#### Abstract.

The Centered around the High Altitude and Long Range (HALO) research aircraft and the collaborative research project on Arctic Amplification (AC)<sup>3</sup>, the airborne field campaign HALO-(AC)<sup>3</sup> took place from 07 March to 12 April 2022 and was designed 2022. Its major goal was to observe the transformation of air masses during their meridional transport in the North Atlantic sector of the Arctic. We evaluate the meteorological and sea ice conditions during the campaign based on the European Centre for Medium-Range Weather Forecasts (ECMWF) Reanalysis v5 (ERA5), satellite data, and atmospheric soundings with respect to climatologyand describe special synoptic events. HALO-(AC)<sup>3</sup> started with a warm period (11– 20 March) where strong southerly winds prevailed that caused moist and warm air intrusions (MWAIs). Two MWAIs were detected as Atmospheric Rivers (ARs). Compared to the ERA5 climatology (1979–2022), record breaking vertically integrated poleward heat and moisture fluxes averaged over 75.0–81.5° N the Fram Strait latitudes were found. The related These warm and moist air masses reached the central Arctic, causing the caused the highest rainfall rates over the sea ice northwest of Svalbard recorded since the beginning of the ERA5 climatology. Subsequently, the cold period of HALO (AC)<sup>3</sup> started During the subsequent cold period, starting after the passage of a Shapiro-Keyser strong cyclone on 21 Marchwhen the wind regime turned to northerlies, advecting, northerly winds advected colder air into the Fram Strait. Until 08 April, marine Marine cold air outbreaks (MCAOs) prevailed including two strong MCAO events on 21–26 March and 01–02 April. In between, until 08 April, interrupted by short periods of aged subpolar warm airwas advected to the Fram Strait with northeasterly and easterly winds. On average, the entire campaign period was warmer than the climatology, especially climatological mean due to the exceptionally strong ARs during the warm periodstrong influence of the ARs. In the Fram Strait, the sea ice concentration (SIC) was within the well within the climatological variability, staying within the 10-90th percentiles of the climatology-over

the entire campaign duration. During However, during the warm period, SIC was strongly reduced and an untypically large polynya opened north of Svalbard. During the cold period, the polynya was closed again and above average SICs were found. We For potential future studies, we describe the environmental conditions of a Polar Lowand far north reaching cirrusin detail, which will be subjects of research using HALO's remote sensing suite in the future. We also present the perspective on the the most significant weather events (ARs, MCAOs, Polar Low, and Arctic cirrus) during HALO-(AC)<sup>3</sup> weather conditions from the research site in detail. Comparing atmospheric conditions over the Fram Strait with Ny-Ålesund, where orographic effects caused by the Svalbardarchipelago and temporal shifts of atmospheric signals due to the propagation of synoptic systems (Svalbard), temporal shifts up to one day have been identified. The temporal shift and orographic effects must be taken into account. Overall, our when combining airborne HALO-(AC)<sup>3</sup> measurements with ground based observations at Ny-Ålesund. Compared to previous airborne field campaigns focusing on the evolution of (mixed-phase) clouds, a larger variety of MCAO conditions were observed during HALO-(AC)<sup>3</sup>. Our study may serve as basis for future analyses of the data collected during HALO-(AC)<sup>3</sup> and to compare synoptic conditions with other field campaigns the campaigns.

## 1 Introduction

The Arctic experiences a drastic temperature increase almost 4 times stronger compared to the rest of the globe (Rantanen et al., 2022). This enhanced warming is known as Arctic Amplification and is caused by several feedback mechanisms (Serreze et al., 2009; Screen and Simmonds, 2010; Serreze and Barry, 2011). While the contribution of some feedback mechanisms to Arctic Amplification can be regarded as scientific consensus (i.e., sea ice albedo feedback, Serreze et al., 2009) (e.g., sea ice-albedo feedback, Serreze et al., 2009), others are not yet sufficiently explored and their contribution is uncertain (i.e., influence of clouds, lapse rate feedback, linkages between Arctic and mid-latitudes, Wendisch et al., 2023)(e.g., influence of clouds, . As the Arctic warms faster than the mid-latitudes, the meridional temperature gradient decreases in most heights of the troposphere, likely resulting in a weaker jet stream with enhanced and possibly enhancing the tendency to meander (more southward and no . Consequently, the frequency (Francis and Vavrus, 2015). A more meandering jet would result in an increasing number of poleward moist and warm air intrusions (MWAIs) and southward cold air outbreaks (CAOs) is expected to increase (Pithan et al., 2018; Mewes a -. However, the tropical upper troposphere warms while the Arctic lower stratosphere cools, enhancing meridional temperature 45 gradients at higher altitudes (Lee et al., 2019; Stendel et al., 2021). The frequency of meridional transport through the North Atlantic has increased during the last decades while it stayed constant or even decreased in other regions (Mewes and Jacobi, 2019) . You et al. (2022) found a positive trend in the frequency and duration of atmospheric blocking over the Barents Sea especially in winter. As blocking situations are associated with meandering jets, both frequency and duration of MWAIs reaching the Arctic through the North Atlantic sector are increasing, supporting the statement of an enhanced North Atlantic pathway for 50 meridional transport.

MWAIs frequently transport large amounts of heat and moisture into the Arctic through the Atlantic sector (Woods and Caballero, 2016). When the warm air glides onto the cold Arctic dome is pushed upwards over cold Arctic air masses, deep cloud systems including mixed-phase clouds form. may form. During MWAIs, cirrus clouds, whose radiative effect is not well explored over sea ice (Hong and Liu, 2015; Marsing et al., 2023), can be formed or advected to the Arctic. Woods et al. (2013) and Woods and Caballero (2016) stress that intense MWAIs have a large effect on the downward terrestrial radiation at the surface, contributing to the warming of the Arctic. Such MWAIs precondition the sea ice for the melting season, resulting in lower sea ice extent at the end of the summer (Kapsch et al., 2013, 2019). Numerical models still struggle to accurately represent the mixed-phase clouds and the transformation processes of the air masses well-(Pithan et al., 2014; Cohen et al., 2020). MWAIs can often be linked with filamentary bands of extreme strong moisture transport, known as Atmospheric Rivers (Newell et al., 1992). Atmospheric Rivers (ARs.) (ARs, Newell et al., 1992). ARs are responsible for over 90% of the poleward moisture transport across the mid-latitudes and are frequently accompanied by extreme strong winds and precipitation (Nash et al., 2018). In the Arctic, ARs-While the precipitation can cause snow accumulation, as well as the opposite, melting of snow and sea ice due to enhanced during ARs in the Arctic, the enhanced emission of downward terrestrial radiation from the clouds by the clouds can lead to melting of snow and sea ice (Neff et al., 2014; Komatsu et al., 2018; Mattingly et al., 2018, 2020; Bresson et al., 2022; Viceto et al., 2022). In a warming climate, ARs are expected to shift polewards and intensify due to the increased moisture load (Ma et al., 2020).

CAOs are often responsible for severe weather events in the high—and mid–latitudes and mainly occur in winter and spring (Fletcher et al., 2016; Pithan et al., 2018). Here, we focus on marine CAOs (MCAOs) where cold and dry air is advected southwards from the sea ice covered Arctic ocean over to the ice—free warm waters of the North Atlantic (Fram Strait, Greenland and Norwegian Seas). The (open) ocean. Over the open ocean, the strong temperature contrast between the ocean surface and the lower tropospheric air leads to intense heat releases (turbulent fluxes of sensible and latent heat) that are presponsible for 60–80% of the oceanic heat losses in that region (Papritz and Spengler, 2017). In the destabilized atmospheric boundary layer, cloud streetsform and This heat and moisture transfer into the atmosphere destabilizes the boundary layer and leads to the formation of cloud streets, which later develop into open cells the air mass moves southwards and takes up heat and moisture. This cloud evolution is not well represented in models but it is an important feature for the performance of climate models (Pithan et al., 2018). MCAOs can also cause the formation of Arctic mesoscale cyclones (Polar Lows, Rasmussen and Turner, 2003; Zahn and von Storch, 2008), which may locally lead to heavy precipitation and strong winds. The formation processes of Polar Lows and their relation to MCAOs are still not fully understood, partly due to the sparsity of measurements in the Arctic (Moreno-Ibáñez et al., 2021).

