Abstract. This study investigates the use of a balloon-launched Uncrewed Aircraft System (UAS) for the measurement of turbulence in the troposphere and lower stratosphere. The UAS was a glider which could conduct an automated descent following a designated flight trajectory and was equipped with in-situ sensors for measuring thermodynamic and kinematic atmospheric properties. In addition, this aircraft was equipped with an infrasonic microphone to assess its suitability for the remote detection of clear-air turbulence. The capabilities of the UAS and sensing systems were tested during three flights conducted in 2021 in New Mexico, U.S.A.. It was found that the profiles of temperature, humidity and horizontal winds measured during descent were in broad agreement with those made by radiosonde data published by the U.S. National Weather Service, separated by up to 380 km spatially and by 3 to 5 hours temporally. Winds measured during controlled flight descent were consistent with the winds measured by global-positioning-system-derived velocity during balloon ascent. During controlled descent with this particular payload, a nominal vertical resolution on the order of 1 m during was achieved for temperature, relative humidity and pressure with a nominal vertical resolution of wind velocity vector on the order of 0.1 m, with the aircraft having a glide slope angle from 1° to 4°. Analysis approaches were developed that provided turbulent kinetic energy and dissipation rate, but it was found that the corresponding Richardson number was sensitive to the methodology used to determine the vertical gradients from a single flight. The low-frequency content of the infrasonic microphone signal was observed to qualitatively align with long-wavelength wind velocity fluctuations detected at high altitude. Moreover, the microphone measured more broadband frequency content when the aircraft approached turbulence produced by the boundary layer.

1 Introduction

By enhancing the exchange of mass, momentum, and energy, the formation and evolution of atmospheric turbulence provides a significant contribution to weather and climate. As atmospheric turbulence is expected to increase in frequency and intensity

in response to climate change (e.g. Williams and Joshi, 2013), increased understanding of its role in atmospheric dynamics is needed. The presence of atmospheric turbulence, particularly clear air turbulence, also poses an aviation hazard that is challenging to predict and detect. This latter point is particularly true for high-altitude autonomous flight, a regime which is being increasingly pursued in the form of High-Altitude Pseudo-Satellite aircraft intended to provide communication and remote observation capabilities at relatively low cost (Gonzalo et al., 2018; D'Oliveira et al., 2016; Hasan et al., 2022). By the nature of the low density conditions under which these aircraft are designed to operate, they tend to be lightweight with narrow performance envelopes for which controlled flight can be maintained, making them susceptible to atmospheric disturbances. Hence, there is motivation to improve our ability to measure and predict stratospheric and upper-tropospheric turbulence, which can occur due to shear instabilities or gravity wave breaking despite the higher static stability at these altitudes. Turbulence in the upper troposphere may also be introduced through mesoscale convective systems (Liu et al., 2014), mountain waves (Cunningham and Keyser, 2015) and wind shear (e.g. as introduced by the jet stream).

Although the turbulence intensity is commonly quantified through the turbulent kinetic energy per unit mass

$$k = \frac{1}{2} \overline{u'_i u'_i}, \quad (1)$$

atmospheric turbulence is often also characterized through the related turbulent kinetic energy dissipation rate, formally defined as

$$\varepsilon = \frac{1}{2} \nu \overline{\left(\frac{\partial u'_i}{\partial x_j} + \frac{\partial u'_j}{\partial x_i} \right) \left(\frac{\partial u'_i}{\partial x_j} + \frac{\partial u'_j}{\partial x_i} \right)}. \quad (2)$$

Here, summation notation has been used with the index indicating the wind velocity components, u_i , and direction components x_i . Furthermore, ν indicates the kinematic viscosity, and $u'_i = u_i - \overline{u_i}$ indicates the unsteady contribution to the velocity component, with the overline denoting an average value.

The presence of turbulence is often related to the local gradient Richardson number

$$Ri = \frac{\frac{g}{\theta_v} \frac{\partial \overline{\theta_v}}{\partial x_3}}{\left(\frac{\partial \overline{u_1}}{\partial x_3} \right)^2 + \left(\frac{\partial \overline{u_2}}{\partial x_3} \right)^2} \quad (3)$$

where g is the gravitational acceleration,

$$\theta_v = T \left(\frac{100000}{P} \right)^{0.2861} (1 + 0.61q) \quad (4)$$

is the virtual potential temperature, u_1 and u_2 are the horizontal components of the wind velocity vector, x_3 is the spatial component aligned in the direction opposing g , q is the water vapor mixing ratio, T is the temperature in Kelvin and P is the

pressure in Pascals. The static stability is quantified through the square Brunt-Väisälä frequency,

$$N^2 = \frac{g}{\theta_v} \frac{\partial \overline{\theta}_v}{\partial x_3} \quad (5)$$

and the square shear frequency provides a measure of potential for turbulence production due to mean velocity shear

$$S^2 = \left(\frac{\partial \overline{u}_1}{\partial x_3} \right)^2 + \left(\frac{\partial \overline{u}_2}{\partial x_3} \right)^2. \quad (6)$$

50 Hence, $Ri = N^2/S^2$, can also be used to attribute the source of turbulence as being from convective or shear instabilities (Söder et al., 2021; Sharman et al., 2014; Kim et al., 2020), and introduces the potential to model the relationship between turbulence in the stratosphere and tropospheric activity (Chunchuzov et al., 2021). A critical Richardson number of $Ri = 0.25$ (below which turbulence is likely) has been empirically identified, although a range of critical values $0.25 < Ri < 1$ have also been proposed (Abarbanel et al., 1984; Galperin et al., 2007).

55 When considering stratospheric turbulence measurements, most experiments have been conducted using balloon-borne instruments (e.g. Wescott et al., 1964; Ehrenberger, 1992; Haack et al., 2014; Alisse et al., 2000; Gavrilov et al., 2005) with some of the earliest of these experiments conducted in the 1960s (Enlich and Mancuso, 1968). Among the most relevant conclusions from these studies is that stratospheric turbulence tends to form in relatively thin atmospheric layers due to intrinsic static stability at these altitudes. In many cases, meteorological balloon soundings rely on indirect measures of turbulence, for example
60 through application of the analysis proposed by Thorpe and Deacon (1977) which analyzes temperature profiles to infer ε and the Thorpe length scale (e.g. Clayson and Kantha, 2008).

One series of balloon-borne experiments investigating stratospheric turbulence using direct measures was the Leibniz-Institute Turbulence Observations in the Stratosphere (LITOS) experiments. The experiments, conducted by LITOS (Haack et al., 2014), were conducted using balloons equipped with a thermal anemometer to measure velocity and temperature fluctuations at high frequency. The resulting measurements were within sub-centimeter resolution, and therefore suitable for resolving
65 the finer scales of turbulence. This experiment reached altitudes up to 30 km, and when ε was compared to both Ri and N^2 , an increase in ε with altitude was observed with clear correlation between turbulent events and $Ri < 0.25$ (Haack et al., 2014). However, in some instances turbulent events were also observed when $Ri > 0.25$ although other studies attribute such behavior to the specifics of the Ri calculation (Galperin et al., 2007; Haack et al., 2014) and later studies suggest that the measurements
70 may have been contaminated by the balloon wake (Söder et al., 2019).

Remote sensing techniques have also been deployed for turbulence studies, for example through the use of radar to measure the turbulent kinetic energy dissipation rate (Bertin et al., 1997; Fukao et al., 1994; Sato and Woodman, 1982; Barat and Bertin, 1984). Early studies found radar-determined dissipation rates were often underestimated due to the low vertical resolution. However, very-high-frequency and ultra-high-frequency radar measurements have presented a better prospect to resolve thin
75 layers of clear air turbulence (Barat and Bertin, 1984). For example, an altitude resolution of 150 m was able to detect the thin layers of turbulence in the lower stratosphere (Sato and Woodman, 1982).

Crewed aircraft measurements have also been utilized to measure high altitude turbulence (e.g. Nastrom and Gage, 1985). Currently, routine measurements of atmospheric turbulence are conducted for operational forecasting through Aircraft Meteorological Data Relay (AMDAR) reports generated by in-situ measurement systems on commercial aircraft using a turbulence
80 detection algorithm developed by Sharman et al. (2014). These systems generally report the turbulence intensity in the form of eddy dissipation rate (EDR), defined as

$$EDR = \epsilon^{1/3}, \tag{7}$$

which is currently used as a standard for turbulence reporting by the International Civil Aviation Organization. In the AMDAR EDR calculation, a fully-formed von Kármán inertial subrange is assumed, and the EDR is determined from either vertical-
85 wind measurements, or the aircraft's gust response measured through acceleration.

Recently, it has become increasingly common to use uncrewed aircraft, or uncrewed aerial systems (UAS), equipped with in-situ sensors (e.g. hot-wire anemometers, sonic anemometers, hot-film probes, pitot tubes, or multi-hole pressure probes) for studies of turbulence in the atmospheric boundary layer and troposphere (e.g. Egger et al., 2002; Hobbs et al., 2002; Balsley et al., 2013; Witte et al., 2017; Rautenberg et al., 2018; Bärffuss et al., 2018; Jacob et al., 2018; Bailey et al., 2019; Al-Ghussain
90 and Bailey, 2022; Lawrence and Balsley, 2013; Balsley et al., 2018; Reuder et al., 2012; Calmer et al., 2018; Luce et al., 2020; Kantha et al., 2017). Many of the UAS used for turbulence studies employ multi-hole probes, which measure the dynamic pressure of the air, with multiple pressure ports combined with a directional calibration used to determine the wind vector components relative to the probe axis. Due to their fragility, hot-wire probes, which measure the convective heat transfer across a very thin heated filament, are usually reserved for short-term scientific studies although they are standard instruments on
95 some UAS (e.g. Hamilton et al., 2022). The fast response of the hot-wire anemometer allows detailed characterization of the turbulence, for example by allowing the measurement of small-scale fluctuations.

One measurement approach with potential for remotely detecting atmospheric turbulence is through infrasound detection, which involves capturing acoustic frequencies below 20 Hz (Shams et al., 2013). This typically requires specialized micro-
100 phones designed for the infrasonic frequency range. Turbulent pressure fluctuations can generate sound waves that, for long-wavelength atmospheric turbulence, propagate as aerodynamic noise at low frequencies. One advantage of using infrasound for remote turbulence detection is its ability to propagate over long distances due to increased acoustic propagation at low frequencies and low kinematic viscosity (Whitaker and Norris, 2008), allowing infrasonic aerodynamic noise to travel through the atmosphere over distances ranging from a few hundred to a few thousand kilometers (Posmentier, 1974). Consequently, infrasonic microphones are being investigated for severe storm detection as well (e.g., Bowman and Bedard, 1971; Elbing et al.,
105 2019; Wilson et al., 2023). Although techniques for quantitatively measuring turbulent properties using infrasound is not yet devised, an array of ground-based microphones was able to detect clear air turbulence at distances up to 360 km (Shams et al., 2013). Within the atmospheric boundary layer, infrasound energy measured in the frequency range spanning from 0.01 Hz to 15 Hz was found to correspond to coincidentally measured boundary layer turbulent kinetic energy, particularly in cases well

110 mixed turbulence such occurs with buoyantly-forced convective turbulence or in the presence of elevated jets (Cuxart et al., 2015).

Infrasound detection therefore holds potential for detecting clear air turbulence on airborne platforms, potentially providing a means to avoid hazardous conditions. As far as we know, these sensors have not yet been tested on UAS for this purpose. However, early studies using balloon-borne infrasonic sensors were able to detect a signal consistent with boundary layer turbulence (Wescott, 1964). Balloon-borne infrasonic microphones are also being investigated for various Earth-sensing applications. For instance, sensitive infrasonic microphones have shown promise in detecting acoustic low-frequency microbaroms (Bowman and Lees, 2015).

