites the large majority of surfaces is flooded, we perform further analyses exclusively on data measured on standing waters. Here we present the statistical analysis of fluxes coming from flooded areas, i.e. areas permanently or seasonally characterized by the presence of water. For this dataset, PCA is performed considering CH₄ fluxes and all environmental variables, alternately excluding sulphate and EC (Fig. 4). The analyses are repeated for CO₂ fluxes.

PCA performed on CH₄ fluxes is influenced by water column height and SO₄²⁻ concentrations: PC1 and PC2 explain the 38.3% and 24% of variance respectively for a total of 62.3% of total variance (Fig. 4a). Similarly, considering EC and water column height in performing the PCA analysis, it is found that PC1 account for 36.1% of variance and PC2 for the 20.1%, for a total of 56.2% of cumulative variance.

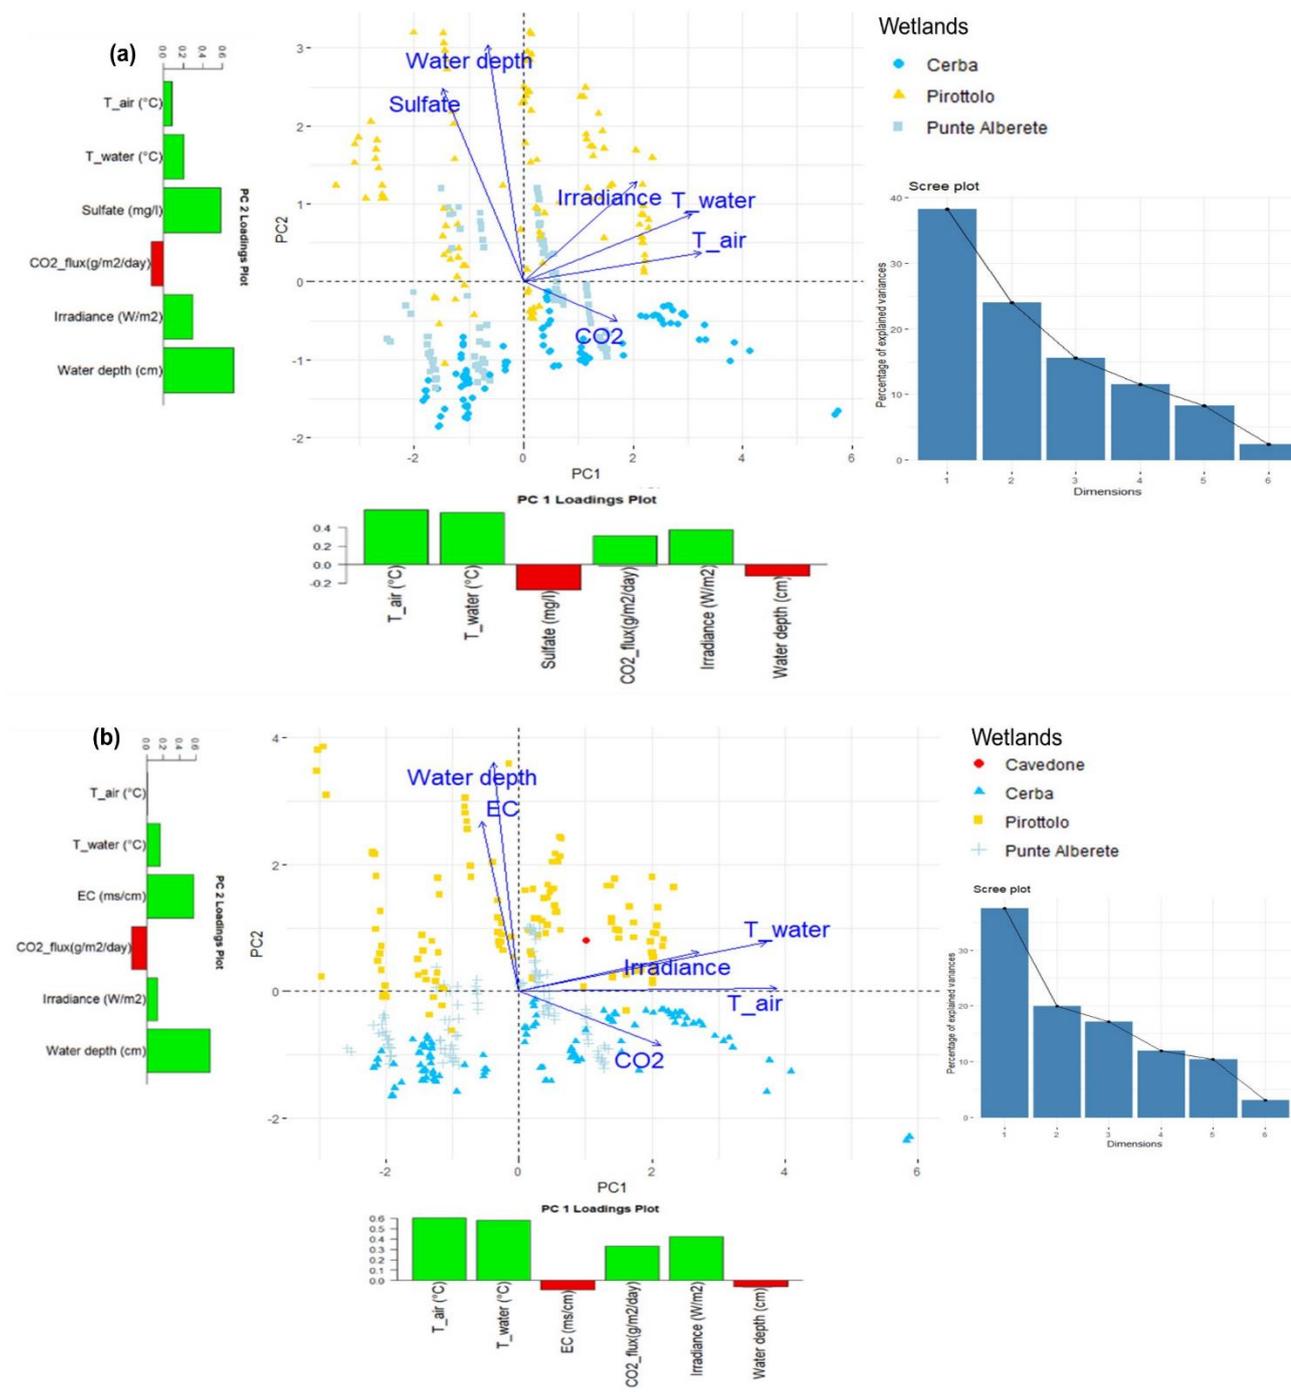

285 Fig. 4 (a and b) shows that air, water temperature, and irradiance vectors cluster together on the right of the graph, suggesting a strong correlation among them. On the opposite side, along PC2, salinity, sulphate and water column increase as PC2 increases, while they are negatively correlated to PC1. CH₄ emissions increase as PC1 increases while decrease as PC2 increases, therefore showing a negative correlation with both EC and water depth. Looking at the distribution of the scores, representing field observations, their variability is controlled by EC and SO₄²⁻ concentrations, water column height, and CH₄ emissions. All measurements collected in PIR (characterized by brackish waters) fall in the higher part of the graph, where PC2 values are positive whereas those collected in CE (shallow and slightly-fresh waters) cluster in the lower-section of the graph, and finally observations collected in PA (deep and fresh waters) are in the mid- section of the graph.