So far, observations of air mass transformations in the Arctic have mostly been conducted from a fixed local position (Eulerian view). Only a few aircraft based samplings of air mass properties over a limited regional area have been reported (i.e., Wendisch et al., 2019; Mech et al., 2022). The Eulerian point of view does not permit the required observations of (e.g., Wendisch et al., 2019; Mech et al., 2022). To observe air mass transformation processes along their meridional pathway in a Eulerian view, multiple stations that are aligned with the wind direction would be needed. Therefore, following Pithan et al. (2018), Pithan et al. (2018) proposed a quasi–Lagrange approach following air masses to and from the Arctic, which motivated the field campaign HALO–(AC)<sup>3</sup> within the Transregional Collaborative Research Center TRR 172 (TRR 172) on "Arctic Amplification: Climate Relevant Atmospheric and Surface Processes and Feedback Mechanisms (AC)<sup>3</sup>". The campaign was designed to obtain quasi–Lagrange observational data of air mass transformations during MWAIs and MCAOs to gain process understanding and evaluate the performance of weather and climate models (Wendisch et al., 2021).

90

100

During HALO–(AC)<sup>3</sup>, extensive remote sensing and in situ measurements of surface, cloud and thermodynamic properties have been performed between the Norwegian Sea and the North Pole from 11 March to 12 April 2022 with three research aircraft between 11 March and 12 April 2022. (HALO, Polar 5, and Polar 6). The High Altitude and LOng-range research aircraft (HALO) operated by the German Aerospace Center (DLR, Ziereis and Gläßer, 2006; Stevens et al., 2019) and was based in Kiruna during HALO–(AC)<sup>3</sup>. HALO is a modified Gulfstream G550, which has a sufficient operating range (9000 km in altitudes up to 15 km) for quasi–Lagrange air mass observations and was based in Kiruna during HALO–(AC)<sup>3</sup>. For HALO–(AC)<sup>3</sup>, it was equipped with a similar instrumental payload as during the EUREC4A campaign (Stevens et al., 2019; Konow et al., 2021). The research aircraft Polar 5 and Polar 6 (P5 and P6) were based in Longyearbyen and operated by the Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI, Wesche et al., 2016) in a similar coordinated way as during the ACLOUD campaign (Wendisch et al., 2019).

In this study, we focus on the analysis of the This study focuses on the environmental conditions during HALO-(AC)<sup>3</sup> and their climatological context to serve as comprehensive reference in future studies. After presenting the data introducing the data basis and methods in Sect. 2, we describe the synoptic development during two dominating periods and the classification of certain synoptic events based on meteorological parameters in Sect. 3.1. We also provide a view on the conditions from at Ny-Ålesund (Sect. 3.2), where future studies will use the extensive measurements from the French-German Atmospheric Observatory AWIPEV. Sea ice conditions in the North Atlantic sector of the Arctic are presented in Sect. 3.3. We further analyse the origin and strength of the MWAIs and ARs (Sect. 4.1), the conditions during the MCAO periods (Sect. 4.2), the formation and environmental characteristics of the Polar Low (Sect. 4.3), and Arctic cirrus clouds (Sect. 4.4), before concluding our study in Sect. 5.

## 115 2.1 Study domain

120

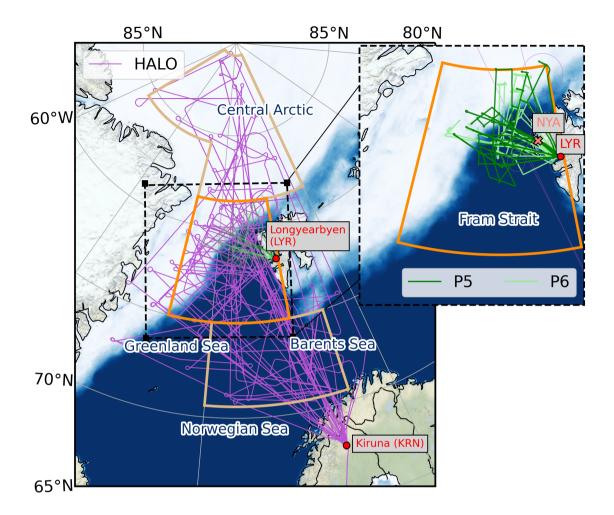

125

As the research flights during HALO-(AC)<sup>3</sup> were conducted in the Norwegian, Greenland, and Barents Seas, the Fram Strait, and central ArcticOcean in early spring, we also confined our analysis to this region. Both region and season for this campaign were selected because the largest fraction of MWAIs enters the Arctic through the North Atlantic during winter and early spring flight tracks cover the North Atlantic sector of the Arctic, the major pathway of MWAIs (Johansson et al., 2017; You et al., 2022). Based on the flight tracks, illustrated in Fig. 1, we selected three domains for which averages of several meteorological variables were calculated in this study. Table A1 summarizes the our synoptic analysis as shown in Fig. 1. The exact geographical coordinates of the domains are listed in Appendix A, Table A1. From north to south the domains are referred to as northern region (central Arctic north of Svalbard and Greenland), central region (Fram Strait and Greenland Sea), and southern region (Greenland and Norwegian Seas between Svalbard and Norway). A particular focus lies on the central regionas most flights were carried out in this domain. Within the central region, flight activities of P5 and P6 remained within 500 km of the northwestern coast of Svalbard due to their limited operating range. HALO covered the entire pathway of MWAIs and MCAOs between Greenland, Svalbard and Norway up to the central Arctic. , where measurements were performed with all three aircraft.

# 2.2 Measurements Atmospheric conditions observed from HALO and at Ny-Ålesund

HALO is equipped with a dropsonde launch system (Airborne Vertical Atmospheric Profiling System, Hock and Franklin, 1999) and RD94 dropsondes were used to obtain Vertical profiles of temperature, relative humidity, and pressure with an accuracy of 0.2 K, 2%, and 0.4 hPa, respectively, between the aircraft flight altitude and the surface (Vaisala, a; George et al., 2021). Wind profiles are derived from the temporal change of the dropsonde's position measured by the GPS receiver.

Measurements gathered pressure and wind were recorded with RD94 dropsondes launched from HALO (Hock and Franklin, 1999; Georg and radiosondes launched at the Atmospheric Observatory of the French-German AWIPEV research base in Ny-Ålesund (Svalbard, 78.92° N, 11.92° E) provide an additional view on the environmental conditions during HALO-(AC)<sup>3</sup> in the central region. At AWIPEV, ground based meteorological measurements (Maturilli et al., 2013; Maturilli, 2020a) are complemented by vertical profiles of wind, temperature, pressure, and relative humidity from daily radiosondes (Maturilli and Kayser, 2016, 2017; Maturil . The currently used Vaisala RS41 radiosondes have uncertainties of temperature, pressure, and relative humidity measurements of 0.2–0.4K, 0.6–1.0hPa, and 3–4%, respectively (Vaisala, b). During the campaign period, the launch frequency of the radiosondes was increased to—) every 6 hours . From these vertical (Vaisala RS41, Maturilli, 2020b). From the radiosonde

**Figure 1.** Flight tracks of HALO (purple), as well as P5 and P6 (dark and light green, zoomed domain in the right panel) during HALO–(AC)<sup>3</sup>. For orientation, the mean sea ice concentration from 07 March to 12 April 2022 based on AMSR2 satellite data (Spreen et al., 2008) is showed as filled contours. The three main measurement regions domains (southern region, central region, and northern region) are marked as yellow and orange boxes. The central region is highlighted. The orange label NYA in the zoomed domain marks the location of Ny–Ålesund.

profiles, we identified the thermal tropopause according to the WMO definition as the lowest level at which the temperature lapse rate falls below  $2 \, \mathrm{K \, km^{-1}}$  and does not exceed this value for the next  $2 \, \mathrm{km}$ . The integrated water vapour (IWV) was calculated from profiles of air pressure and specific humidity, which was derived from the temperature and relative humidity measurements. In addition to the radiosonde dataGround based meteorological measurements gathered at AWIPEV provide an additional view on the environmental conditions during HALO–(AC)<sup>3</sup> in the central region (Maturilli et al., 2013; Maturilli, 2020a). Additionally, we used data from the CL–51 ceilometer (Maturilli and Ebell, 2018; Maturilli, 2022) to assess the cloud conditions at Ny–Ålesund (Maturilli and Ebell, 2018; Maturilli, 2022).

145

## 2.3 Satellite observations of sea ice

We focused on sea ice concentration (SIC), i.e., the percentage of a satellite pixel (grid cell in ERA5) covered by sea ice, derived from satellite measurements to describe the sea ice conditions during HALO–(AC)<sup>3</sup>. In general, we separated observations for areas with and without sea ice (latter is also termed open water) through the threshold of 15% SIC. Starting with the launch of the Numbus–7 satellite in 1978, Satellite based passive microwave radiometers from space provide a long–term observation of sea ice (Spreen and Kern, 2016). To put SIC during HALO–(AC)<sup>3</sup> into a climatological contextHere, we used the OSI SAF Global Sea Ice Concentration Climate Data Record (SIC CDR v2.0), namely the product OSI–450 from 1979 to 2015, and the complementary Interim Climate Data Record OSI–430–b from 2016 onwards (OSI SAF, 2017; Copernicus Climate Change Service (C3S), 2020). It The product is based on satellite microwave data from a series of instruments: SMMR (1979–1987), SSM/I (1987–2008), and SSMIS (2006–today). The dynamic hybrid algorithm low–frequency passive microwave satellite data and is described in Lavergne et al. (2019)and it processes frequency channels at 19 and 37. The datasets are available daily with a grid spacing of 25 km×25 km.