Here, we present measurements from a balloon-launched stratospheric glider UAS intended for turbulence measurement. Alongside in-situ sensors aimed at quantifying turbulence encountered by the aircraft, a novel infrasonic microphone was also installed to assess its capability in detecting airborne acoustic signatures of turbulence. This configuration was tested in a series of three high-altitude flight tests with the aircraft carried by balloon from 25 km up to 30 km above sea level. After reaching these altitudes, it was released from the balloon and conducted autonomous flight to a designated measurement location, thereafter following a pre-programmed helical flight path to a designated landing location. During its descent, the aircraft's glide slope was 1° to 4° , which allowed it to measure over a distance of up to 50 m horizontally for a 1 m change of altitude, while maintaining a relatively constant location over the surface. One drawback of this approach is that the current regulatory environment means deploying this type of UAS within a national airspace system requires permission from the corresponding regulatory body, requiring additional measures to ensure deconfliction with crewed aircraft. Here, the flights were conducted in the restricted airspace above Spaceport America, New Mexico U.S.A., coordinating with the adjacent White Sands Missile Range and utilizing airspace closed to crewed aircraft. However, this approach to deconfliction restricts the geographical location at which such measurements can be taken.

130 The remainder of this manuscript is divided into three main sections: Section 2 describes the aircraft and measurement systems, along with information about the flight location and flight path; Section 3 describes the approaches which were used to extract turbulence statistics from the data acquired during the flights; with Section 4 summarizing the main findings from this study.

2 Experiment Description

135 2.1 Aircraft

Key to this research was the use of the host UAS platform, the HiDRON H2 (see Fig. 1), operated by Stratodynamics Inc. The HiDRON H2 is a balloon-launched carbon-fiber/fiberglass glider UAS that is capable of autonomous and soaring flight modes. It has a wingspan of 3.8 m and its nominal flight weight is approximately 5.7 kg with the payload. To achieve initial altitudes in excess of 30 km, the HiDRON H2 is launched using latex sounding balloons. Different sizes of balloons were used in this study with 2000 g, 1200 g and 3000 g balloons employed for each of three flights, referred to as Flights 1, 2 and 3, respectively. After release, the aircraft is controlled by a UAVOS Inc. autopilot to follow a pre-programmed descent pattern

Figure 1. Images of HiDRON H2 showing: (a) close up of aircraft nose showing five-hole probe and temperature and humidity sensor location; (b) aircraft during launch; and (c) aircraft during landing.

towards a designated landing point. An operator can track the HiDRON H2 position from launch to landing and changes to the flight plan can be made in real time through radio telemetry, which also allows operational parameters to be transmitted to the ground at distances up to 100 km. Full telemetry information was produced at 10 Hz by the autopilot for all three flights, including location, ground speed, 6 degree-of-freedom orientation information as well as pressure, temperature and humidity information from an integrated sensing system. This 10 Hz sample rate telemetry was intrinsic to the radio modem used for the command-and-control link and telemetry. The specific rate was selected for maximum efficiency in the transmission and recording of data packets and to maintain reliability of the radio communication and corresponding command-and-control link.

Other safety features include a parachute, dual-redundant balloon release system and geofencing safety protocols that prevent the aircraft from leaving the designated airspace. During prior flights, including flights exceeding altitudes of 30 km, the HiDRON H2 has shown reliability in remaining controllable in high-wind (as high as 32 m s^{-1}), operating in low-temperature conditions ($< -60^\circ\text{C}$), and in returning to a predefined landing site. For the flights reported here, the winds were less than 25 m s^{-1} and the minimum temperature was -65°C .

For all flights, the autopilot was set to maintain the aircraft's kinetic energy (reflected through the indicated airspeed), with the value selected near the optimal lift-to-drag ratio (the maximum distance that can be travelled per loss in altitude). To maintain the set airspeed the autopilot adjusts the pitch angle on the elevator to control the angle of attack of the main wing airfoil. The velocity of the aircraft relative to the air, V_R , may therefore fluctuate slightly due to the pitch angle adjustments.

Also, as the aircraft descends in altitude the air density increases and the HiDRON H2's aerodynamic performance improves; thus, \mathbf{V}_R gradually decreased as the aircraft descended. Figure 2 shows the magnitude of horizontal ground speed, $|\mathbf{V}_G|$, descent speed, V_D , relative to the ground, as well as the magnitude of the aircraft's velocity relative to the air, $|\mathbf{V}_R|$, for the helical descent portion of each of the three flights as a function of the altitude above sea level (a.s.l.). The horizontal velocities are related through $\mathbf{V}_R = (V_{G_x} - u)\mathbf{e}_1 + (V_{G_y} - v)\mathbf{e}_2 - (V_D e + w)\mathbf{e}_3$ where $\mathbf{V}_G = V_{G_x}\mathbf{e}_1 + V_{G_y}\mathbf{e}_2$ is the horizontal velocity of the aircraft relative to the ground in the Earth-fixed, inertial frame of reference with \mathbf{e}_1 , \mathbf{e}_2 , \mathbf{e}_3 the basis vectors aligned to the East, North, and up, respectively. The vector $\mathbf{U} = u\mathbf{e}_1 + v\mathbf{e}_2 + w\mathbf{e}_3$ is the wind vector and $-V_D\mathbf{e}_3$ the aircraft's descent speed in the inertial frame. The method used to obtain the wind velocity vector is provided in Section 2.2.

Figure 2. Horizontal ground speed in inertial Earth-fixed coordinates, $|\mathbf{V}_G|$, magnitude of the descent speed in inertial Earth-fixed coordinates, V_D , and relative air velocity magnitude in aircraft-fixed coordinates, $|\mathbf{V}_R|$, for (a) Flight 1, (b) Flight 2 and (c) Flight 3.

As noted above, to measure atmospheric conditions, the aircraft was equipped with an integrated InterMet Systems iMet-XF atmospheric sensing system having fast-response bead thermistor to measure air temperature, T , and a capacitive relative humidity, RH , sensor. The manufacturer-provided specifications (International Met Systems) state the pressure sensor provided a ± 1.5 hPa accuracy for pressure, P , with humidity sensor supporting a full 0 - 100 %RH range at ± 5 %RH accuracy with a resolution of 0.7 %RH. The temperature sensor provided a $\pm 0.3^\circ\text{C}$ accuracy with a resolution of 0.01°C up to a maximum of 50°C . The stated response times of these sensors are on the order of 10 ms for pressure, 5 s for humidity and 2 s for temperature in still air, with the autopilot sampling these sensors at 10 Hz. The pressure and temperature sensors were mounted with the

sensing elements exposed to the airflow upstream of the wing support (see Fig. 1a) to ensure aspiration of the sensors during forward flight.

175 2.2 Payload

The turbulence-measuring payload was a combination of four components: (1) a five-hole probe; (2) an infrasonic microphone; (3) a data acquisition board; and (4) an embedded computer. These components were installed in the nose of the HiDRON H2, which could be accessed via removal of the nose cone, as shown in Fig. 3c.

Figure 3. (a) Five-hole probe, (b) infrasonic microphone, and (c) nose payload bay open between flights, with embedded computer shown removed for data retrieval. Infrasonic microphone is below embedded computer but was installed in aircraft nose facing forward during flight.

2.2.1 Five-Hole Probe:

180 Wind speed and direction relative to the aircraft were measured using a bespoke five-hole probe mounted such that the probe projected upstream of the nose of the aircraft, as shown in Fig. 1. The probe, detailed in Fig. 3a, is similar to that used in Bailey et al. (2019, 2020); Al-Ghussain and Bailey (2022) and was manufactured from a carbon-fiber tube equipped with a beveled aluminum tip. The tip of the probe was arranged with one center hole normal to the probe axis surrounded by four other holes arranged symmetrically around it having their plane normal vector aligned 20° to the probe axis. For this measurement, the pressure difference between the central hole (measuring total stagnation pressure) and a series of additional holes arranged on the carbon fiber tube (measuring static pressure) were used to determine the approximate dynamic pressure at the probe tip.

185 The pressure measured by this hole combination differs from the true dynamic pressure, Q , depending on the alignment of the wind vector with the probe axis. The two horizontally-opposed circumferential holes are arranged to produce a pressure difference which changes with the sideslip angle, β , of the air flow relative to the probe axis. Similarly, the two vertically-

190 opposed circumferential holes were arranged to produce a pressure difference which changes with the angle of attack, α , of the air flow relative to the probe axis. Thus, Q , α and β can be determined by measuring the pressure differences across the different holes arranged on the probe.

Prior to installation on the HiDRON H2, the probe was calibrated in a wind tunnel to determine its directional response using an apparatus designed to pitch and yaw the probe at α and β angles up to 25° relative to the mean wind vector. Based off

195 of established procedures, e.g. as outlined by Bohn and Simon (1975); Treaster and Yocum (1978); van den Kroonenberg et al. (2008) and Wildmann et al. (2014), and utilizing an implementation approach very similar to that used by Witte et al. (2017), the pressure differences at each α and β angle combination experienced during directional response calibration were used to build pressure coefficients

$$C_{\beta}(\alpha, \beta) = \frac{\Delta P_{32}}{\Delta P_1 + 0.5(\Delta P_{32} + \Delta P_{54})} \quad (8a)$$

200

$$C_{\alpha}(\alpha, \beta) = \frac{\Delta P_{54}}{\Delta P_1 + 0.5(\Delta P_{32} + \Delta P_{54})} \quad (8b)$$

$$C_q(\alpha, \beta) = \frac{\Delta P_1 - Q}{\Delta P_1 + 0.5(\Delta P_{32} + \Delta P_{54})} \quad (8c)$$

where ΔP_1 is the pressure difference between the central hole and the static pressure, ΔP_{32} is the pressure difference across
 205 the horizontal probe holes, ΔP_{54} is the pressure difference across the vertical probe holes and Q is the dynamic pressure. The probe design resulted in unique combinations of C_{β} , C_{α} and C_q for each α and β angle of the probe to the relative air velocity vector. These relationships are stored in tables following the wind tunnel calibration.

To calculate the relative wind velocity vector measured during flight, C_{α} and C_{β} were calculated for every sample point from the measured ΔP_1 , ΔP_{32} and ΔP_{54} . Using the calibration tables, the values of α and β which produces that combination of
 210 C_{α} and C_{β} could be identified. A similar process was used to identify the corresponding value of C_q measured at that C_{α} and C_{β} combination, which allowed Q to be determined. The result is knowledge of the magnitude and direction of the dynamic pressure vector relative to the probe axis for every sampled combination of ΔP_1 , ΔP_{32} and ΔP_{54} . The dynamic pressure was then converted to velocity using the density determined from iMet-XF measurements of the ambient pressure, temperature and humidity.

215 The probe used on these flights was also heated to prevent ice formation within the probe during flight. This was accomplished by wrapping the probe body in nickel-chromium resistance wire. A feedback circuit, using a thermistor attached to the probe tip, passed current through the wire at a rate sufficient to maintain the probe tip temperature at 50°C. By repeating the wind tunnel directional response calibrations with and without heating active, it was determined that there was no influence of probe heating on ΔP_1 , ΔP_{32} and ΔP_{54} , or their dependence on α and β . These calibration checks were also conducted
 220 both at 20 m s⁻¹, which replicated the expected flight dynamic pressure of $Q \approx 200$ Pa, and at 5 m s⁻¹ to check for any Reynolds-number dependence of C_{β} , C_{α} and C_q . No evidence of Reynolds number was dependence found.

To measure ΔP_1 , ΔP_{32} and ΔP_{54} , the probe was connected to differential pressure transducers through 50 cm of 1.75 mm diameter flexible polymer tubing, specifically Tygon polyvinyl chloride tubing. To ensure that the low-density conditions at flight altitude did not result in pressure differences below the sensitivity of an individual transducer, the measured pressure

225 difference was converted to analog voltage using two different sets of transducers by teeing the tubing to each transducer set, i.e. a low and high sensitivity transducer was used for each pressure difference ΔP_1 , ΔP_{32} and ΔP_{54} . The low-sensitivity transducer set was comprised of TE Connected Measurements 4515-DS5A002DP differential pressure transducers with a 500 Pa range. The second transducer set was comprised of Allsensors DS-0368 differential pressure transducers with a 65 Pa range. Both sets of analog output voltages were linearly scaled relative to the maximum transducer range with a nominal span of 4.5V and 4.0V respectively. During flight, the autopilot maintained flight speeds sufficient to produce pressure differences well within the range of the low-sensitivity transducers (i.e. the dynamic pressure was maintained between 100 Pa and 200 Pa) which exceeded the range of the high sensitivity transducer connected to ΔP_1 . Hence, only the readings from the low-sensitivity sensors were used for data analysis. However, the high sensitivity ΔP_{32} and ΔP_{54} transducers provided a means to estimate the uncertainty of the pressure measurement by comparison with their low-sensitivity counterparts, as will be described later.