290 When CO₂ fluxes are considered together with sulphate and water column height (Fig. 5a+b), PC1 and PC2 explain respectively 39.5% and 24% of dataset variance, for a total of 63.5% of cumulative variance (Fig. 5b). When performing the same analysis on the dataset considering EC and water depth the first two components explain a total of 57.5% of the variance. PC1 account of 37.5% of variance and PC2 for the 20% (Fig. 5b). In both analysis on CH₄ and CO₂ fluxes, the presence of sulphate can better describe the dataset. The results from the biplot (Fig. 5a and 5b) are similar to those obtained for CH₄ (Fig. 4a and 4b). The vectors of air, water temperature, and irradiance are correlated positively with CO₂ production and distribute along PC1 (Fig. 5b). EC, sulphate, and water depth column follow the PC2 axis and have a negative correlation with CO₂ emissions.

310

3.3.2 Water column effect

The effect of water temperature and water column height on CH₄ and CO₂ fluxes distribution is examined and shown in Fig.6a-b and 6c-d respectively. High fluxes occur when the water height is lower than 50 cm, tendentially with high temperatures. For larger water heights, the emissions are small despite the presence of high temperatures.

315

320

Fig. 6- a) and c) Heat maps showing fluxes distribution depending on water column height; the colours indicate the water temperature; b) and d) represent the Probability Density Function (PDF) showing at which water columns height is more probable to observe high (blue), medium (green), and low (pink) fluxes. Top panels are for CH₄ fluxes, while bottom panels are for CO₂ fluxes.

The Probability Density Function (PDF) in Fig. 6b shows the probability to observe certain ranges of CH₄ fluxes for different water column heights. Results show that low fluxes of CH₄ (i.e. 1-100 g/m²/day) are observed in both shallow and deep waters but medium and high fluxes (i.e. 100-7000 g/m²/day) are observed only when the water column height is less than 50 cm deep. To further confirm these results, data are grouped in two classes of deep (> 50 cm) and shallow (<50 cm) waters.