To study the evolution of SIC during HALO–(AC)<sup>3</sup> at a higher spatial resolution, we used the merged MODIS–AMSR2 SIC dataset, available daily at 1 km resolution. It is based on passive microwave (AMSR2 sensor on GCOM–W1 (JAXA)) and thermal infrared (MODIS sensor on AQUA (NASA)) satellite data. The merged The merged MODIS–AMSR2 product (Ludwig et al., 2020) takes advantage of the high spatial resolution of thermal infrared , where SIC computed from temperature anomalies (Drüe and Heinemann, 2004), and of the independence of cloud cover of microwaves . SIC is computed from polarization differences at 89 GHz between open ocean and sea ice (ASI algorithm, Spreen et al., 2008). (Spreen et al., 2008)

## 2.4 Reanalysis data

165

For the analysis of the To analyse the weather development, we used the ERA5 reanalysis from the European Centre for Medium–Range Weather Forecasts (ECMWF), which has . ERA5 offers hourly data output since 1950 with a horizontal resolution of 31 km with and 137 vertical model levels and offers hourly data output from 1950 until present (Hersbach et al., 2018a, b, 2020). Climatological comparisons are based on the years 1979–2022 to cover the inter–annual variability of atmospheric conditions, unless specified differently. In the following, we describe the processing of (Hersbach et al., 2018a, b, 2020). ERA5 data and derivation of indices calculated for our analysis.

## 2.4.1 Basic meteorological parameters

Daily means of basic meteorological variables, such as the mean sea level pressure, 2m air temperature, 10m wind speed, IWV, total daily precipitation (in liquid and frozen form), were calculated and averaged for each of the three measurement regions for the description of the synoptic evolution represents clouds and precipitation in the Arctic better than other reanalyses (Graham et al., 2019a; Avila-Diaz et al., 2021). Additionally, ERA5 features a higher vertical resolution than other reanalyses, which leads to more accurate wind fields and, thus, to improved water vapour transport estimates (Graham et al., 2019b)

180 . However, ERA5 shows higher warm biases over sea ice of near surface temperatures than other reanalyses due to the

misrepresentation of the stable stratification (Wang et al., 2019; Yu et al., 2021). During HALO–(AC)<sup>3</sup>, dropsonde measurements launched from HALO were assimilated into ERA5. The climatological comparisons presented here are based on the years 1979–2022 unless specified differently. Grid points with a land fraction  $\geq 0$  were excluded. We respected the increasing data point density with increasing latitudes (due to the  $0.25^{\circ} \times 0.25^{\circ}$  grid) by computing regional averages > 0 have been excluded from our analysis according to the ERA5 land–sea–mask. Domain averages of the regularly gridded ERA5 quantities were calculated as area averages weighted by the cosine of latitudes. Additionally, we computed averages of vertically integrated meridional heat (IHT<sub>north</sub>) and moisture flux (IVT<sub>north</sub>) over the ocean grid points of the central region latitudes for information about the time and location of MWAIs, the latitude to respect the increasing data point density with increasing latitudes. In the following, we describe the processing of ERA5 data and derivation of indices calculated for our analysis.

We assessed the weather conditions during HALO–(AC)<sup>3</sup> with respect to the climatological reference period with anomalies of temperature at 850 hPa and 2 m height, 500 hPa geopotential height, and IWV. Evaluating the temperature anomalies at these two levels reveals the vertical extent of the temperature anomalies in the lower troposphere. We computed means over the elimatology years of these variables for three (sub–)periods of HALO–(AC)<sup>3</sup>: 11–20 March, 21 March–12 April, 07 March–12 April. We obtained the anomalies by subtracting the long–term means from the mean of the respective time period in 2022 so that positive (negative) values correspond to anomalies above (below) the long–term mean.

## 2.4.1 Detection of Atmospheric Rivers and moist and warm air intrusions

185

190

195

200

205

210

The northward component of vertically integrated water vapour transport (IVT<sub>north</sub>) is used to detect periods of increased poleward water vapour transport. Woods and Caballero (2016) defined Woods and Caballero (2016) detect moist air intrusions into the Arctic using when the vertically integrated meridional moisture flux (IVT<sub>north</sub>) at 70° N above certain threshold (exceeds  $200\,\mathrm{Tg}\,\mathrm{d}^{-1}\,\mathrm{deg}^{-1}$  ( $60.6\,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$ ) over a duration of at least 1.5 days and a zonal extent of at least 9°. HereFor our purpose, we adapted this definition to our campaign site detection and defined MWAIs with positive daily means of IVT<sub>north</sub> averaged over the central region. An MWAI is considered weak when this variable does not exceed (strong) when IVT<sub>north</sub> is below (equal or above)  $100\,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$ . Values above this threshold suggest strong MWAI conditions. Additionally, we computed the elimatological mean, as well as the temporal mean,  $25-75^{th}$  and  $10-90^{th}$  percentiles over the climatology years for each day.

period. In this study, ARs were identified with a global algorithm by Guan and Waliser (2015) in its revised version (Guan et al., 2018). IVT must exceed the  $85^{th}$  percentile of the season and grid cell, and must reach an absolute value of  $100 \, \mathrm{kg} \, \mathrm{m}^{-1} \, \mathrm{s}^{-1}$ , while fulfilling geometrical requirements (length  $> 2000 \, \mathrm{km}$ , length to width ratio of > 2, IVT direction within  $45^{\circ}$  of the detected AR axis). To account for the adapted to the lower moisture content in the polar atmosphere, the absolute IVT threshold is reduced to  $50 \, \mathrm{kg} \, \mathrm{m}^{-1} \, \mathrm{s}^{-1}$ . In case a detected AR at the  $85^{th}$  percentile threshold does not fulfill other requirements (e.g., related to its structure or geometry), higher IVT thresholds are successively tested ( $85-95^{th}$  in steps of 2.5). This procedure ensures detection of an AR that is embedded in a wide area of enhanced moisture transport with respect to the local climatology of the Arctic (Lauer et al., 2023).

## 2.4.2 Marine cold air outbreak index

220

225

A key feature of MCAOs are strong temperature decreases with increasing height especially in the lower troposphere . It over open ocean. This forms the basis for the MCAO index M to identify them and to quantify their strength. The MCAO index M was calculated following Papritz and Spengler (2017) and Dahlke et al. (2022):

$$M = \theta_{\text{SKT}} - \theta_{850} \tag{1}$$

with  $\theta_{SKT}$  ( $\theta_{850}$ ) as the potential skin temperature (potential temperature at 850 hPa). It was averaged over the central region, excluding grid points classified as land according to the ERA5 land–sea–mask. Furthermore, grid points Grid points with skin temperatures below 271.5 K (e.g., over assumed i.e., over sea ice) were also masked (Dahlke et al., 2022) and excluded from further processing. As for IVTas in Dahlke et al. (2022). We averaged over the central region and computed the climatology as for IVT<sub>north</sub>, we computed the mean, 25–75<sup>th</sup> and 10–90<sup>th</sup> percentiles for the climatology.

Note that both Papritz and Spengler (2017) and Dahlke et al. (2022) defined the Fram Strait box slightly different for their ealculations of M (75° N  $-80^\circ$  N,  $10^\circ$  W  $-10^\circ$  E). Following Papritz and Spengler (2017), MCAO conditions are present when  $M>0\,\mathrm{K}$  and its strength can be classified as weak ( $0\,\mathrm{K} < M \le 4\,\mathrm{K}$ ), moderate ( $4\,\mathrm{K} < M \le 8\,\mathrm{K}$ ), strong ( $8\,\mathrm{K} < M \le 12\,\mathrm{K}$ ) or very strong ( $M>12\,\mathrm{K}$ ).

## 2.4.3 Lower tropospheric parameters for marine cold air outbreak analysis

For a detailed analysis of the MCAO conditions over the campaign (Sect. 4.2), we used hourly ERA5 data of wind, temperature, and relative humidity at 850, 925, and 1000 hPa, as well as cloud cover, precipitation and surface turbulent heat fluxes (sensible and latent). All grid points classified as land were neglected. All pressure level variables were temporally averaged over 6 hour intervals and spatially averaged over each of the three measurement regions. Similar averaging was applied to turbulent flux data, where we used the mean values over 1 hour at each grid point instead of the instantaneous values (Hersbach et al., 2020). Because our focus is on the intensity of the upward fluxes (positive sign) over open water during the MCAOs, we only considered the central and southern region, for which we applied spatial averaging neglecting sea ice surfaces (SIC > 15%), respectively.