235 To convert the air velocity vector components relative to the probe axis into a frame of reference relative to the ground, an additional coordinate transformation was conducted using the aircraft's pitch, yaw, and roll angles as measured by the autopilot. Details of this process are provided in Witte et al. (2017) and are based off of procedures described in Lenschow (1972) for measurements using similar probes mounted on crewed aircraft. This process assumes that the coordinate system of the probe during wind tunnel calibration is perfectly aligned with the body-frame coordinate system of the autopilot, which is difficult to achieve in practice. Therefore, an additional procedure was used to correct for any misalignment of the probe axis and aircraft's body-frame axis. This approach, described in Al-Ghussain and Bailey (2021), also corrects for airframe influence on the measured Q , and time misalignment between the probe's pressure sensors and the aircraft's kinematic sensors.

As the autopilot and payload data acquisition systems were acquired asynchronously, alignment of autopilot kinematic data and five-hole-probe pressure data in time was conducted during post-processing by cross-correlating the dynamic pressure measured by the aircraft's intrinsic pitot probe (recorded by the autopilot along with the aircraft position and orientation information) and ΔP_1 of the five-hole probe recorded by the payload data acquisition system. The time lag between the two systems was then removed before performing the transformation of the velocity vector in the aircraft body frame to the Earth-fixed frame of reference. To do so, the aircraft position and orientation information was up-sampled from the autopilot's 10 Hz sample rate to the 1 kHz sample rate used by the on-board data acquisition system, with the up-sampling conducted using simple linear interpolation.

The result of these procedures is a time-dependent wind velocity vector described using components $u(t)$, $v(t)$, and $w(t)$ which are aligned to the East, to the North, and up, respectively. The time-dependent horizontal wind velocity magnitude and direction could then be found from

$$U(t) = (u(t)^2 + v(t)^2)^{-0.5} \quad (9)$$

255 and

$$\gamma(t) = \text{atan2}(-u(t), -v(t)) \quad (10)$$

where atan2 indicates a numerical implementation of the \tan^{-1} function used to disambiguate the polar direction using the quadrant formed by the sign of the velocity components.

Note also that, although data was acquired at a 1 kHz sample rate to ensure that the infrasonic microphone response was fully resolved, the actual probe frequency response was much lower due to viscous attenuation of the pressure fluctuations within the tubing, coupled with inaccuracies introduced by high-frequency resonance within the transducer cavity (Grimshaw and Taylor, 2016). At ambient conditions, the maximum frequency response of the five-hole-probe was estimated to be on the order of 20 Hz using the same measurement approach utilized in Grimshaw and Taylor (2016) and Witte et al. (2017), which measures the response of the system following a step change in pressure. Similar response tests conducted in an environment chamber at -70°C and 8000 Pa indicated that, consistent with the model presented in Grimshaw and Taylor (2016), both the resonance in the transducer cavity and viscous attenuation can be expected to increase with altitude, resulting in a slightly lower maximum frequency response of 10 Hz.

Figure 4a shows an example of the intrinsic electrical noise observed in the pressure transducer signals. Although this particular excerpt was measured from the low-sensitivity ΔP_1 transducer during the environment test at -70°C and 8000 Pa, similar signals were measured by the other pressure transducers at ambient conditions, during environment testing, and during Flights 1, 2 and 3. The electrical noise was found to be composed of a $\sim \pm 2$ Pa stochastic component combined with a -8 Pa to 0 Pa quasi-periodic component. As similar characteristics were observed for both low- and high-sensitivity transducers, scaling with the range of the transducers, it is hypothesized that this noise is introduced through the common five volt reference signal used to power all pressure transducers. As shown in Fig. 4b, which compares the one-sided autospectral density, $F_{PP}(f)$, calculated from five minutes of the low-sensitivity ΔP_1 transducer time series measured during the environment chamber test at ambient conditions to an equivalent measurement made at -70°C and 8000 Pa, the frequency content of this noise signal was independent of ambient pressure and temperature conditions. Furthermore, Fig. 4c shows the equivalent autospectral density calculated from a quiescent period of the Flight 1 low-sensitivity ΔP_1 time series in red, specifically from a five minute portion of the time series while the aircraft was on the ground prior to launch. This autospectral density shows similar energy content to that measured in the environment chamber was also present during the flight tests. Also shown in Fig. 4c is the frequency content measured during every five minute segment of the ΔP_1 time series during the controlled descent portion of Flight 1. Although the low frequency content of the signal produced $F_{PP}(f)$ values up to four orders of magnitude higher than the intrinsic noise, at frequencies higher than the maximum frequency response of the five-hole-probe (specifically when $f > 100$ Hz), the frequency content of the signal remained independent of ambient conditions.

To minimize any possible impact of this electrical noise on the statistical analysis of the five-hole-probe measurements, during post-processing a background noise subtraction procedure was conducted. This procedure filtered the voltage signals by subtracting the background noise energy content in the frequency domain prior to scaling the voltage to pressure. For this purpose, a 5-minute segment of each pressure transducer signal measured before balloon launch was chosen, specifically when the probe's cover was installed (as depicted in Fig. 1a). This portion of the time series was assumed to be representative of the background electrical noise. The amplitude of its Fourier transform was subtracted from the corresponding Fourier-transformed

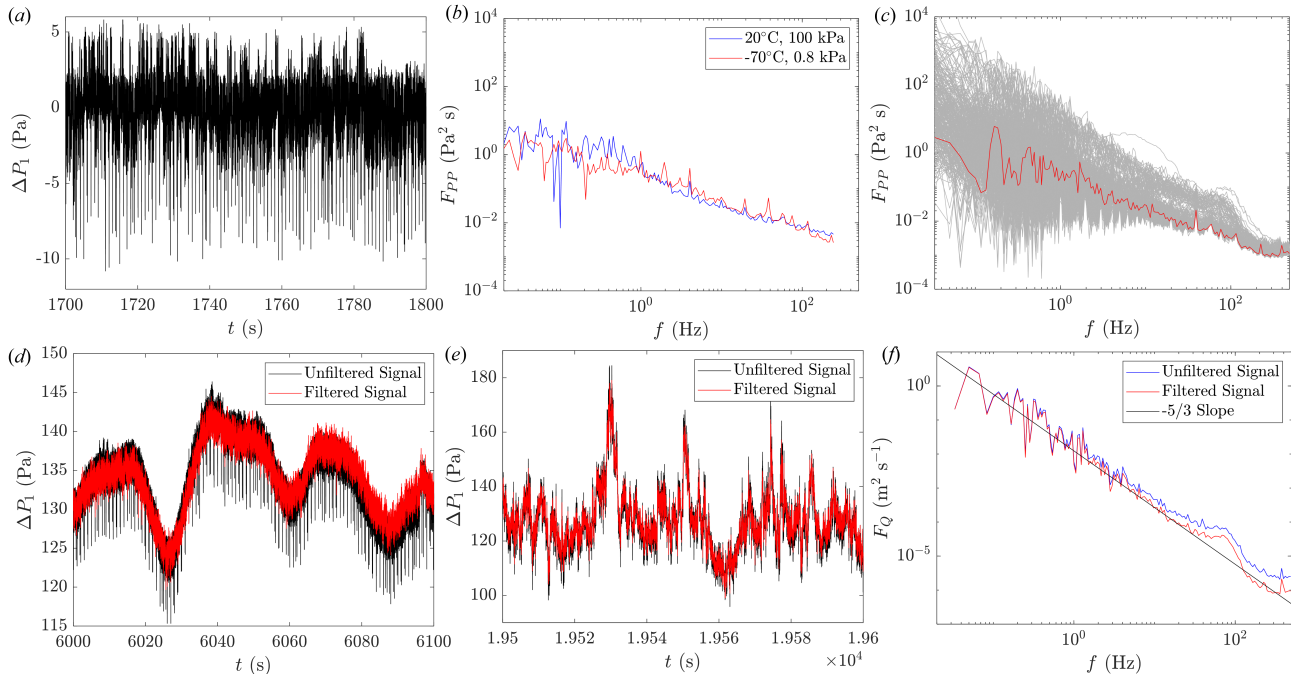

Figure 4. (a) Time-series showing intrinsic electrical noise in pressure transducer signal measured during environment test at -70°C and 8000 Pa, and (b) one-sided autospectral density from same test comparing frequency content in ΔP_1 transducer from five minute periods at ambient conditions and -70°C and 8000 Pa. (c) One-sided autospectral density from ΔP_1 transducer measured during quiescent five minute period before launch, shown in red, compared to one-sided autospectral density calculated from same transducer's time signal for every five minute period during controlled descent of HiDRON H2. Comparison of time series from the ΔP_1 transducer measured before (unfiltered signal) and after (filtered signal) noise removal process (d) during Flight 1 while the HiDRON H2 was in the stratosphere and (e) while the HiDRON H2 was in the atmospheric boundary layer. (f) Comparison of one-sided autospectral density of $(\Delta P_1 \rho^{-1})^{-1/2}$ measured while aircraft is in atmospheric boundary layer with and without noise removal applied. Also shown in (f) is a solid line showing $-5/3$ slope.

voltage signal in five-minute intervals, while preserving the phase information of the original segment. The filtered signal was then returned to the time domain by conducting an inverse Fourier transform.

A 100 s long segment of the original, unfiltered, low-sensitivity ΔP_1 time series is shown in Fig. 4d from a portion of Flight 1 when the HiDRON H2 was within the stratosphere, when the frequency content of the signal was small. Also shown in this figure is the same segment of the time series following the frequency domain filtering described above. The comparison indicates that the filter was successful in removing the quasi-periodic contribution of the noise but, due to its stochastic nature, the low-amplitude ± 2 Pa contribution to the electrical noise remains. A similar comparison is provided in Fig. 4e from a portion of the ΔP_1 time series measured when the HiDRON H2 was within the turbulent boundary layer during Flight 1. This figure illustrates that when in conditions where there is significant frequency content in the signal, this content is preserved during the filtering process. This last point is perhaps better illustrated in Fig. 4f, which shows the one-sided autospectral density, $F_Q(f)$, of the frequency content of $(\Delta P_1 \rho^{-1})^{1/2}$ (which approximately corresponds to the magnitude of the air velocity relative to the probe), measured within the boundary layer during Flight 1 with and without the filter applied. Figure 4f illustrates how the

low frequency ($f < 1$ Hz) content of the measured signal is largely unaffected by the filtering process, with the filter increasing in impact as the energy within the signal decreases at higher frequencies. Also shown in Fig. 4f is how application of the filter increases the agreement of the frequency dependent roll-off of $F_Q(f)$ with the $f^{-5/3}$ dependence expected for inertial subrange turbulence. The broadband peak in $F_Q(f)$ evident at $f \approx 100$ Hz is attributed to resonance within the transducer cavity.

Finally, it should be noted that the ΔP_{54} pressure line was inadvertently disconnected during maintenance prior to Flights 2 and 3 and not discovered until after Flight 3. Therefore, for these flights, conversion of five-hole probe voltages was conducted with α provided by the autopilot's telemetry data. The value of α was derived through a combination of factors. These included the true airspeed determined from the aircraft's pitot probe, the vertical speed calculated through a Kalman filter fusion of the static pressure rate of change, vertical acceleration, and global positioning system velocity, as well as the aircraft orientation measured by the autopilot gyroscopes. This orientation data allowed transformation of the vertical speed from inertial to body-fixed coordinates. The definition of C_α and C_β used for directional calibration and recovery of Q and β were also modified to not include ΔP_{54} . While not ideal, we were able to verify that this approach was justified by analyzing the Flight 1 data with and without inclusion of ΔP_{54} . The average difference between the resulting $u(t)$, $v(t)$ and $w(t)$ values was found to be less than 0.25 m s^{-1} with the average difference in the Reynolds normal stresses found to be less than $0.09 \text{ m}^2 \text{ s}^{-2}$. Importantly, the altitude dependence of these quantities was preserved. Figures comparing the differences resulting from the processing methods are presented in Appendix A.