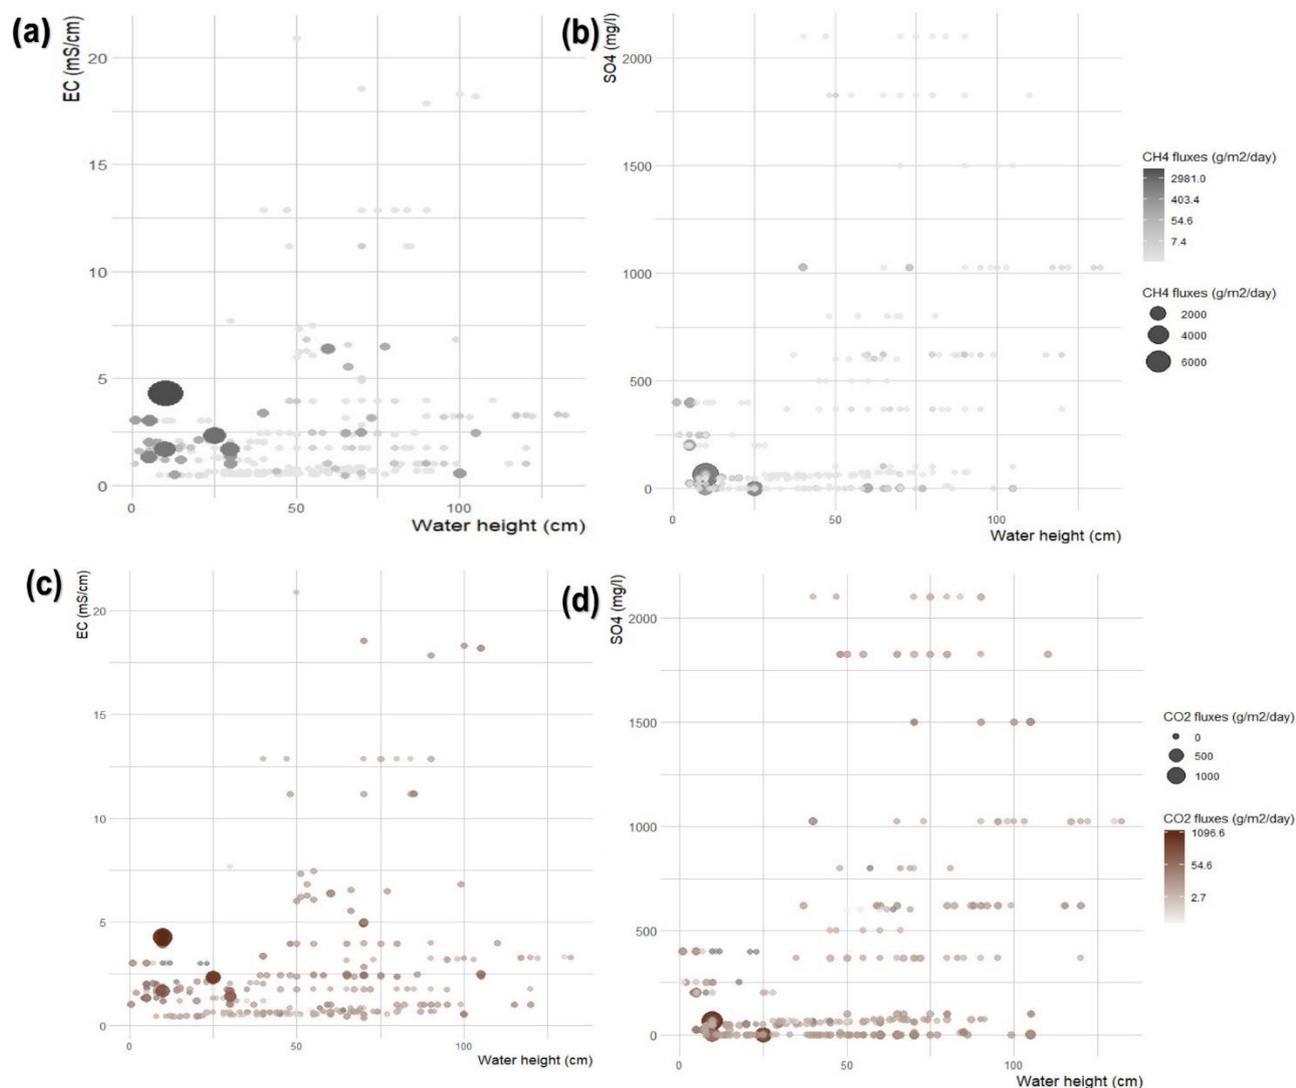

325 A Mann-Whitney test is run on the two data classes, returning a *p* value of 4.66 e-06 for CH₄ (Fig. S11 Supplement) confirming that the two classes are statistically different and that there is a threshold depth below which the wetland becomes an important source of CH₄.

The same analysis is applied to CO₂ fluxes (Fig. 6c). The heatmap shows a behaviour similar to CH₄, with higher fluxes recorded only for low waters, (Fig. 6c), independently of the water temperature. The PDF in Fig. 6d confirms that low fluxes of CO₂ (i.e. 330 1-100 g/m²/day) are observed in both shallow and deep waters while higher fluxes (i.e. 100-1300 g/m²/day) are observed only when the water column height is less than 50 cm deep. However, differently from the analysis performed on CH₄ measurements, the Mann-Whitney test shows a non-significant difference for the two water height classes > 50 cm and < 50 cm of water depth for CO₂ emissions (*p*=0.82 for CO₂) (Fig. S12 Supplement).

When the influence of salinity and sulphates is considered, both heatmaps in Fig. 7a and Fig. 7b show that higher CH₄ 335 emissions are concentrated in the low-left portion of the graphs, i.e. at water heights smaller than 50 cm and low EC and sulphate concentrations, and this happens for both EC and sulphates even though it is more pronounced for sulphate than for EC. When the water level is higher than 50 cm, CH₄ emissions are small, whatever EC and SO₄²⁻ concentrations were measured. We notice that there are no data available for the case low water-high EC or for low water-high sulphates, we speculate because our study sites do not include shallow salted wetlands.