For low, medium and high-level cloud cover, we computed the median value including 5, 25, 75, and 95<sup>th</sup> percentiles, also for 6 hour intervals. Moreover, cloud cover the central region. Cloud cover was confined to open water surfaces only (SIC<15%) as ERA5 tends to overestimate especially low-level cloud cover over sea ice surfaces (Di Biagio et al., 2021).

240 For precipitation, we used the spatially averaged accumulated values over 6 hour intervals (only for the central and southern region), where we distinguished between open water and sea ice covered surfaces (SIC<15% and SIC≥15%, respectively). For precipitation in terms of snowfall, we further distinguished between large-scale and convective precipitation. The latter is defined in ERA5 as the frozen precipitation resulting from the convection scheme and thus from subgrid-scale convection. Total precipitation is then the sum of the convective and the large-scale part (Hersbach et al., 2020). (Di Biagio et al., 2021).

245 Details can be found in Appendix A.

## 2.4.4 Environmental conditions of Polar Lows

250

255

260

265

We analyse the environment for Polar Low formation with a set of conditions (C1–C6) suggested by Radovan et al. (2019) and Terpstra et al. (2016) in a 200 km radius around the Polar Low's centre (pressure minimum): C1: sea surface temperature (SST) – 500 hPa temperature, C2: SST – 2m temperature, C3: mean lapse rate below 850 hPa, C4<sub>i</sub>: mean relative humidity below 950 hPa, C4<sub>ii</sub>: mean relative humidity between 850 and 950 hPa, C5: 10 m wind speed (here, gust), C6: 500 hPa geopotential height anomaly.

Condition C1 is a measure of the convection potential as it evaluates the mean temperature gradient between the surface and the mid-troposphere. Large differences between the 2 temperature and the SST (C2) promote strong sensible heat fluxes, stressing the air–sea interaction. Condition Condition C3 is evaluated as the vertical mean of the vertical potential temperature gradient  $\frac{\partial \theta}{\partial z}$  (with  $\theta$  as potential temperature and z as height) between the surface and the 850 hPa pressure level. Positive values of C3 represent an increase of potential temperature with height. At least conditionally unstable conditions (unstable (stable) for moisture–saturated (unsaturated) air parcels) should be present ( $\frac{\partial \theta}{\partial z} \le 3 \text{K km}^{-1}$ ). The relative humidity conditions C4<sub>1</sub> and C4<sub>11</sub> are an important measure for the availability of moisture for latent heat release, a major energy source of a Polar Low. Maximum 10 m wind speed (C5) is an indicator of the Polar Low's strength. The geopotential height condition (C6) is selected to ensure the presence of an upper level trough The meaning of each condition is summarized in Appendix A.

For conditions C1–C4, the 75<sup>th</sup> percentile, for C5, the maximum, and for C6, the mean in a 200km radius around the Polar Low's centre were computed. Wahl et al. (2017) found that scales of multiples of the grid cell spacing are required to realistically represent the energy spectrum of a wind field. We decided to use the maximum 10 m wind gust instead of mean wind to get a better estimate of the near–surface wind field of this small–scale phenomenon that might be hidden due to the coarse resolution of ERA5. The climatology of the 500 hPa geopotential height for C6 consists of all days of April between 1979 and 2022 for each grid point within the 200 km radius. Subsequently, the geopotential height anomaly was computed as the difference between the conditions during HALO–(AC)<sup>3</sup> and the climatology, and C6 was obtained by averaging over the 200 km circle. Table 1 summarizes the conditions and their thresholds (Rasmussen and Turner, 2003; Zahn and von Storch, 2008; Radovan

Furthermore, we calculated vorticity from 10 dropsonde measurements taken within 1 hour arranged on a circular pattern. Following Lenschow et al. (2007) and Bony and Stevens (2019), we assumed horizontal variations in the wind field to be linear and expanded the wind vector with taylor Taylor expansion around the centre of the circle. The wind vector v can be expressed as-

$$\boldsymbol{v} = \boldsymbol{v_0} + \frac{\partial \boldsymbol{v}}{\partial \boldsymbol{\vartheta}} + \frac{\partial \boldsymbol{v}}{\partial \boldsymbol{\phi}}$$

for spherical coordinates  $\theta$  and  $\phi$  and the average wind velocity vector of all dropsondes  $v_0$ . By performing least–squares regression, the horizontal gradients  $\frac{\partial v}{\partial \theta}$  and  $\frac{\partial v}{\partial \phi}$  were obtained to calculate the relative vorticity

$$\zeta = \frac{1}{r \sin \vartheta_0} \left( \frac{\partial v}{\partial \phi} - \frac{\partial u \sin \vartheta}{\partial \vartheta} \right).$$

in spherical coordinates.

## 2.4.5 Trajectory calculations

Trajectory calculations were performed using LAGRANTO (Sprenger and Wernli, 2015) and wind fields from ERA5(Hersbach et al., 2020) retrieved on native resolution (0.25° × 0.25°, 1 hour, 137 model levels). To assess the origin of sampled cirrus air masses, 72 hour back–trajectories for the northernmost sections of the flights on 11 and 12 April were computed. Trajectories were initialized at the pressure levels 350–550 hPa in 50 hPa steps, where the single–layer cirrus had been observed by HALO –(Sect. 4.4). Furthermore, 72 hour back– and 48 hour forward–trajectories were computed to identify the pathways of the MWAIs (ARs) on 13 and 15 March (Appendix C). These trajectories were initialized along the 77.5° N latitude with 1° zonal spacing between 20° W and 13° E at 18:00 UTC on the respective days at the pressure levels 700, 850, and 925 hPa.

## 3 Meteorological and sea ice conditions during HALO-(AC)<sup>3</sup>

## 3.1 Analysis and identification of synoptic events

In this section, we characterize weather events during HALO– $(AC)^3$  and assess their strength with in the climatological context. At first, we separate the campaign into two major periods based on IVT<sub>north</sub> and the MCAO index (M) in the central region in (see Fig. 2). The campaign started with a warm and humid period with positive IVT<sub>north</sub> and negative values of M, coinciding with enhanced static stability, from 11 to 20 March 2022. The warm period was followed by a cold and dry period from 21 March to 12 April 2022, where IVT<sub>north</sub> (M) was almost exclusively negative (positive).

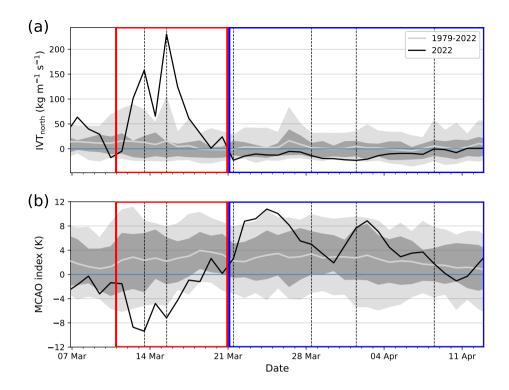

Within the warm and cold periods, we classified a large variety of weather events based on IVT<sub>north</sub> and *M*, the large scale pressure constellation, and regional averages of basic meteorological variables from ERA5 (Fig. 3 and 4). HHT<sub>north</sub> and In Fig. 5, we show latitude—averages of IVT<sub>north</sub>, averaged—and the vertically integrated meridional heat flux IHT<sub>north</sub> over the central region latitudes, were used to spatially and temporally localize meridional heat and moisture transport corresponding with MWAIs and MCAOs(Fig. 5). For the warm, cold, and the entire HALO—(AC)<sup>3</sup> period, we present. Negative values of IHT<sub>north</sub> and IVT<sub>north</sub> indicate southward fluxes. To put the weather conditions into climatological context, anomalies of temperature at 850 hPa and 2m above the surface, geopotential height at 500 hPa, and IWV with respect to the climatology (Fig. 6). were computed for the warm, cold and the entire campaign period. Positive (negative) anomalies correspond to values above (below) the long—term mean. Evaluating the temperature anomalies at these two levels reveals the vertical extent of the temperature anomalies in the lower troposphere.