2.2.2 Infrasonic Microphone:

Infrasonic measurements of acoustic frequencies were conducted using an infrasonic microphone. For these tests a microphone and acoustic measurement system developed at NASA Langley Research Center was used. The microphone, shown in Fig. 1b, when coupled with a PCB Piezotronics 485M49 amplifier, was capable of infrasound (acoustic frequencies lower than 20 Hz) detection with a sensitivity of 115 mV Pa^{-1} (amplified to $\pm 10 \text{ V}$) having a power consumption of 35 mW and weight of 186 g. The geometry of the 38.1 mm diameter microphone diaphragm was designed with a high compliance (low diaphragm tension) such that membrane motion was substantially critically damped and optimally dimensioned for the 0.01 Hz to 20 Hz frequency range, with the full bandwidth of the sensor being 0.01 Hz to 1 kHz.

The microphone was mounted rigidly within the nose of the aircraft with the diaphragm plane normal to the forward flight direction. By being located within the fuselage, the microphone was protected by dynamic pressure fluctuations. As the wavelengths of infrasonic sound exceed 10 m, sound attenuation by the fuselage was not expected for frequencies lower than 20 Hz.

2.2.3 Data Acquisition:

A Measurement Computing Systems MCC USB-1608FS-Plus data acquisition system (DAQ) was used to digitize the voltage output from the pressure transducers and microphone signal conditioning unit. The DAQ also provided the 5 V signal used to power the pressure transducers. This particular DAQ was capable of recording eight single-ended analog inputs simultaneously at 16-bit resolution at rates of up to 400 kHz. During these experiments the DAQ sampled at 1 kHz the seven channels

containing the analog voltage signals from all six pressure transducers and the infrasonic microphone. Digitized voltage values were then transferred through universal serial bus to the embedded computer for logging.

2.2.4 Embedded Computer:

The DAQ was connected via universal serial bus (USB) to a mini stick computer with an Intel Atom Z8350 processor, 128 GB eMMC non-volatile memory, and 4 GB RAM. To minimize radio frequency interference and shield the computer from high altitude radiation, the computer was encased in a copper shield (Fig. 3c). A custom script was used to control data acquisition and storage. The computer stored all recorded data on its eMMC memory which was then downloaded post-flight via USB connection for archiving and further analysis. To allow payload operational verification during flight, an RS232 connection was established between the computer and the autopilot. Through this channel, sensor voltage variance and preliminary turbulence detection parameters were passed to the autopilot to be included in the telemetry stream. This information was also later available for preliminary temporal alignment of sensor and autopilot data.

2.3 Uncertainty Estimation of Wind Measurement

As described above, measurement of the wind vector was a multi-step process involving information from different sensors, calibrations and corrections. Therefore, to assess the uncertainty of the wind vector measurement, a Monte-Carlo method was used to estimate the error propagation from the sensors to the final wind estimate. To do so, the post-processing calculations were repeated for 100 iterations with each iteration having the sensor values perturbed from their measured value by an amount determined using normally-distributed random number generators. The standard deviation of the normal distributions were selected to correspond to each sensor's uncertainties.

Specifically, for a measured sensor value, here represented as $\Phi(t)$, a perturbed value $\Phi_i(t)$, was found for each iteration, i , following

$$\Phi_i(t) = \Phi(t) + \frac{E_B}{2}\mathcal{N} + \frac{E_P}{2}\mathcal{N}(t) \quad (11)$$

where \mathcal{N} represents a normally distributed random number, drawn from a standard normal distribution having mean of zero and standard deviation of unity. The quantities E_B or E_P represent the estimated bias (accuracy) and precision (resolution) errors for the sensor being perturbed, with the bias error perturbation, \mathcal{N} , added to $\Phi(t)$ only once per iteration, and the precision perturbation, $\mathcal{N}(t)$, added for every sample in time. Here E_B and E_P are taken to represent the 95% uncertainty range, twice the standard deviation of their distribution.

The analysis produced an ensemble of 100 time-dependent (and hence altitude-dependent) measurements of wind for each flight, randomly distributed via the propagation of the perturbed sensor readings, each perturbed following Equation 11. The uncertainty estimate was then found for the magnitude and direction from twice the ensemble standard deviation at each measurement time, t , (corresponding to a 95% probability) of the 100 iterations. Note that this approach is similar to that employed by Van den Kroonenberg et al. (2008), but by employing the Monte-Carlo analysis this approach allows the uncertainty to vary

Table 1. Bias and precision errors for each sensor value used in wind estimate

Measured value	E_B	E_P
$\Delta P_1, \Delta P_{32}, \Delta P_{54}$	5 Pa	2 Pa
P	150 Pa	1 Pa
T	0.3 °C	0.01 °C
RH	5%	0.7%
yaw	0.2°	0.01°
pitch	0.2°	0.01°
roll	0.2°	0.01°
V_{G_x}, V_{G_y}	0.1 m s ⁻¹	0.02 m s ⁻¹

in time (and hence altitude) as well as incorporating any additional uncertainty which may occur due to coupling of sensor errors.

The values for E_B and E_P used in the uncertainty propagation analysis are provided in Table 1 and required different methods for their determination. For the pressure differences measured by the transducers connected to the five-hole-probe ($\Delta P_1, \Delta P_{32}, \Delta P_{54}$), E_B was estimated from the average difference between the low-sensitivity and high sensitivity ΔP_{32} and ΔP_{54} transducer values recorded during each flight, whereas E_P was estimated using twice the standard deviation of the difference. For P, T and RH , the manufacturer-provided accuracy and resolution values were used for E_B and E_P , respectively. Finally, the uncertainty of the attitude and heading reference system (AHRS) used by the autopilot was not available, so the values for accuracy and resolution values from a different manufacturer’s equivalent AHRS system were used as proxy values.

Note that this analysis does not take into account additional uncertainty introduced by errors in the directional calibration, misalignment in time between the sensors, and any altitude-dependent variability in the values provided in Table 1. To accommodate these undetected uncertainties in the analysis, the E_B and E_P values provided in Table 1 were doubled prior to implementation in Equation 11.

The mean value of U across the 100 iterations at each time step is shown in Fig. 5a-c for Flights 1, 2 and 3, along with the corresponding 95% (two standard deviation) uncertainty bounds. The resulting uncertainty in the wind estimate was found to be altitude dependent, with the highest uncertainty of approximately 3.5 m s⁻¹ observed at the highest altitudes, decreasing to approximately 0.5 m s⁻¹ at the lowest altitudes measured. This altitude dependence directly arises from the influence of P, T and RH uncertainty on the air density estimate. The magnitude of the uncertainty presented in Fig. 5 is consistent with the results of an intercomparison study presented in Barbieri et al. (2019). In this intercomparison, wind estimates from probes and procedures very similar to that used here were found to be within ± 1 m s⁻¹ of a ground-based reference velocity sensor.

Furthermore, although not directly apparent in Fig. 5, the uncertainty in wind magnitude was found to be most dependent on the yaw angle, which is consistent with the observations of Van den Kroonenberg et al. (2008). This is due to the dependence of wind magnitude on aircraft yaw, pitch, and roll introduced during the coordinate transformation between body-fixed and inertial

Figure 5. Result of uncertainty analysis for (a) Flight 1; (b) Flight 2; and (c) Flight 3. Red lines show velocity magnitude calculated from the mean of 100 ensembles, with corresponding 95% uncertainty bounds shown as black lines.

coordinate systems. During flight, the yaw angle can vary from 0° to 360° degrees, whereas the α , β , pitch and roll angles are near zero. The result is that during the coordinate transformation the u and v wind components are primarily determined from the true airspeed multiplied by the sine of yaw angle and cosine of pitch angle for u and cosine of yaw angle and sine of pitch angle for v (see, for example, Van den Kroonenberg et al., 2008). The result is that during an orbit, the horizontal velocity components will have highest sensitivity to error the aircraft’s yaw angle both at yaw angles of 0° degrees (for u) and 90° (for v) which, for a helical flight path such as flown in this study, can introduce periodic artifacts into the wind estimates. The vertical component of wind velocity, w , is most sensitive to error in pitch angle due to this component of wind being primarily determined by the true airspeed multiplied by the sine of the pitch angle (which is near 0° degrees for most of the flight).

2.4 Experiment Overview

The aircraft and payload combination was deployed in a measurement campaign conducted in the restricted airspace above Spaceport America, located near Truth or Consequences, New Mexico, U.S.A. between the Black Range and San Andres mountain ranges (Fig. 6), from June 1, 2021 through June 6, 2021. The height above sea level of launch and recovery of the aircraft was 1406 m above sea level (a.s.l.). Three flights were conducted by the HiDRON H2 on different dates, with Flight 1 being conducted on June 1; Flight 2 conducted on June 4; and Flight 3 being conducted on June 6. Each flight consisted of a weather-balloon carrying the glider aloft at an ascent rate of approximately 7 m s^{-1} to a release altitude of 25 km

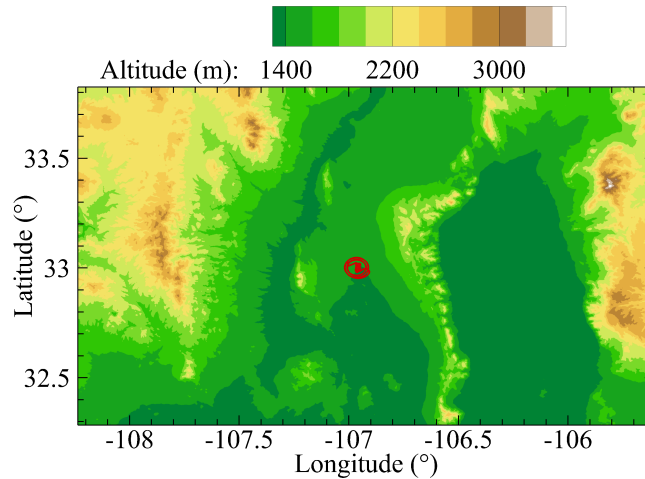

Figure 6. The topography of the flight area with Spaceport America with the trajectory of Flight 3 indicated by a red line to illustrate region of measurement.

a.s.l. for Flights 1 and 2, and 30 km a.s.l. for Flight 3 (corresponding to $z = 23.6$ km and $z = 28.6$ km above ground level, a.g.l., respectively). After release from the balloon, the aircraft conducted an automated descent along a pre-determined flight path towards the Spaceport America runway. Autopilot-controlled approach, landing and recovery occurred on the Spaceport America main runway, at which point the aircraft, payload and all logged data were recovered.

410 2.5 Flight Profiles:

The flight trajectories for all three flights are presented in Fig. 7 showing balloon launch, ascent to 25 km or 30 km altitude a.s.l., release of the HiDRON H2 aircraft, controlled return to the airspace above the launch and control point, and helical descent to the landing point. The helical descent was conducted at an initial radius of approximately 5 km, selected as a compromise between optimizing aerodynamic efficiency of the aircraft in a turn (by minimizing the bank angle) and to stay
 415 in close proximity to the landing runway. As the aircraft descended, this radius was reduced to approximately 4 km and, eventually, 1 km to keep the aircraft within gliding distance of the designated landing point. During the descent phase of the flight, as shown in Fig. 2, the rate of descent decreased from 5 m s^{-1} to 1 m s^{-1} (producing a nominal descent rate of 2 m s^{-1}). Overall flight time was approximately 6 hours with 4 hours of that being the descent phase. Note that, during descent, several tests were conducted of the HiDRON H2's flight control system (including a test of autonomous soaring during Flight 3 which
 420 resulted in the aircraft gaining altitude for approximately 10 minutes). The result of these tests were occasional deviations of the flight path from the nominal helical trajectory.

All three flights started in the morning hours, with Flight 1 launched at 13:47 UTC (07:47 LT) on June 1 2021, released from the balloon at 14:35 UTC (08:35 LT), and landing at 18:42 UTC (12:42 LT). Flight 2 launched at 14:04 UTC (08:04 LT) on June 4 2021, released at 15:15 UTC (11:15 LT) and landed at 18:39 UTC (12:39 LT). Finally, Flight 3 launched at 14:07 UTC

425 (08:07 LT) on June 6 2021, released at 15:17 UTC (09:17 LT), and landed at 19:43 UTC (12:43 LT). Local time, LT, at Spaceport America was Mountain Daylight Time (UTC -6:00).