340 If we compare Fig. 6a, 6b, 7a and 7b we notice that independently of T, EC and SO₄²⁻, emissions of CH₄ are low for water height larger than 50 cm.

Similar results are obtained for CO₂ fluxes. Fig. 7c, d show that high CO₂ emissions are only recorded when the water height is lower than 50 cm, while in deeper waters the CO₂ emissions are always small, independently from EC and sulphate 345 concentrations. In line with the results shown for CH₄ fluxes, also in the case of CO₂ we confirm that high values of T, EC and SO₄²⁻ do not influence CO₂ emissions (Fig. 6c, 6d, 7c and 7d), that remain small when the water height exceeds 50 cm. As already stated, no data were available for low salted waters.

350 **Fig. 7- Heat maps comparing the CH₄ fluxes distribution depending on water column height and EC values (a) and SO₄²⁻ concentrations (b). Heat maps comparing the CO₂ fluxes distribution depending on water column height and EC values (c) and SO₄²⁻ concentrations (d).**

4. Discussion

This study explores how the spatial and temporal variability of environmental drivers such as water and air T, salinity, irradiance and inundation levels, influence CH₄ and CO₂ emissions in four adjacent coastal wetlands.

355 In general, when all data collected on flooded areas as well as on wet soils were considered, lower fluxes of CH₄ were observed in meso/polyhaline environments (PIR and CAV), compared to what was observed in freshwater sites (PA and CE) (Tab.1). PIR and CAV are the richest in SO₄²⁻ (Fig. 1), an ion that can be used by sulphate-reducing bacteria as a terminal electron acceptor during anaerobic decomposition (Hackney and Avery, 2015; Zhou et al., 2022). In contrast to

methanogenesis, the sulphate reduction process is naturally favoured since sulphate reducer bacteria compete more efficiently for available substrates, like acetate and hydrogen, than methanogenic bacteria (Lovley and Klug, 1986).

360 Our results confirm the strong inhibiting function of EC and sulphates. In fact, CH₄ emissions are found to be negatively correlated to EC and SO₄²⁻ (Fig. S7 Supplement), which is consistent with the existing literature on coastal wetlands (Hines, 1996; Poffenbarger et al., 2011; Chen et al., 2018)..

On average from PCA results, it is possible to observe two groups of environmental controls: i) one aggregated component related to seasonality, grouping air and water T and irradiance, with a strong positive control on GHGs emissions; ii) one
365 related to the hydrological aspect of the wetlands represented by EC, SO₄²⁻ and water column height with a significative negative impact on GHGs production.

CH₄ emissions show a seasonal pattern and generally are higher in the warmer season (Emery and Fulweiler, 2014; Al-Haj and Fulweiler, 2020), as shown in Fig. 2 with the highest values recorded in summer (Tab.2). In general, CH₄ and CO₂ emissions are positively correlated with air and water temperature, and irradiance. Temperature affects directly CH₄ production
370 stimulating methanogenic kinetics (Zinder and Koch, 1984) (Fig. 3a). In fact, methanogens bacteria are reported to be generally mesophilic, with a growth temperature between 30° and 40° (Zinder, 1993).

CO₂ fluxes are also correlated to temperature and irradiance (Fig.S8 Supplement), highlighting a seasonal pattern with higher fluxes in the Spring-Summer season. It is known that CO₂ fluxes mainly come from soil respiration, including roots and microbial activity (Rustad et al., 2000). Additionally, methanotrophs in the soil surface layer may be able to oxidize part of
375 the CH₄ and aerobic microbes can use more O₂ to oxidize organic matter. This condition is observed in CE (Tab. 2), which accounts for the overall highest mean fluxes of CO₂ during spring and summer.