## 3.1.1 Warm period

295

We start our analysis on 07 March to capture the initial conditions of HALO-(AC)<sup>3</sup>. Before the warm periodstarted, southerly and southwesterly winds dominated over the southern and central regions (07–09 March 2022, Fig. 3d). The During the warm period, the corresponding general circulation pattern was initially characterized by a high surface pressure system extending from the North Sea to Baltic Sea and Scandinavia – (Fig. 4a, b). The surface high was connected to a ridge in the 500 hPa geopotential height. Low surface pressure and low 500 hPa geopotential height were located over Greenland and the North Atlantic. A weak MWAI (IVT<sub>north</sub> < 100 kg m<sup>-1</sup> s<sup>-1</sup>) associated with the southwesterly flow barely reached the central region on 08–09 March (Fig. 3a). No signal This pressure constellation resulted in a consistent southerly and southwesterly flow with only a few short–lived interruptions in the three measurement regions. The interruptions can be seen in the central Arctic regarding temperature and IWV increases during that time (Fig. 3c, e). Subsequently, on 10–11 March, a weak high pressure system at the surface and ridge in the 500 hPa geopotential height temporarily caused northerly winds between two lows over the Fram Strait. The brief interruption of the southerly flow is reflected in the 2 m temperature drop (as near-surface temperature drops and wind direction change (e.g., 11 March, Fig. 3c) on 10–11 March, d).

At the beginning of the warm period (On 11–13 March), the high pressure ridge over Scandinavia intensified and established 15–16 March, the pressure gradients between Greenland and Scandinavia were intensified and blocking (Omega Block) was established over most of Europe. Intense MWAIs are connected to blocking situations over the eastern border of a large

**Figure 2.** Daily means of (a) northwards component of integrated water vapour transport (IVT<sub>north</sub>), (b) Marine Cold Air Outbreak (MCAO) index (M) based on ERA5 and averaged over the central region for HALO–(AC)<sup>3</sup> (black line). Daily values of the climatological The mean(1979–2022, grey line), as well as the 10–90<sup>th</sup> and 25–75<sup>th</sup> percentiles of the climatology (1979–2022) are illustrated as grey line, light and dark grey shadingshadings. The red (blue) box indicates the warm (cold) period dominated by MWAIs (MCAOs). Vertical dashed black lines mark the days shown in Fig. 4.

basin (here, North Atlantic), redirecting cyclones northward as the typical eastward propagation is blocked (Woods et al., 2013). Consequently, warm and moist air masses originating from the North Atlantic were transported towards our three main measurement areas, driven by several low pressure systems that formed between Iceland and eastern Greenland.

Besides the before mentioned weak MWAI event, we identified a much stronger We identified a strong MWAI event during the first week of the campaign (Fig. 3a) with area-averaged IVT<sub>north</sub> up to  $160 \, \mathrm{kg} \, \mathrm{m}^{-1} \, \mathrm{s}^{-1}$ . (Fig. 2a). The event was detected as AR and passed through the measurement regions on 12–13 March. It was connected with a more pronounced and narrow meridional flow due to the intensified pressure contrast between Scandinavia and Greenland (Fig. 4a). Exceptionally warm and moist air masses were transported from the British Isles over the Fram Strait towards the North Pole. As a result, equivalent potential temperature values at 850 hPa in the northern regionwere elevated by up to 30K compared to later parts of the campaign (Fig. 4a). In the same regionIn the northern region, IWV reached the maximum value of the campaign with an area-average above its campaign maximum (8 kg m<sup>-2</sup>) on 13 March and declined afterwards (Fig. 3e). The while the 2 m

temperature in the central Arctic northern region continued to increase until the following day, reflecting the typical delay of the surface warm front (corresponding to the MWAI / AR event) compared to higher altitudes.

At the beginning of the second campaign week, on 14 March, the mean wind speed over the measurement areas increased ((Fig. 3d). This was due to a rising pressure gradient over the Norwegian and Greenland Seas between a steering low that reached southern Greenland and the persisting high pressure ridge over Scandinavia (Fig. 4b). The confluent tropospheric southwesterly flow between the two pressure systems formed and sustained a new AR between, e).

340

350

355

360

365

370

A second AR followed on 15 and 16 March (Fig. 3a). The new AR had a similar orientation as the MWAI / AR event on 12–13 March, which had a more distinct confluent tropospheric southwesterly flow between the Greenland low and the Scandinavian high (Fig. 4a, b). In the central Arctic Ocean, the strongest warming occurred on 16 March and resulted in the highest 2 m temperature in March averaged over all ERA5 grid points north of  $80^{\circ}$  N (latitude–weighted) for all days in March between since 1979 and 2022 (not shown). Simultaneously, the central region featured the largest-latitude–averaged IHT<sub>north</sub> and IVT<sub>north</sub> with a maximum of exceeded the previous maxima from 1996 ( $9.44 \cdot 10^{10} \,\mathrm{W m^{-1}}$  vs.  $9.32 \cdot 10^{10} \,\mathrm{W m^{-1}}$ , and  $388 \,\mathrm{kg m^{-1} s^{-1}}$ , respectively (Fig. 5).

Compared to climatological values, the latitude–averaged IHT<sub>north</sub> and IVT<sub>north</sub> show new records for the days between 07 March and 12 April, surpassing the previous records of  $9.32 \cdot 10^{10} \, \mathrm{W \, m^{-1}}$  and vs. 384 kg m<sup>-1</sup> s<sup>-1</sup> from 1996, respectively. The area–averaged IVT<sub>north</sub> over the central region also strongly exceeds the climatological 90<sup>th</sup> percentile with a maximum value of around  $230 \, \mathrm{kg \, m^{-1} \, s^{-1}}$  (Fig. 2a). It should be noted that this does not necessarily reflect the most intense MWAI during HALO–(AC)<sup>3</sup>, but only the strongest fluxes passing the central region.

While the mean 2 m temperature, Fig. 5). In some parts of the northern regionstarted to decrease on 15 March, the standard deviation in Fig. 3e indicates temperatures close to 0°C until 16 March. Beyond the one standard deviation, temperatures, near–surface temperatures were above freezing in some parts of the northern region. Thus, it is consistent that and even liquid precipitation was documented over the sea ice in the northern region (Fig. 3c, f, analysed in greater detail in Sect. 4.1). The northern region also showed the highest area–averaged daily precipitation on 13–16 March AR on 15–16 March also caused the highest daily precipitation of the northern region over the campaign period. In the central region, the area–averaged 2 m temperature was above freezing and a high fraction of rainfall to the total daily precipitation was found.

After the ARerossed Svalbard on 16 March, 2m temperatures in the measurement areas decreased while the wind turned to southwesterlies (Fig. 3c, d). Low pressure systems were dominating especially over the central and southern region so that precipitation further increased (Fig. 3f). The latitude–averaged IHT<sub>north</sub> and IVT<sub>north</sub> remained positive in the central region but were strongly reduced because the AR propagated eastwards and dissolved (Fig. 5). The moisture flux decreased faster than the heat flux, illustrating that the air masses behind the AR were-, much drier but still relatively warm but much drier.

On 19 March, one of the low pressure systems moved from the central Fram Strait to the eastern side of Svalbard. The resulting northerly off–ice flow over the northeastern Fram Strait led to slightly negative latitude–averaged IHTair followed, leading to a strong reduction in IVT<sub>north</sub> and IVTa slight reduction in IHT<sub>north</sub>, and thus a weak MCAO over the northeastern Fram Strait (Fig. 2b, 3a, and 5). Moreover, the large–scale pressure constellation was changing considerably since As a surface based high pressure system formed over Greenland, the large–scale pressure constellation started to change. However, at upper

levels, low geopotential persisted, promoting the formation of a strong low pressure system near Iceland on 20 March. The low quickly propagated towards the northeast and was characterized by rapid deepening (> 25 hPa core pressure decrease in 24 hours) and a frontal structure representative of a Shapiro–Keyser cyclone (Shapiro and Keyser, 1990). Unlike the Norwegian eyelone model, its warm front keeps circling around the centre, forming a warm core, instead of being caught up by the cold front (known as occlusion). On the eastern flank of the Shapiro–Keyser cyclone, IHT<sub>north</sub> and IVT<sub>north</sub> were similarly high indicate similarly strong fluxes as on 12 March (Fig. 5). However, as the moisture transport sufficiently dissipated before reaching the southern or central region, we did not classify this as an AR. Because of the low amount of heat in the cold air to the west of the Shapiro–Keyser cyclone, strongly negative IHT<sub>north</sub> was absent.

In the climatological perspective, the prevailing pressure gradient between Scandinavia and Greenland  $\div$  is reflected in the extremely strong gradient of the 500 hPa geopotential height anomalies (> 10 gpdm over Scandinavia, < -10 gpdm over Greenland, Fig. 6h)  $\div$  and was responsible for the associated warming. Moreover, we found positive temperature anomalies at 850 hPa of more than 7 K over the Fram Strait and up to 9 K over Scandinavia and around Franz Josef Land over the warm period ((northeast of Svalbard, Fig. 6b). At 2 m, the warming was amplified to more than 16 K above climatology over Franz Josef Land and more than 10 K over the Greenland Sea and Fram Strait (Fig. 6e). The bottom–amplified warming is consistent to the findings of Woods and Caballero (2016), confirming the reduction of the Arctic boundary layer inversion strength through intense MWAIs. Additionally, the high amounts of moisture carried by the ARs resulted in positive IWV anomalies of more than  $2 \text{kg m}^{-2}$  over the southern, central, and parts of the northern region (up to  $4 \text{kg m}^{-2}$  in the Norwegian and Greenland Seas, Fig. 6k).