3 Results

In this section, we present the measured values of temperature, relative humidity, wind vector, and infrasonic microphone signal amplitude, as well as presenting calculation approaches and results for selected statistics. The temperature and humidity
430 sensors were mounted on the front side of the wing support pillar (as shown in Figure 1a) and during ascent they were in a stagnant region within the wing pillar wake and not sufficiently aspirated to prevent self-heating and delayed air exchange with the environment. Hence, only data from the controlled descent phase of the flight are presented for temperature and humidity in this section. Here, z is used to indicate the vertical distance referenced to ground level, i.e. above ground level (a.g.l.) with

$z = 0$ corresponding to the launch and recovery altitude of 1406 m a.s.l.. In addition, when presenting results measured during
 435 descent we limit the data to $z < 20$ km for Flights 1 and 2 and $z < 25$ km for Flight 3, i.e. the portion of the flight when the
 aircraft was following a the helical trajectory (see Fig. 7) and within ± 5 km of a fixed geographic location. This latter constraint
 is introduced since even the low-sensitivity ΔP_1 exceeded the transducer's range shortly after the aircraft was released and
 started its flight towards the helical orbit location. By the time the aircraft reached the orbit location, ΔP_1 had returned to a
 range measurable by the low-sensitivity transducer, although it never reduced to a value measurable by the high-sensitivity
 440 ΔP_1 transducer.

Figure 8. Time series of velocity magnitude low-pass-filtered at 1 Hz for (a) controlled descent portion of Flight 1 with $t = 0$ corresponding to startup of data acquisition system prior to balloon release. Subfigures (b), (c) and (d) show selected portions of time series in stratosphere, troposphere and boundary layer, respectively.

The time series of $U(t)$ measured during descent is presented in Fig. 8a. For this figure, the time series has been low-pass-filtered at 1 Hz to better visualize some of the features of the time series. By inspection, it was observed that while the aircraft was in the stratosphere ($t < 7000$ s), the velocity fluctuations were largely composed of low frequency motion having

periods on the order of 400 s, as illustrated in the segment of the time series shown in Fig. 8b. For the nominal $|\mathbf{V}_R|$ of
445 approximately 60 m s^{-1} in this altitude range (see Fig. 2) this corresponds to wavelengths on the order of 24 km. Interspersed
with these low frequency motions were irregular occurrences of high frequency fluctuations more characteristic of turbulence,
such as shown in Fig. 8b around $t = 6000 \text{ s}$. These latter events occurred in bursts lasting on the order of 100 s (or 6 km).
As the aircraft descended through the troposphere, similar behavior was observed, although the duration of high-frequency
events were typically longer, on the order of 300 s (as illustrated in Fig. 8c around $t = 12000 \text{ s}$ and $t = 12500 \text{ s}$). However,
450 $|\mathbf{V}_R| \approx 20 \text{ m s}^{-1}$ at these altitudes so the corresponding lengths of these events remained near 6 km. Towards the end of the
flight, the intensity and frequency of the high frequency occurrences increased (Fig. 8d), consistent with the UAS approaching
and entering the boundary layer ($t > 16500 \text{ s}$). Similar behavior was observed for Flights 2 and 3.

Following these observations, to capture the statistical properties of the high frequency portions of the time-series, the
descent portion of the flight was divided into 3 km statistical segments, determined using $|\mathbf{V}_R|\Delta t$, where Δt is the amount
455 of time included in each segment. Due to the spiralling flight path (as illustrated in Fig. 7) each 3 km segment represents
approximately 150 m of vertical descent. Quantities averaged over these segments use $\langle \rangle$ brackets, and we assume that the
characteristics of the atmosphere within these segments are horizontally homogeneous (i.e. they are a function of z only).
This assumption becomes less restrictive as the aircraft's orbit radius is reduced, and at higher altitudes is predicated on
the consideration that the stability in the upper troposphere and stratosphere will promote horizontal homogeneity. In order
460 to decrease the vertical spacing between statistical values, each segment is overlapped with its neighbor by 50%, thereby
decreasing the spacing of statistical quantities to 75 m vertically. Finally, to minimize the effects of low frequency bias on the
statistics calculated for each segment, when statistics require the subtraction of a local mean value (e.g. as required to determine
 $u'(t)$, $v'(t)$ or $w'(t)$), rather than subtracting the segment's mean value, we instead subtract the linear trend within that segment
(i.e. by detrending the segment).

465 3.1 Mean quantities

To establish the ambient conditions during each flight we averaged P , T , RH , U and γ over each statistical segment and
compare vertical profiles of these quantities to publicly-available 12:00 UTC National Weather Service (NWS) radiosonde
weather soundings launched from the El Paso (EPZ), Albuquerque (ABQ) and Tuscon (TUS) NWS forecast offices. These
forecast offices and sounding times were selected due to their proximity to the launch site and flight times, with the launch
470 site within the triangle formed by these three locations. To assist with comparison across sites in z , we have set $z = 0$ at
1406 m a.s.l. for all soundings. Furthermore, to assist with comparison, the National Oceanic and Atmospheric Administration
(NOAA) upper air maps at 250 mbar and National Aeronautics and Space Administration (NASA) satellite imagery for the
approximate time of Flights 1 through 3 are provided in Appendix B with the NWS sounding sites and Spaceport America
(SPA) indicated on them. The NWS soundings employed Graw DFM-17 radiosondes with manufacturer-provided accuracies
475 of $\pm 0.2^\circ\text{C}$ in temperature, $\pm 4\%$ in RH , $\pm 0.1 \text{ m s}^{-1}$ in wind speed and $\pm 1^\circ$ in wind direction.

Vertical profiles of $\langle T \rangle$ and $\langle RH \rangle$, measured by the HiDRON H2, are compared to the radiosonde profiles for all three
flights in Fig. 9. The HiDRON H2 temperature is consistent with the trends produced by the radiosonde values, but shows a

Figure 9. Temperature profiles measured during (a) Flight 1; (b) Flight 2; and (c) Flight 3 compared to NWS radiosonde soundings from the Albuquerque (ABQ), El Paso (EPZ), and Tuscon (TUS) forecast offices. Corresponding relative humidity profiles shown for (d) Flight 1; (e) Flight 2; and (f) Flight 3.

Figure 10. Horizontal wind magnitude as measured during (a) Flight 1; (b) Flight 2; and (c) Flight 3 compared to NWS radiosonde soundings from the Albuquerque (ABQ), El Paso (EPZ), and Tucson (TUS) forecast offices. Corresponding wind direction shown for (d) Flight 1; (e) Flight 2; and (f) Flight 3.

noticeable warm bias compared to the radiosondes for $z > 16$ km that appears most evident in the results from Flight 3. Note that no density or other correction was applied to this sensor measurement to account for the reduced convective heat transfer at these altitudes. The lapse-rate in the troposphere also appears to deviate from the radiosonde lapse rates for $z < 5$ km, although it is not clear if this is due to a sensor-related issue or due to spatial variability in the atmospheric conditions.

Figures 9d-f compare the corresponding $\langle RH \rangle$ measurements from the HiDRON H2 and NWS radiosondes. Significant differences are clearly evident among the profiles. However, noting that the radiosonde data were obtained from disparate locations up to 380 km away from the flight location, differences can be attributed to spatial heterogeneity in the atmospheric moisture concentration. This is qualitatively illustrated by comparison of the cloud coverage in satellite observations (Appendix B). However, on all three days, the HiDRON H2 reported consistently lower RH values for $z > 7$ km, so a dry bias in the humidity sensor under cold conditions cannot be discounted.

The magnitude and direction of the horizontal winds for all three flights are shown in Fig. 10. In addition to comparison to the radiosonde soundings from ABQ, EPZ and TUS, we also compare the profiles measured during descent to those estimated from the ascent phase of each flight using (V_{G_x}, V_{G_y}) as measured by the autopilot's global positioning system (GPS). To mitigate any possible influence of pendulum motion of the aircraft on the balloon tether (estimated to have a natural period of approximately 5 s), the velocity values were filtered by applying a 25 s moving average. The resulting wind estimates are treated as approximately equivalent to those produced by radiosondes, although the significantly increased weight of the aircraft relative to a radiosonde can be expected to produce a corresponding increase in the time constant compared to that of a radiosonde.

In general, the wind magnitude and direction measured by the HiDRON H2 are within the bounds provided by the radiosonde soundings, with the wind direction measured during descent producing good agreement with that reported by the radiosondes and by the GPS on ascent. To assess the agreement in wind magnitude, we computed the average of the three NWS radiosonde profiles at each altitude recorded by the HiDRON H2. Subsequently, we determined the difference in U at each altitude. The resulting median of the absolute values of these differences was 1.9 m s^{-1} , 3.4 m s^{-1} , and 2.3 m s^{-1} for Flights 1, 2 and 3, respectively. Similarly, comparing U measured during ascent and descent by HiDRON H2 yielded median absolute difference values of 2.4 m s^{-1} , 3.0 m s^{-1} , and 2.7 m s^{-1} for Flights 1, 2 and 3, respectively.

With respect to the wind magnitude profile itself, the HiDRON measurements do contain short wavelength (e.g. < 1 km) fluctuations that were evident in both ascent (GPS ground velocity) and descent (five-hole-probe) wind velocity measurements made using the HiDRON H2. One significant difference between ascent and descent measurements are stronger long-wavelength fluctuations (on the order of 2.5 km) measured during descent than were measured during ascent for Flight 1 in the range $7.5 < z < 12.5$ km, and for Flight 2 in the range $11 < z < 13$ km. These low frequency waves are close to that of the orbit pitch at these altitudes (varying from 2 km to 3 km) and therefore may reflect bias in the wind estimate introduced by the orbital path. However, the magnitude of the differences exceeds the anticipated uncertainty bounds presented in Fig. 5. Furthermore, as discussed in Section 2.3, such periodic bias tends to be produced by error in yaw angle, which propagates through the transformation from body-fixed to inertial coordinate system. However, this yaw error influences u and v with phase and therefore also tends to appear in the wind direction as well (as shown in Al-Ghussain and Bailey, 2021, for example). How-

ever, as shown in Fig. 10d, for Flight 1 in the range $7.5 < z < 12.5$ km the $\langle \gamma \rangle$ estimates have close correspondence to the $\langle \gamma \rangle$ measured during ascent. It is also possible that the long-wavelength fluctuations in $\langle U \rangle$ may be evidence of horizontal heterogeneity in the wind magnitude at these altitudes, although this cannot be determined from the current measurements. Some periodicity in $\langle \gamma \rangle$ is evident during Flights 2 and 3 that is not measured during ascent, for example between 5 km and 10 km in the Flight 2 $\langle \gamma \rangle$ profiles. However, no corresponding periodicity is evident in $\langle U \rangle$ at these altitudes, and the wavelength of the periodicity is shorter than the pitch of the helical flight path at these altitudes, and therefore these oscillations are not believed to be due to bias introduced by the flight path.

Finally, differences in wind magnitude on the order of 5 m s^{-1} were observed between measurements made during ascent and descent in the troposphere during Flights 2 and 3. It is not clear what the source of this difference is, although there was a time difference of 2 to 4 hours between when the aircraft ascended through this region on its balloon and when it descended through the same region in a glide.

To summarize the observations of mean quantities provided in Figs. 9-10, atmospheric conditions were similar for Flights 2 and 3, which differed from Flight 1. The strongest winds occurred during Flight 1, which had an environmental lapse rate of $8.4 \text{ }^\circ\text{C km}^{-1}$ (Fig. 9a) and winds coming from 270° , increasing with altitude to a peak value over 20 m s^{-1} just above the tropopause ($z = 12.5$ km), after which the magnitude decreased with increasing z to the stratospheric inversion near $z = 17$ km. This pattern of constant wind direction and high wind magnitude is consistent with the presence of a jet stream, and the NOAA upper air wind meteorological maps (e.g. as provided in Appendix B) indicate that during Flight 1 a tropical jet stream was centered to the southeast of the flight location, over central Texas, such that the flight path was on the outer edge of the jet. The relative position of the jet stream for Flight 1 also explains the higher wind magnitudes measured at EPZ, which was closer to the center of the jet. Above the jet stream for Flight 1, the winds increase with altitude again, with significant directionality shift indicating horizontal shear was present above the temperature inversion.