CO₂ and CH₄ emissions are also linked to vegetation composition and organic matter presence. In our case, the second highest mean fluxes of CO₂ are measured at PIR (Tab. 2). This can be mainly related to the high presence in this area of *Phragmites australis*, which is reported to be particularly effective in transporting gas through its structures, from the submerged soil to
380 the atmosphere (Martin and Moseman-Valtierra, 2015). Moreover, the high presence of *Phragmites* has the potential of increasing C turnover rates providing an higher rates of primary production that may be offset by enhanced rates of plant litter decomposition (Duke et al., 2015). Anyway, this could also explain the high percentage of %SOM measured at the PIR site (Tab. 1).

When we concentrate on flooded areas examining only fluxes collected over standing waters, we observe some important
385 differences. Even though the principal components are pretty much in line with those determined for the entire dataset (Fig. 4 and 5), we find a strong influence of water depth on CH₄ and CO₂ emissions. Fig. 6 and 7 show that there is a water column height threshold that separates low from high emissions. It is known that CH₄ emission from wetlands depends, in part, on the balance between methanogenesis and CH₄ oxidation. Methanogenesis occurs in the submerged, anoxic soil layers, and so it depends on the vertical extension of the saturated zone determined by the water table level. When the level of the
390 water table increases reaching the soil surface, creating anaerobic conditions favouring methanogenesis, which is a strict anaerobic process (Mander et al., 2011; Calabrese et al., 2021).. After being produced, CH₄ can be transported vertically or horizontally. The nature of the transport pathway (length, direction, presence of methanotrophs) determines the potential for CH₄ to be oxidized or, on the contrary, released as it is in the atmosphere (Dean et al., 2018). The constant presence of a deep water column on top of sediments creates the temporal and spatial condition for methanotrophs bacteria to consume
395 CH₄ in the water column (Henneberger et al., 2015; Sawakuchi et al., 2016), resulting in decreasing rate of CH₄ fluxes, as shown in Fig. 6. This agrees with the case of PA (Tab. 2) where the lower CH₄ fluxes compared to those in CE could be linked to a deep and permanent water column that may act as a physical barrier to CH₄ diffusion (Cheng et al., 2007).. The ensemble of these processes creates a critical zone where availability of methanogenic substrates, anoxic portions of soil, and gas

transport compete in creating either a favourable or unfavourable environment for CH₄ emissions (Calabrese et al., 2021). A
400 further increase in the water column level, however, is more likely to decrease CH₄ production limiting plant growth and
available substrate for decomposition (Calabrese et al., 2021)

Even though these processes are well known, in the literature it is not clear if the CH₄ emissions steadily increase with
decreasing the water depth or if, on the contrary, there is a threshold in water column height that separates emitting
condition from no-emission condition. For the first time regarding temperate coastal wetlands, our results suggest that there
405 is a critical threshold of water height, which, in our case, corresponds to about 50 cm below which wetlands release large
quantities of CH₄ to the atmosphere. Fig. 6a and 6b show that high CH₄ emissions are recorded only where the water height
is lower than this threshold as further confirmed by the Mann-Whitney test performed on shallow and deep waters (Fig. S11
Supplement). This process explains, for instance, also the differences in observed emissions between CA and PA where in
CA, CH₄ emission are 8 times higher than those measured in PA (Tab.2). These two sites have comparable salinity and
410 temperature but differ greatly in their inundation levels (54 cm in PA and 18 cm in CE).

As for the case of CO₂ emissions, the behaviour is similar to CH₄, however the Mann-Whitney Test suggests that there is no
significant difference between CO₂ emissions in waters higher and lower than 50 cm (Fig. S12 Supplement). Bacteria
responsible for CH₄ oxidation are less limited by exposure to anoxic condition than methanogenic bacteria to oxic (Roslev
and King, 1996), so CO₂ fluxes can be expected at low as well as at high water levels. Moreover, CO₂ emissions in seawater
415 have been shown to be higher than in freshwater for the increased availability of SO₄²⁻ to serve as a terminal electron
acceptor in anaerobic microbial respiration (Zhao et al., 2020). Finally, there is a relation between oxidation mechanisms
and CH₄ fluxes depending on the efficiency of the gas transport within the ecosystem (Torres-Alvarado et al., 2005). This
means that diffusion of CH₄ in shallow waters avoids significant oxidation by oxidizing bacteria, hence CO₂ fluxes are higher
in high waters. The combinations of all these processes may explain why we do not observe significant differences between
420 CO₂ emissions in waters deeper and shallower than 50 cm as we instead do for CH₄ emissions.