## 3.1.2 Cold period

385

400

The intense On 21 March 2022, the Shapiro-Keyser cyclone, together with a strong high pressure system over Greenland, marked a turning point in the dominating weather conditions over all measurement areas at the beginning of the third campaign week (21–27 March 2022). Due to anomalously high pressure over Greenland (even exceeding the 90th percentile on some days between 21 and 31 March, not shown), a strong circulation pattern (Fig. 4c). Compared to the warm period, the zonal pressure gradient resulted over the Fram Strait, which caused northerly winds across the North Atlantic has been inverted. The resulting northerly winds caused negative IHT<sub>north</sub> and IVT<sub>north</sub> after the cyclone passed (Fig. 3d and 5). Although the sign of the pressure gradient remained until the end of the campaign (12 April), the position and strength of the synoptic—and meso—scale circulations changed over time. Figure 4e shows the position of the low pressure system and the advection of the cold air masses for 21 March. As Kolstad et al. (2009) showed, there is a connection between such a circulation pattern and the onset of MCAOs in that region.

With the high amounts of water vapour circled around the cyclone's centre, we found the strongest southward latitude—averaged  $IVT_{north}$  on the cyclone's western flank ( $-90 \, \mathrm{kg} \, \mathrm{m}^{-1} \, \mathrm{s}^{-1}$ , Fig. 5b). As the cyclone stayed over the Barents Sea while being filled up, it got access to cold, dry air from the sea ice covered Arctic Ocean, causing a quick reduction of absolute  $IVT_{north}$  values. The negative  $IHT_{north}$  and northerly winds associated with the cold air advection (Fig. 5a and 3d) favoured the development of an MCAO period. Convective cloud streets emerged over the Fram Strait as cold Arctic air masses were transported over

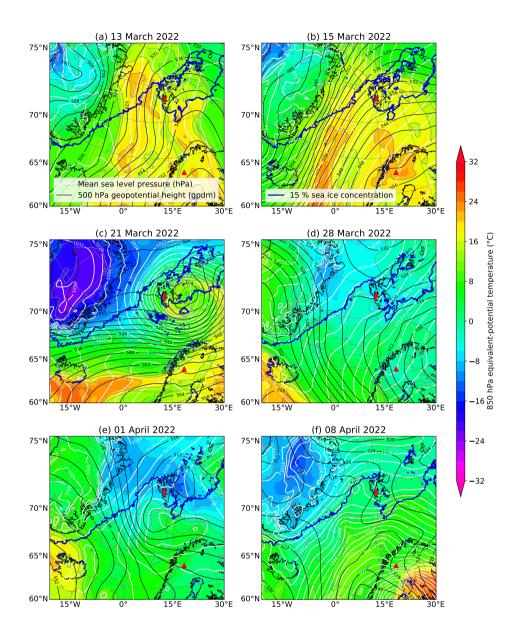

Figure 4. Maps of mean sea level pressure (white contour lines), 500 hPa geopotential height (black contour lines), and 850 hPa equivalent-potential temperature (shading and grey contours) from ERA5 data for representative days of the main weather conditions at 12 UTC. 13 March (a) and 15 March (b) represent the moist and warm air intrusions with AR characteristics, (c) shows the Shapiro–Keyser cyclone on 21 March that marked the beginning of the cold air outbreak period, 28 March (d) and 01 April (e) represent the persistent northeasterlies with varying cold air advection strength, and (f) features the Polar Low west of Svalbard on 08 April. The 15% sea ice concentration from AMSR2 (Spreen et al., 2008) is displayed as blue contour line.

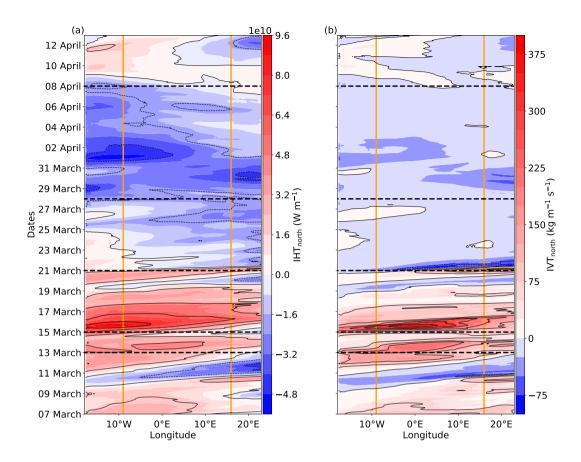

Figure 5. Hovmöller diagram of hourly vertically integrated meridional fluxes of (a) heat (IHT $_{north}$ ), and (b) moisture (IVT $_{north}$ ) during HALO–(AC) $^3$ , averaged over the central region latitudes. Positive (negative) values indicate northward (southward) fluxes. Orange vertical lines indicate the longitude boundaries of the central region. Important synoptic events shown in Fig. 4 are marked by horizontal dashed lines. Data is based on ERA5.

the relatively warm ocean. In all three measurement regions, the area-averaged 2m temperature including standard deviation remained below 0°C in the third campaign week until 07 April (Fig. 3c).

As the Shapiro–Keyser cyclone stayed over the Barents Sea while dissipating, IWV dropped to the lowest area–averaged values in the northern region (1.4–2.4 kg m<sup>-2</sup>, Fig. 3e). The moderate to strong MCAO conditions (5 K < M < 10 K) lasted for Two strong MCAO events were observed during the cold period. The first one lasted for almost the entire third campaign week , partly exceeding with a maximum M of 10 K, which exceeded the 90<sup>th</sup> percentile of the climatology (see Fig. 2b). Towards the end of the week, the MCAOs The second MCAO event occurred on 01–02 April and exceeded the 75<sup>th</sup> percentile with M up to 9 K. This event showed the minimum latitude–averaged IHT<sub>north</sub> of the campaign ( $-5.32 \cdot 10^{10}$  W m<sup>-1</sup>, Fig. 5) and did not reach the  $0.02^{th}$  percentile of the climatology.

Between the two strong MCAO events and after the second one, the MCAO conditions weakened (decreasing MCAO index 415 M) in the western Fram Strait due to increasing pressure decreasing pressure gradients and calming winds, which turned more towards easterlies =

The fourth week of the campaign (28 March – 03 April) was predominantly marked by a northeasterly and easterly flow ((Fig. 3d). While a high pressure system was still located over Greenland, a new anticyclone formed over the central Arctic and a low pressure complex developed over northwestern Russia (see Fig. 4d). The latter two systems advected Especially in the central region, the near-surface temperature increase (Fig. 3c) indicated the advection of relatively warm air masses from 420 different subpolar regions (partly through from several subpolar regions across the central Arctic) to the measurement areas. On their way north, the air masses were cooled over the sea ice covered Arctic Ocean. We classified this event as an . We classified these events as aged warm air period periods (Fig. 3a) during which we observed mainly three recurring patterns. First, the easterly winds over Svalbard resulted in cloud-free areas west of the island due to lee effects in the lee of Svalbard. Second, converging winds over the central Fram Strait led to increased convective cloud formation. Third, some cloud streets 425 developed in a narrow band over the Fram Strait in the westernmost ice-free area over the western Fram Strait due to a less disturbed off-ice flow. Both position and intensity of these patterns varied from day to day. Southward advection of On 05-06 April, the relatively warm air led to stronger southward heat and moisture fluxes (more negative IHTnorth and IVTnorth) between 27 March and 03 April compared to the week before (Fig. 5a). Averaged over the central region, IVT<sub>north</sub> was partly below the 430 25<sup>th</sup> percentile (Fig. 2a).

Another strong MCAO event (M up to  $9\,\mathrm{K}$ , exceeding the  $75^\mathrm{th}$  percentile) occurred on 01–02 April, associated with a weak eyelone that formed at the southern edge of Svalbard ahead of a trough in the  $500\,\mathrm{hPa}$  geopotential (Fig. 4e). Temporarily, it advected slightly colder air masses with more intense northerly winds compared to the days before (Fig. 3d). The intensified northerly winds resulted in the strongest southward latitude–averaged heat flux of the campaign (Fig. 5a). With a value of  $-5.32 \cdot 10^{10}\,\mathrm{W\,m^{-1}}$ , it is the  $99.8^\mathrm{th}$  percentile of the southward latitude–averaged heat flux climatology.