The jet stream had moved to the east by the time of Flights 2 and 3 (as shown in Appendix B), which is reflected in the reduced wind magnitude measured during these flights (Fig. 10b,e and Fig. 10c,f respectively), typically below $\langle U \rangle = 10 \text{ m s}^{-1}$. Wind direction was consistently from the north for $z < 15$ km for Flight 2, with directional shear observed between $z = 15$ km and $z = 20$ km. An environmental lapse rate of $7.9 \text{ }^\circ\text{C km}^{-1}$ was measured for Flight 2 with a corresponding value of $8.2 \text{ }^\circ\text{C km}^{-1}$ measured for Flight 3. Wind observations during Flight 3 can be summarized as being nearly constant values of $\langle U \rangle \approx 10 \text{ m s}^{-1}$ up to $z = 30$ km, with winds coming from 300° in the troposphere changing with altitude to be from 100° at $z = 20$ km.

3.2 Turbulent Quantities

The HiDRON H2 measurements can be used to quantify the intensity of turbulence at different altitudes. For example through the turbulent kinetic energy, $\langle k \rangle$ which was calculated for each statistical segment using

$$\langle k \rangle = \frac{1}{2} (\langle u'^2 \rangle + \langle v'^2 \rangle + \langle w'^2 \rangle). \quad (12)$$

Note that since $u(t)$, $v(t)$ and $w(t)$ were oversampled, an additional filtering step was taken to minimize the influence of high-
 545 frequency noise on $\langle u'^2 \rangle$, $\langle v'^2 \rangle$, and $\langle w'^2 \rangle$. To do this, these quantities were calculated by integrating the corresponding velocity
 spectrum, $F_{uu}(f)$, $F_{vv}(f)$, and $F_{ww}(f)$ (equivalent to the one-sided autospectral density function of the detrended velocity
 component, following the terminology of Bendat and Piersol, 2000). The velocity spectra were found for each statistical
 segment using Welch's periodogram method implemented with a variance-preserving Hanning window, three subintervals,
 and a 50% overlap, implemented using the Matlab function 'pwelch'. The final low-pass filtered estimates of $\langle u'^2 \rangle$, $\langle v'^2 \rangle$ and
 550 $\langle w'^2 \rangle$ were then determined by integrating $F_{uu}(f)$, $F_{vv}(f)$ and $F_{ww}(f)$ over the frequency range where they were above the
 noise floor. The upper limit of this range was determined by identifying the frequency at which noise began to dominate the
 integration over velocity fluctuations, leading to an increase in F_{uu} , F_{vv} , or F_{ww} with rising f . This upper bound was consistent
 with the probe's maximum frequency response in the boundary layer and varied between 1 Hz and 20 Hz above the boundary
 layer, with the higher upper frequency bounds corresponding to instances where there was increased low frequency content in
 555 F_{uu} , F_{vv} or F_{ww} . It's worth noting that the Reynolds stresses filtered in this manner were observed to be an average of 85% of
 the variance of the corresponding unfiltered signal, reflecting the influence of high frequency noise on statistics.

Due to the time averaging used, the value of $\langle k \rangle$ will only incorporate contributions from relatively short wavelengths,
 corresponding to the distance travelled by the aircraft during the averaging time. Thus, an additional metric that can be used
 to quantify turbulence is the turbulent kinetic energy dissipation rate, ε . Within equilibrium homogeneous turbulence, ε can be
 560 expected to scale with the rate of production of k , and within the inertial subrange it should scale with k and the wavenumber
 range of the inertial subrange. The dissipation rate is particularly useful for turbulent quantification in atmospheric turbulence
 for which the scale of the energy containing eddies may be quite large or ill-defined since ε can be determined from small-scale
 fluctuations, without requiring resolution of the low wavenumber turbulence.

As determination of ε using Equation 2 requires measurement of spatial gradients of velocity over distances on the order of
 565 the Kolmogorov scale, it is challenging to directly measure ε in the atmosphere without additional assumptions. Thus, indirect
 estimates of ε are usually employed. Here, we assume the presence of sufficiently high Reynolds number for the formation
 of an inertial subrange in the energy spectrum. Under such conditions, the one-dimensional longitudinal wavenumber velocity
 spectrum in the inertial subrange is expected to follow a scaling such that

$$E_{\ell\ell}(\kappa_\ell) = 0.49\varepsilon^{2/3}\kappa_\ell^{-5/3} \quad (13)$$

570 as suggested by Kolmogorov (1941) using the one-dimensional Kolmogorov constant of 0.49 empirically determined by Sad-
 doughi and Veeravalli (1994). κ_ℓ is the longitudinal wavenumber and the wavenumber velocity spectrum calculated using the
 velocity component parallel to κ_ℓ .

To determine $\langle \varepsilon \rangle$ within each statistical segment, $E_{\ell\ell}(\kappa_\ell)$ was estimated using the component of the wind velocity aligned
 with $-\mathbf{V}_R$. This was calculated by first rotating the (u, v, w) coordinate system from the east-north-up alignment to instead
 575 align u with an axis parallel to the velocity of the aircraft within the air, i.e. we define $u_\ell(t)$ as the component of the wind
 velocity vector found by projection of the wind velocity vector, \mathbf{U} , in the direction formed by $\langle -\mathbf{V}_R \rangle$. The velocity spectrum

of $u_\ell(t)$ in the frequency domain, $F_{\ell\ell}(f)$, was then calculated on the rotated wind velocity vector following the same procedure used to calculate the Reynolds stresses. Noting that since Equation 13 is defined in the wavenumber domain, $F_{\ell\ell}(f)$ was then transformed to $E_{\ell\ell}(\kappa_\ell)$. To do this, the longitudinal wavenumber, κ_ℓ , was approximated using Taylor's frozen-flow hypothesis such that $\kappa_\ell \approx f2\pi|\langle \mathbf{V}_R \rangle|^{-1}$. We then found the longitudinal velocity spectrum in the wavenumber domain as $E_{\ell\ell} = F_{\ell\ell}|\langle \mathbf{V}_R \rangle|(2\pi)^{-1}$, where this last operation was conducted to ensure that

$$\int_0^\infty E_{\ell\ell}(\kappa_\ell) d\kappa_\ell = \langle u_\ell^2 \rangle. \quad (14)$$

Finally, Equation 13 was used to estimate $\langle \varepsilon \rangle$ by least-squares fit to $E_{\ell\ell}$. This fit was conducted over the κ_ℓ range corresponding to the frequency range used in the calculation of $\langle k \rangle$. The result is an estimate of ε for each statistical segment, i.e. $\langle \varepsilon \rangle$. Note that the approach used here provides only an approximation of $\langle \varepsilon \rangle$ as $E_{\ell\ell}(\kappa_\ell)$ will only follow Equation 13 in the presence of inertial turbulence, whereas the fit will always provide a non-zero value of $\langle \varepsilon \rangle$ even if no turbulence is present. Therefore, some caution is required when interpreting these values.

The values of $\langle k \rangle$ are compared to the corresponding values of $\langle \varepsilon \rangle$ in Fig. 11. Although there is significant scatter, the general trend follows the $\langle k \rangle \propto \langle \varepsilon \rangle^{2/3}$ expected for this calculation approach, demonstrating some intrinsic consistency in the different calculations. Additionally, it's important to note that alongside the implicit assumptions inherent in calculating $\langle \varepsilon \rangle$, the method employed to compute $\langle k \rangle$ only incorporates the energy content corresponding to wavelengths smaller than the statistical segment length (or frequencies higher than the inverse of the time taken to traverse that segment length).

The corresponding statistic of eddy dissipation rate, $EDR = \varepsilon^{1/3}$, is often used in the aviation industry to quantify turbulence. Following Huang et al. (2019), this metric allows the turbulence to be characterized as: steady for $EDR < 0.1$; weak for EDR between 0.1 and 0.3; moderate for EDR between 0.3 and 0.5; strong for EDR between 0.5 and 0.8; and very strong for $EDR > 0.8$. The measured profiles of $\langle k \rangle$ and $\langle EDR \rangle^2$ are compared to each other for all three flights in Figs. 12a, c, and e. For all flights, the $\langle EDR \rangle$ values indicate only weak turbulence was present. The most noticeable region of turbulence is just above and within the boundary layer, evident in Fig. 12a as an increase in $\langle k \rangle$ and $\langle EDR \rangle^2$ for $z < 2$ km, with slightly thicker regions of elevated $\langle k \rangle$ evident in Fig. 12b and c over the range $z < 4$ km and $z < 3$ km for Flights 2 and 3, respectively.

Above the boundary layer turbulence $\langle k \rangle$ and $\langle EDR \rangle^2$ are largely in agreement, although for stratospheric altitudes there are numerous localized regions where elevated $\langle k \rangle$ values were measured during Flights 2 and 3. To investigate these regions further we employ the continuous wavelet transform, an approach often used in time-frequency analysis due to its ability to discriminate frequency content within a signal as a function of time. Here, we employ the wavelet transform to examine the energy content of the measured velocity signal due to the presence of both low-frequency and high-frequency motions, which, as observed in Fig. 8, vary with altitude and, consequently, with time. Wavelet transforms eliminate the need for segmenting the time series, as required for calculating $F_{\ell\ell}(f)$, thereby avoiding potential bias introduced by the selection of segment length. Thus, we chose to leverage the wavelet transform's capability to discern the time (and hence altitude) dependence of the frequency content of $u_\ell(t)$.

Figure 11. Comparison of turbulent kinetic energy and turbulent kinetic energy dissipation rate calculated within each statistical segment. Solid line indicates $k^{3/2}$ slope.

The continuous wavelet transform is defined through convolution of the time-dependent signal, here $u_\ell(t)$, with a wavelet function, Ψ , such that

$$W(a, b) = \int_{-\infty}^{\infty} u_\ell(t) \frac{1}{a} \Psi^* \left(\frac{t-b}{a} \right) dt \quad (15)$$

where Ψ^* is the complex conjugate of the selected wavelet function, a is the scale parameter, and b the position parameter. The result of the transform is the wavelet coefficient, W , as a function of a and b which can be related to f and t , respectively (see, for example, Tavoularis, 2005). The wavelet coefficient is therefore a complex-valued result whose amplitude reflects the frequency-dependent amplitude of Ψ providing the best agreement with the original signal at each point in its time series. In this implementation, we utilized the analytical Morlet wavelet in Matlab over a frequency range from 0.001 Hz to 5 Hz. These frequencies correspond to approximately the rate at which orbits were completed and half the maximum frequency response of the probe at low pressure and temperature conditions, respectively. The Morlet wavelet is a complex harmonic function modulated by a Gaussian envelope and provides a measure of the frequency content of a signal over a short time interval $\sim 3/f$ s long.