Concluding, our results suggest that above a certain threshold, the water depth is the main limiting factor of GHG emissions,
and that at our study sites such threshold is 50 cm. When water is higher than the threshold, the emission of CH₄ and CO₂ is
very limited, regardless the temperature being high or low (Fig. 5), but also independently of EC and sulphate concentrations
425 (Fig. 7). High CH₄ emissions are observed only in shallow waters with small EC and sulphate concentrations (Fig. 7).

The results presented in this study are of relevance for the water management of this and other wetland areas that are
controlled and managed by authorities. Knowing that the water depth should never be lower than 50 cm in order to minimize
GHG emissions is crucial information for proper management of the area, especially for the overall well-being of the
ecosystem. The water recharge of this area is influenced by meteorological conditions (precipitation and evapotranspiration),
430 vegetation, and external sources (recharge and discharge from and to external water bodies), as well as artificial recharging
(Antonellini et al., 2008).

5. Conclusions

This study aims to identify the driving and limiting environmental factors for CH₄ and CO₂ production in temperate coastal
wetlands with varying water salinity. It shows, for the first time, that CH₄ and CO₂ emissions in the Po River Delta Natural
435 Park exhibit strong variations within a few kilometres and during different periods of the year, indicating a strong dependence
on seasonality and temperature. However, the main finding of our research is that, irrespective of temperature and salinity

conditions, there exists a water level threshold that controls GHG emissions, particularly CH₄ emissions, which are significantly higher when the water column height is less than 50 cm. In fact, high CH₄ emissions were recorded only when the water level was below this threshold, while in deeper water conditions, emissions were minimal, regardless of
440 temperature values, EC, and sulphate concentrations.

For water column heights smaller than 50 cm, we observed other limiting factors. Specifically, we have shown that salinity and sulphate concentrations limit CH₄ emissions, but we could not determine any specific threshold values for these variables.

445 Considering that all the environmental variables investigated in this study are influenced by climate change, such as increasing salinization, temperature, and water levels, we emphasize the importance of carefully studying and managing temperate coastal wetlands. It is essential to understand all the competing processes involved in the C cycle, which is inextricably linked to other elemental cycles, such as sulphur, through microbial processes. Therefore, further studies involving microbial processes are needed.

450 In general, our findings are of relevance for the water management of the area. Given the pressures of climate change on these coastal environments, understanding the dynamic of CH₄ and CO₂ production is critically important to define specific management strategies to lower wetlands emissions. This is necessary to meet climate targets, such as the 2030 Agenda for Sustainable Development and with the objectives of the Paris Agreement on Climate Change (European Commission, 2020; Salimi et al., 2021).

Acknowledgement

455 The authors thank Mr. Mauro Altizio and Mr. Marco Assiri for the invaluable help during fieldwork, Prof. Enrico Dinelli and the BiGeA Department for providing the instrumentation. This study was performed with the support of the Ravenna municipality (Italy) that granted access to the reserve and the support of the Office for Biodiversity Protection of Punta Marina (Carabinieri Forestali).

460 Author contribution

EC, BMSG and SS conceptualized the research and carried out the field sampling campaign for data collection. All authors (EC, BMSG, DZ, SS, MA) participated into the methodology development and supplied the necessities resources for the research. BMSG, SS, MA supervised the research. EC performed the formal analysis. EC, BMSG and SS interpreted and validated the results. EC prepared the original draft and the visualization content, while all authors (EC, BMSG, DZ, SS, MA)
465 participated in the revision and editing process.

Competing interests

The authors declare that they have no conflict of interest.