In the first half of the fifth campaign week (04–10 April), the weather conditions in the measurement areas were similar to the previous week. The large system of low 500 geopotential, which was responsible for the strong MCAO on 01–02 April, moved to northern Scandinavia and intensified. As a result, the main wind direction turned slightly more towards easterlies in the southern and central region. Consequently, the off–ice flow over the Fram Strait, and the southward heat and moisture fluxes weakened (IHT<sub>north</sub> and IVT<sub>north</sub> closer to 0, Fig. 5), reducing the MCAO activity. Gradually, 2m temperatures and IWV increased over all three measurement regions (Fig. 3c, e)was still present in the measurement regions, but the advection was weaker due to reduced horizontal pressure gradients. Therefore, we did not attribute these days to one of the weather classes defined in Fig. 3.

440

An upper–level trough reached the Fram Strait from the east on On 07 April, which led to another weak MCAO (Fig. 3a and 2b). Moreover, and the positive vorticity of the trough together with the MCAO an upper–level trough reaching Fram Strait promoted the formation of a mesoscale cyclone with features of a Polar Low (Fig. 4f, details in Sect. 4.3). The Polar Low caused slightly positive latitude–averaged IHT<sub>north</sub> as warm air was advected northward from the North Atlantic in the eastern Fram Strait, ending a period of consistently negative meridional heat fluxes (Fig. 5a). In the following two days, the Polar Low

moved to the northwest and dissipated over the sea ice northeast of Greenland<del>due to the loss of atmospheric instability and strongly reduced upward sensible and latent heat fluxes (Fig. 4f).</del>

450

460

465

475

480

Parallel to the evolution of the Polar Low, the \_ In parallel, a low pressure complex , whose core had moved to northern Seandinavia , formed a region of over Scandinavia advected warm and moist air advection in conjunction with a high pressure ridge over western Siberia. The moist air advection from Siberia , passing over southern Novaya Zemlya from Siberia towards the Norwegian Sea, led to . This air mass caused an increase of IWV above 10 kg m<sup>-2</sup> over parts of the southern region (Fig. 3e) . On the final days of the campaign and was advected northwards with a southerly upper–level flow in the following days (10–12 April), the moist air was advected northwards to the sea ice covered. The elevated moist air led to the formation of cirrus clouds over the western Fram Strait with a southerly upper–level flow (see also IHT<sub>north</sub> in Fig. 5a). Cirrus clouds observed during research flights (see (see Sect. 4.4)indicate the moist air at high altitudes. However, the corresponding large–scale circulation pattern during these days was not clearly attributable to one of the event classes we defined.

Overall, the period of pronounced MCAO activity lasting from 21 March to 12 April  $\frac{2022}{\text{(as indicated by almost exclusively}}$  M > 0 K, Fig. 2b) reflects much more the typical, elimatological much better reflects the typical state of the central region than the previous MWAI eventspreceeding warm period. Climatologically, the full period from 07 March to 12 April entire campaign period is characterized by weak MCAO conditions (M between 1 and 3 K). With a duration of 5–6 days, the first HALO–(AC)<sup>3</sup> MCAO period (21–26 March) was slightly longer than the mean duration of MCAO events  $\frac{(3-4)}{4}$  days, see Terpstra et al., 2021)

(3-4 days, Terpstra et al., 2021). During the cold period, negative the 500hPa geopotential height anomalies (and low surface pressure) were located were negative over Scandinavia and northwestern Russia, and positive geopotential height anomalies (and high (coinciding with low surface pressure), and positive over the central Arctic and Greenland (coinciding with high surface pressure, Fig. 6i). The persistence of the northerly winds due to the this anomalous pressure constellation during the cold period explains the longevity of the MCAO conditions. Negative temperature anomalies at 2m and at 850 hPa were found most prominent in the central Fram Strait, Norwegian Sea and parts of the Greenland Sea, which were affected by the cold air advection (Fig. 6c, f). Reduced IWV compared to the climatology overlaps well with the negative 850 hPa temperature anomalies (Fig. 6l). The Arctic Ocean north of Greenland and the central Fram Strait featured the strongest negative 2m temperature anomalies with -5.5 K and -4.5 K, respectively. Positive temperature anomalies at 850 hPa were restricted to regions that were not affected by cold air advection (central Arctic, eastern Barents Sea). Interestingly, the central Arctic Ocean showed negative temperature anomalies at 2m and positive anomalies at 850 hPa, suggesting enhanced static stability compared to the climatological mean (Fig. 6c, f). In the This area also shows slightly positive subsidence anomalies at 850 hPa (not shown). In contrast, the static stability is reduced in the area between Svalbard and Franz Josef Land, the opposite applies (with positive anomalies at the surface, and negative anomalies at 850 hPa). In the central Arctic, where the temperature anomalies at different height levels cancel each other out, we found only slightly negative IWV anomalies (Fig. 6l).

## 3.1.3 Climatological assessment of the full HALO-(AC)<sup>3</sup> period

The 2m temperature anomalies for the entire HALO-(AC)<sup>3</sup> period (07 March-12 April) were positive in most regions shown in Fig. 6d. Only in the central Fram Strait and north of Greenland negative 2m temperature anomalies down to -1.2K and -2.4K, respectively, were found, coinciding with the regions of strongest negative 2m temperature anomalies during the cold period. Over Slightly positive 2m temperature anomalies over the sea ice in the western Fram Strait, 2m temperature anomalies were slightly positive, indicating indicate that the extremely positive anomalies of > 8K of during the warm period were not completely balanced out by negative anomalies during the longer cold period (Fig. 6d-f). Temperature anomalies at 850hPa were positive in all regions shown in Fig. 6. The strongest anomalies with 2-3.5K were located in found over the central Arctic Ocean and northern Barents Sea, coinciding with the regions where of positive 850hPa temperature anomalies were positive in during the cold period (Fig. 6a, c). Positive temperature anomalies combined with high surface pressure over Scandinavia (central Arctic) in the warm (cold) period resulted in overall positive 500hPa geopotential height anomalies over these regions (Fig. 6g). Geopotential height anomalies at The lowest 500hPa were only close to 0 geopotential height anomalies were located over the east coast of Greenland, where low geopotential also remained during the first part of the cold perioddespite high surface pressure due to extremely low temperatures.

Over the central region, we found small northward heat fluxes (IHT $_{north}$  of  $5.4 \cdot 10^8 \, \mathrm{W \, m^{-1}}$ ) and moisture fluxes (IVT $_{north}$  of  $18 \, \mathrm{kg \, m^{-1} \, s^{-1}}$ ). Consequently, the thermal energy input into the Arctic through this pathway was slightly positive and the brief but intense MWAIs / ARs overcompensated the long MCAO period. Similarly, the dry air masses associated with the MCAOs were not sufficient to balance out the extreme moisture transport related to the MWAIs / ARs during the warm periodIn previous years, IHT $_{north}$  and IVT $_{north}$  were often smaller or even negative over the campaign days and the central region.

# 3.2 Ny-Ålesund

485

490

495

500

505

The extensive remote sensing observations at Ny-Ålesund, with its fixed location in the northwest of Svalbard, adds a Eulerian view to the synoptic events described above. Describing the relationship between the weather conditions in the may complement the airborne observations during HALO–(AC)³regions and. However, Ny-Ålesund helps to find the context in future studies that might include the additional observations at Ny-Ålesund. The is located at the eastern edge of the central region and measurements may be influenced by the local orography. Based on the temperature profiles (Fig. 7a), the atmospheric conditions at Ny-Ålesund were also can also be divided into a warm (11–21 March) and a colder period (22 March–12 April), which is shifted by one day compared. Compared to the full central region(Fig. 7). , this indicates a temporal shift of one day.