Figures 12b, d, and f present the wavelet transform of $u_\ell(t)$ for Flights 1, 2 and 3 respectively as logarithmically-scaled isocontours of the complex modulus of the wavelet coefficient squared, $\log_{10} |W|^2$, which is referred to as the wavelet power

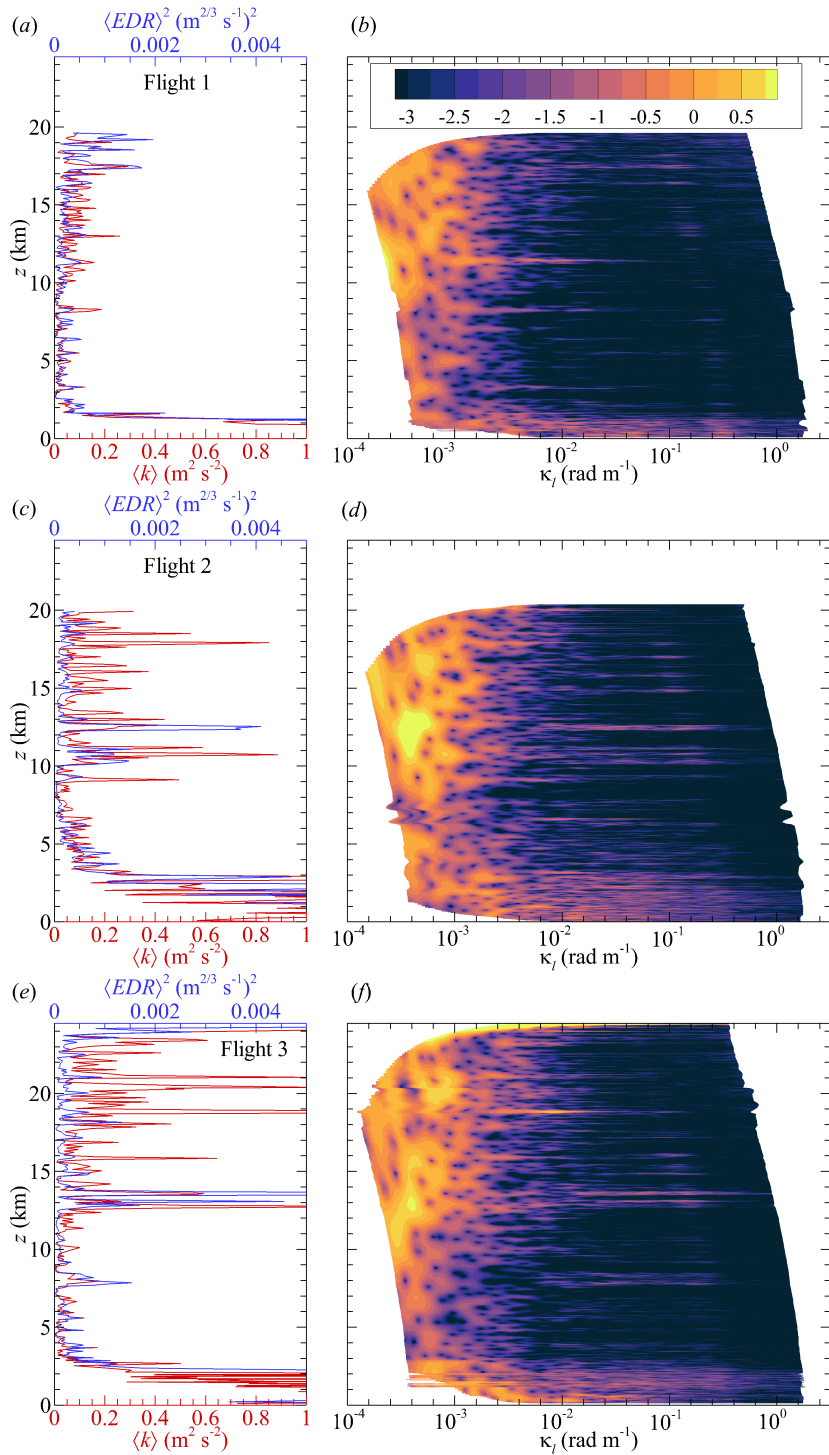

Figure 12. Profiles of $\langle k \rangle$ and $\langle EDR \rangle^2$ for (a) Flight 1, (c) Flight 2, and (e) Flight 3. Contours of $\log_{10} |W|^2$ are also shown for (b) Flight 1, (d) Flight 2, and (f) Flight 3 as functions of κ_ℓ and z . Contour levels are the same in (b), (d) and (f).

spectrum. To transform the results from the time-frequency domain to the spatial domain, the plot is presented as a function of z (which is time-dependent) and $\kappa_\ell \approx f2\pi|\langle \mathbf{V}_R \rangle|^{-1}$. Note that at the start and end of the time series the scale of Ψ which can be convoluted with $u_\ell(t)$ is limited by the length of the available signal in time, and hence the low frequency boundary of the wavelet power spectrum shown in Fig. 12b, d, and f is time-dependent.

Noticeable in Figs. 12b, d, and f is the significant long wavelength content for $\kappa_\ell < 0.003$ (wavelengths larger than 2 km), with the highest coefficient values measured during Flights 2 and 3 when $z > 10$ km. This long wavelength content is the signature of the long period fluctuations in Fig. 8 and fluctuations with altitude measured in Fig. 10. High frequency content is also evident, not only in the proximity of the boundary layer but also in thin regions corresponding to altitudes where elevated $\langle k \rangle$ and $\langle EDR \rangle$ are observed in Figs. 12a, c, and e. For example, for Flight 1, distinct regions of elevated $|W|$ appear for $\kappa_\ell < 0.1$ at $z \approx 8$ km and $z \approx 12$ km and with higher wavenumber content around $z \approx 17$ km. It can be observed that the $\langle EDR \rangle^2$ and $\langle k \rangle$ have the greatest agreement when u_ℓ contains high wavenumber content, i.e., when an inertial subrange is present (as implied by the approach used to determine $\langle \varepsilon \rangle$). Conversely when $\langle k \rangle$ is much larger than $\langle EDR \rangle^2$, specifically the larger spikes in $\langle k \rangle$ measured during Flights 2 and 3 above $z = 10$ km, it can be observed that these events correspond to instances where u_ℓ has energy content at low wavenumbers. Hence, the elevated $\langle k \rangle$ for $z > 15$ km in Figs. 12c and e appears to be due to low wavenumber energetic contributions to $\langle k \rangle$ and the $\langle EDR \rangle$ calculation approach used here is unable to capture these low wavenumber contributions.

3.3 Infrasonic Detection of Turbulence

Before we can explore the connection between the infrasonic sound energy detected by the microphone and the turbulent kinetic energy measured by the five-hole probe, we need to quantify the measured infrasound energy. To do this we use the variance of the pressure fluctuations in the acoustic signal measured by the microphone, σ^2 . We note that σ^2 will include pressure waves generated by the long wavelength fluctuations shown in Fig. 12b, d, and f (which indicate significant energy content in the velocity fluctuations at wavenumbers below 0.003) in addition to any inertial turbulence that may be present at higher frequencies. To capture this long wavelength motion and corresponding low frequency acoustic waves, we expand our segment length to 240 s (corresponding to the nominal time it took the HiDRON H2 to complete half an orbit) in order to ensure that the low frequency content is included in the variance calculation for both the infrasound and wind velocity fluctuations. Statistical averages calculated over this longer segment size are indicated by [] brackets. Profiles of $[\sigma^2]$ measured during all three flights are presented in Fig. 13a-c.

Noticeably, there was a decrease in signal amplitude measured with increasing altitude for all three flights. It was found that this decrease closely corresponds to the reduction in local atmospheric pressure, and therefore is attributed to increased atmospheric absorption due to the increase in molecular mean free path with altitude (Bass et al., 2007). Despite this altitude dependence, localized increases in $[\sigma^2]$ were observed, particularly near the boundary layer. When we isolate only the infrasonic part of the acoustic amplitude by integrating the power spectrum of the microphone signal over the frequency range below 20 Hz, which we refer to as $[\sigma^2]_{LF}$, we observe a similar but unequal attenuation, as also depicted in Fig. 13a-c.

Figure 13. Infrasonic microphone signal as measured through its variance, $[\sigma^2]$, compared to variance of the signal low-pass-filtered at 20 Hz, $[\sigma^2]_{LF}$, for (a) Flight 1, (b) Flight 2, and (c) Flight 3. The ratio $[\sigma^2]_{LF}/[\sigma^2]$ compared to turbulent kinetic energy, $[k]$, for (d) Flight 1, (e) Flight 2, and (f) Flight 3.

Any altitude-dependent attenuation resulting from the decrease in molecular mean free path will be contingent on both local temperature and pressure and apply uniformly across the bandwidth of the microphone. Therefore, the ratio $[\sigma^2]_{LF}/[\sigma^2]$, which indicates the proportion of the total microphone energy measured within the infrasonic range, can serve to adjust for signal absorption with altitude, assuming a consistent frequency response of the microphone across different altitudes. This ratio is
 660 compared to $[k]$ in Fig. 13d-f, with $[k]$ selected for this comparison over $\langle k \rangle$ due to its inclusion of the long wavelength turbulent kinetic energy content shown in Fig. 12d-f. When analyzed in this manner, the resulting profile of infrasonic amplitude shows a pronounced correspondence to the $[k]$ profile. Consequently, it appears that the infrasonic microphone is particularly sensitive to the long wavelengths detected in the stratosphere, and to a lesser extent, those in the vicinity of the boundary layer. However, the $[\sigma^2_{LF}]/[\sigma^2]$ profile appears as a filtered version of the $[k]$ profile.

665 Because the infrasonic microphone registers pressure waves that have traveled an unknown distance from their origin, whereas the five-hole probe can only measure the velocity fluctuations in-situ, we shouldn't anticipate a precise correlation between $[\sigma^2_{LF}]/[\sigma^2]$ and $[k]$. Moreover, the omnidirectional propagation of sound adds complexity, implying that the microphone may pick up sound from sources not measured by the five-hole-probe. Hence, these results can only provide qualitative support for the ability of the microphone to detect atmospheric turbulence, as a quantitative analysis would also require information
 670 about the distance and strength of the source of infrasonic energy.

It is worth noting that the normalization of $[\sigma^2_{LF}]/[\sigma^2]$ employed here doesn't account for the rise in $[k]$ observed near the boundary layer. This is due to the increase in $[\sigma]$ as a consequence of the heightened broadband turbulent activity in the boundary layer. Consequently, the ratio $[\sigma^2_{LF}]/[\sigma^2]$ remains relatively constant across the boundary layer. However, Fig. 13a-c demonstrate that there is a rise in $[\sigma^2_{LF}]$ within the boundary layer, aligning with the increase in $[k]$. This observation is
 675 consistent with the ground-based findings of Cuxart et al. (2015).

3.4 Stability Conditions

Profiles of the square Brunt-Väisälä frequency, N^2 , and square shear frequency, S^2 , provide some perspective about the altitude dependence of static stability and horizontal velocity shear, and hence potential for turbulence generation. However, approximating the mean vertical gradients of wind and virtual potential temperature required to calculate N^2 and S^2 using
 680 Equations 5 and 6 becomes somewhat ambiguous the HiDRON H2 measurements. This is due to the shallow glide slope of the particular helical flight path flown in these experiments, which introduces an increased sensitivity to horizontal gradients of U and θ_v compared to that of the vertical gradients.

Therefore, different approaches were attempted to calculate N^2 and S^2 . For the initial approach we present here, we assume horizontal homogeneity and attempt to replicate the expected response of a radiosonde to changes in the vertical wind structure,
 685 $\partial U/\partial z$. To do so, we assume a radiosonde time response for wind on the order of 40 s (Dirksen et al., 2014) which is introduced in commercial radiosondes by filtering of the pendulum effects and GPS noise, as well as the inertia of the balloon itself (Scoggins, 1965). This time response, when combined with a typical rise rate of 5 m s^{-1} , equates to a vertical resolution of approximately 200 m. Therefore, prior to calculating the vertical gradients, $u(t)$ and $v(t)$ were filtered using a moving average over a time span equivalent to a change in z of 200 m. Then, to enable calculation of gradients in the vertical direction over

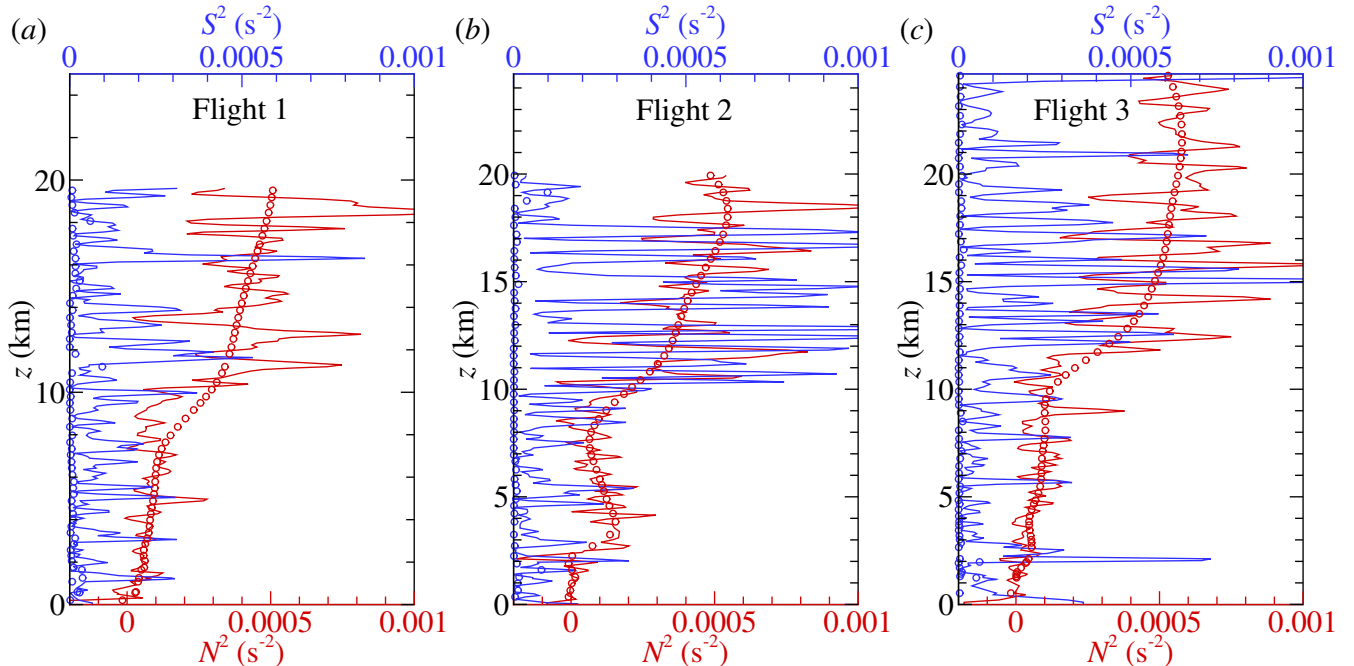

Figure 14. Square Brunt–Väisälä frequency, N^2 , and square shear frequency, S^2 , profiles for (a) Flight 1; (b) Flight 2; and (c) Flight 3. Solid lines show profiles calculated using vertical gradients calculated along flight trajectory, symbols show profiles calculated using vertical gradients calculated between neighboring orbits at same azimuthal position.

690 $\Delta z = 100$ m intervals (the approximate turbulent layer thickness estimated by Ko et al., 2019), the wind components $u(t)$, $v(t)$ and $\theta_v(t)$ were then averaged over $\Delta z = 100$ m bins allowing calculation of the vertical gradients using the resulting bin averaged values separated by $\Delta z = 100$ m. However, these gradient values were no longer at the same z location as the location where $\langle \theta_v \rangle$ values were calculated. Therefore, prior to calculating N^2 and S^2 , the gradients calculated at a resolution of $\Delta z = 100$ m had to be interpolated to the z location corresponding to each statistical segment.

695 The square Brunt–Väisälä frequency and square shear frequency calculated this way are presented as solid lines in Fig. 14 for each flight. The results show large oscillations with altitude for all three flights, particularly in S^2 , which can be expected from Fig. 10. However, when $Ri = N^2/S^2$ is compared to both $\langle k \rangle$ and $\langle EDR \rangle$ as done in Fig. 15a and b respectively, the resulting trend is generally consistent with the expected behavior of increased turbulence intensity at low Ri . Specifically, the high turbulence intensity events (independent of whether quantified through $\langle k \rangle$ as done in Fig. 15a or $\langle EDR \rangle$ as done in
700 Fig. 15b) largely occur when $Ri < 1$, although there are some instances of elevated turbulence when $Ri > 1$ and instances where no turbulence is evident when $Ri < 1$.

As the helical descent of the aircraft results in approximately 1500 m of horizontal travel for every 100 m of decent, horizontal variability in the measured variables have an outsized impact on the calculation of Ri . In an attempt to eliminate the required assumption of horizontal homogeneity for the calculation of Ri , an alternative approach was attempted to calculate
705 vertical gradients whereby the vertical profiles were expanded along the circumference of the aircraft’s orbit. For each statisti-

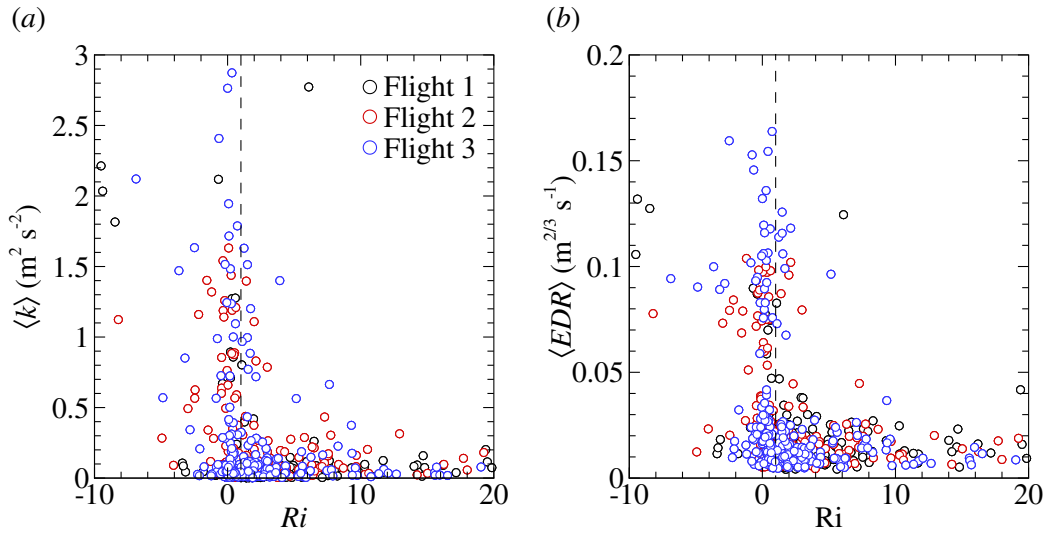

Figure 15. Comparison of (a) turbulent kinetic energy, $\langle k \rangle$, and (b) eddy dissipation rate, $\langle EDR \rangle$, to gradient Richardson number, Ri , calculated along flight trajectory. Dashed vertical line indicates $Ri = 1$.

cal segment the two nearest segments in the z direction were used to calculate the vertical gradients using central differencing. In this way, the gradients were calculated vertically across individual orbits, rather than along the helical path. However this results in a gradient calculation with a vertical scale of the same order as the pitch of the helix, which was approximately 2.5 km and therefore much larger than the thickness of the layers of turbulence observed in Fig. 12.

710 The values of S^2 and N^2 calculated this way are shown using symbols on Fig. 14a-c. This calculation approach effectively reproduces the trend of the N^2 vertical profiles calculated along the flight path, but contains fewer fluctuations, particularly for $z > 10$ km. The corresponding S^2 profiles, however, were an order of magnitude smaller when calculated across the orbits than when calculated along the flight path (reflected in the values near zero in Fig. 14a-c) and therefore resulted in Ri values on the order of 10^3 . The lower values of S^2 when calculated between the orbits likely reflects the larger vertical distances involved in
 715 the differencing across the orbits which will effectively filter out many of the vertical wind gradients shown in Fig. 10a-c. This approach is presented here as it may be more successful for flight trajectories with smaller orbit diameter, and smaller vertical pitch between orbits.

4 Summary and Conclusions

This report describes a balloon-launched glider UAS and instrumentation intended for measuring the statistical structure of
 720 atmospheric turbulence. To conduct these quantitative measurements, the aircraft was equipped with a five-hole-probe for measuring the three-component wind vector, and pressure, temperature and humidity sensors integrated into the aircraft.

These instruments allowed the measurement of vertical profiles of T , RH , U and γ up to $z = 25$ km above ground level. These profiles compared favorably with the nearest publicly-available National Weather Service radiosonde data for T and

725 RH , although there were some noticeable differences in the RH values, which were lower than the radiosonde values for $z > 7$ km. There were also indications that additional corrections may be needed to T within the stratosphere. Wind profiles had a median difference on the order of 2.5 m s^{-1} with the available National Weather Service radiosonde profiles and the GPS-derived wind velocity measured during ascent.

730 The descent trajectory allowed for the calculation of $\langle k \rangle$ and $\langle \varepsilon \rangle$ over a large horizontal distance relative to the vertical distance traveled. The resulting vertical profiles suggest that isolated regions of weak turbulence were present in all three flights, and by examining the wavelet transform of the longitudinal velocity it was observed that these isolated regions could have different wavelength content depending on altitude. The wavelet transforms also indicated that long-wavelength fluctuations provided a significant contribution to the energy content for $z > 10$ km. The on-board infrasonic microphone captured these long-wavelength fluctuations as low-frequency acoustic energy. As the UAS approached the boundary layer, the microphone also detected a rise in broadband acoustic energy, consistent with the broader frequency content of turbulence within this layer
735 measured by the five-hole-probe. While these findings are qualitative, they imply that the infrasonic microphone is responsive to long-wavelength turbulent kinetic energy. Future research aims to establish a more quantitative relationship, necessitating additional information about the distance of the sensor from the source of turbulent kinetic energy, as well as the turbulence strength at the source.

An attempt was also made to calculate the gradient Richardson number from the temperature and wind profiles, however the
740 helical flight trajectory of the UAS introduces ambiguity in the time and length scales used for determining the mean vertical gradients. A method was proposed which smoothed the wind velocity prior to calculating the gradients across 100 m vertical increments. This resulted in gradient Richardson numbers that corresponded to enhanced $\langle k \rangle$ and $\langle \varepsilon \rangle$ when $Ri < 1$, however there were outliers which suggested improvements could be made to the calculation approach. An alternative approach was presented which calculated the vertical gradients across the pitch of the helical flight path. This produced similar results for
745 N^2 , however the S^2 results were an order of magnitude smaller due to the pitch being on the order of 2.5 km. The result was very high Ri values that predicted stable conditions even when turbulence was present.

Despite this ambiguity, these initial flights suggest the potential exists for this measurement approach to be used for high altitude turbulence research, for example enabling detailed analysis of length scales and anisotropy of the turbulence. However, additional flights will be beneficial for assessing the capabilities of this measurement technique. For example, for the three
750 flights considered here, the turbulence above the boundary layer was relatively weak and limited in occurrence. Measurements in more unstable conditions would lead to increased opportunities to conduct turbulent observations. Furthermore, flight patterns can be designed to allow examination of potential inhomogeneity of the statistics, for example by taking advantage of the helical trajectory taken by the glider during its descent to produce depictions of the horizontal heterogeneity of measured statistics. Additional flight patterns can also be designed with tighter helical descent to better calculate gradient Richardson number,
755 with higher vertical resolution. Finally, improvements can be made to the data acquisition system that would lessen the signal-to-noise ratio of the acquisition system, simplifying post-processing of the measurements and providing higher resolution of instances of any turbulence encountered.

Data availability. Data from these flights are available from the corresponding author on request.

Video supplement. A video compilation of aircraft preparation, flight and recovery is publicly available at <https://vimeo.com/568101900>

Appendix A: Comparison of wind and Reynolds normal stress profiles with and without use of all transducers

Figure A1. Figures showing comparison of (a) horizontal wind velocity magnitude, (b) horizontal wind direction, and (c) vertical component of wind velocity calculated using the ΔP_1 , ΔP_{32} , and ΔP_{54} transducers to find Q , α and β (shown in red) with the same properties calculated using only the ΔP_1 and ΔP_{32} transducers to calculate Q and β with α determined from the aircraft angle of attack measurement (shown in black). Comparison of resulting (d) $\langle u'^2 \rangle$, (e) $\langle v'^2 \rangle$, and (f) $\langle w'^2 \rangle$ Reynolds stress tensor components is also shown.

Appendix B: Upper Air Maps and Satellite Imagery

Figure B1. NOAA Jet stream maps at 250 mb (10.366 km) for (a) Flight 1, (b) Flight 2, (c) Flight 3 and satellite images of cloud cover (NASA) for (d) Flight 1, (e) Flight 2, (f) Flight 3. Red pins indicate NWS sounding sites and yellow pin indicates measurement location at SpacePort America (SPA).