The warm air advection related to the first AR led to an increase of 2m temperature from about  $-14\,^{\circ}$ C to  $+2\,^{\circ}$ C within 19 hours (meteorological tower measurements, not shown). As a consequence of high surface pressure (>  $1010\,h\text{Pa}$ ), and high temperatures and moisture load (IWV>  $10\,k\text{g}\,m^{-2}$ , Fig. 7b), the troposphere extended up to a tropopause height up Vertical advection of heat and moisture lifted the tropopause to 12.9km (measured by the 12 UTC radiosonde on 12 March, Fig. 7a). Lower surface pressure resulted in reduced tropopause heights on 15–16 March although the highest temperature and humidity

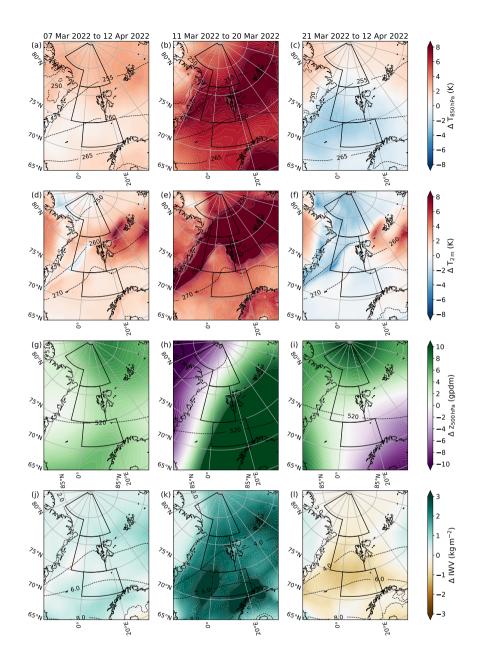

Figure 6. Anomaly maps of (a–c) temperature at  $850\,hPa~(\Delta T_{850\,hPa})$ , (d–f)  $2\,m$  temperature ( $\Delta T_{2\,m}$ ), (g–i) geopotential height at  $500\,hPa~(\Delta Z_{500\,hPa})$ , and (j–l) vertically integrated water vapour ( $\Delta IWV$ ) based on ERA5 for the entire campaign, the warm, and the cold period in the left, middle, and right column. The coloured contours show the long—term mean subtracted from the mean of the time period in 2022 so that positive (negative) values correspond to anomalies above (below) the long-term mean. The dashed black isolines describe the long—term climatology in each panel. The three measurement regions (shown in Fig. 1) are illustrated as black boxes.

were observed on these days (IWV of 14.5 kg m<sup>-2</sup> on 15 March at 18 UTC, Fig. 7b). The 2 m temperature remained above freezing for five days and even reached a new record high temperature for all days of maximum for March on 15 March (5.5 °C). On this day, also the highest IWV was observed (14.5 kg m<sup>-2</sup>, Fig. 7b).

The warm period was characterized by constant low-level cloud cover over Ny-Ålesund detected by the ceilometer, interrupted only by a few hours of high-level cloud occurrence in connection with a high pressure ridge passing the site in the night of 14–15 March (not shown). The situation changed during the course of 17 March, when the cloud deck started to dissolve and the 2 m temperature dropped below 0 °C.

The influence of the Shapiro–Keyser cyclone (see Sect. 3.1) delayed the beginning of the cold period over Svalbard compared to the central region by about one day. Northerly winds corresponding to the MCAO period led to extremely dry conditions with IWV down to  $1.1 \,\mathrm{kg} \,\mathrm{m}^{-2}$  (closest grid point in ERA5 with land–fraction < 0.25:  $1.5 \,\mathrm{kg} \,\mathrm{m}^{-2}$ ) on 24 March at 06 UTC (Fig. 7b), which. This IWV is below the 3<sup>rd</sup> percentile of all radiosondes between 07 March and 12 April 1993–2022 (Maturilli and Kayser, 2016, 2017; Maturilli, 2020b). At Ny–Ålesund, the MCAO conditions between 23 and 29 March on 23–30 March, and on 01–05 April were mostly associated with clear sky and 2m temperatures below —15°C—12°C. Aged warm air reached Ny–Ålesund on 28–28–29 March with more humidity, increasing IWV up with slightly higher temperatures and IWV increasing to  $4 \,\mathrm{kg} \,\mathrm{m}^{-2}$ . After the subsequent stronger MCAO on 01–02 April, clear sky conditions due to orographic lee effects (foehn) associated with the calm easterly winds persisted until 05 April.

Generally, the Ny-Ålesund observations provide a ground based view on the atmospheric events that occurred in the Svalbard region during HALO-(AC)<sup>3</sup>. Because of orographic effects especially in Especially during the cold period, the perspective of cloud conditions at Ny-Ålesund is are not representative for the entire central region, and much less for the southern and northern regionscentral region because of lee effects as visible on MODIS images (e.g., NASA Worldview, not shown). Additionally, the temporal delay related to the propagation of synoptic systems from other areas to Ny-Ålesund during the warm period must be kept in mind when considering other observations from combining Ny-Ålesund in relation to with HALO-(AC)<sup>3</sup> in future studies observations.

## 3.3 Sea ice conditions

520

525

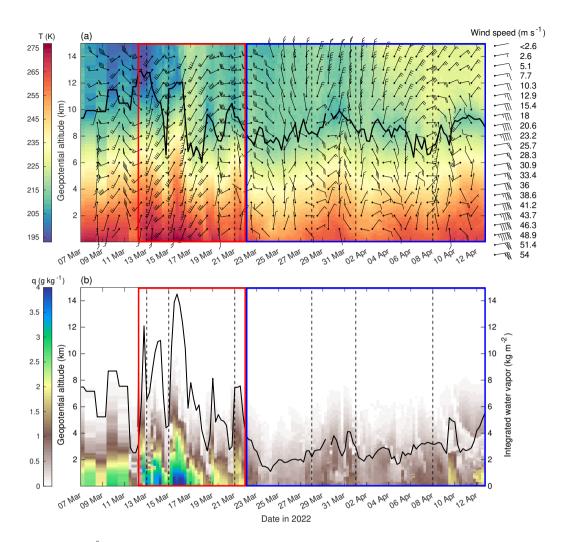

530

535

545

The different synoptic patterns changed affected the sea ice conditions in the measurement areas. In Fig. 8a–c, we present the spatial distribution of SIC for three selected time periods. We selected before (09–11 March, ) and during (14–16 March, and 10–12 April 2022 to show SIC before and during the MWAIs March) the MWAIs, as well as after the MCAO period (10–12 April). SIC was > 90% in almost the entire northern region in the first period (Fig. 8a). In the central region, this was true for about the sea ice covered 30–40% of the area with a southwest–northeast oriented sea ice edge, approximately from the lower left to the upper right corner of the boxedge. The southern region was almost completely ice–free over the entire campaign duration (Fig. 8a–c). A time series of SIC for the central region compared to the climatology is shown in Fig. 8d.

The MWAI / AR events on 12–13 and 15 March showed a clear impact on the sea ice due to a caused a reduction of SIC in the northwestern part of the central region, resulting in the lowest values of the entire campaign period (Fig. 8b). Averaged over the central region, SIC reached its minimum for the campaign duration, which is , d). SIC was below the climatological

**Figure 7.** Time series of Ny-Ålesund radiosondes of (a) temperature profiles (shading), height of thermal tropopause (black line), and wind barbs in selected levels, and (b) specific humidity profiles (shading) and resulting IWV (black line, right axis). Vertical dashed black lines indicate the days shown in Fig. 4. The red (blue) box indicates the shifted warm (cold) period.

mean but within the 10–90<sup>th</sup> quantiles percentiles. Furthermore, an unusually large polynya opened from north of Svalbard to Franz Josef Land, which resulted in the below-average static stability during the cold period in this region (Fig. 8db). We assume that ice dynamics related to strong winds caused the SIC decrease, but ice melt cannot be excluded as well because temperatures were above freezing and liquid precipitation was observed over sea ice. Rapid ice melt has been attributed to warm air advections and induced increases of heat flux in summer (Tjernström et al., 2015; Woods and Caballero, 2016). After the two AR events, an unusually large polynya opened from north of Svalbard to Franz Josef Land (Fig. 8b). Although the liquid precipitation on snow alters the signal of the microwave radiometry and might have increased the uncertainty of the

550

SIC product (Stroeve et al., 2022; Rückert et al., 2023), that SIC reduction was obvious in visual satellite images as well (e.g., NASA Worldview, not shown). The events during HALO–(AC)<sup>3</sup> and the wealth of measurements on water vapour, clouds and precipitation are thus an interesting case for future research about the interplay of atmosphere and sea ice and the role of strong MWAIs and ARs on SIC during springtime.

After the AR events, the sea ice conditions recovered and the polynya closed again (Fig. 8c, d) mostly due to sea ice transport from the central Arctictowards the Fram Strait. Also the large polynya between Svalbard and Franz Josef Land was closed again (Fig. 8c). The . This southward transport can be attributed to the winds during the high MCAO activity between 21 March and 07 April, where northerly and northeasterly winds and near-surface temperatures below freezing dominated.

560

575

For most of the campaign timeperiod, the average SIC in the central region was higher compared to the climatology above the climatological mean (Fig. 8d).

We found less SIC with respect to the climatology south A map of SIC anomalies compared to the climatological mean is illustrated in Fig. 8e. Southwest of 75° N and west of 0° E as well as northeast and southeast of Svalbardand a higher SIC in the central and western Fram Strait (Fig. 8e). The , SIC anomalies were negative. In contrast, a positive SIC anomaly was found in the central and western Fram Strait, which overlaps well with the negative 2 m temperature anomalies seen shown in Fig. 6d, f. During HALO (AC)<sup>3</sup>, there was no sea ice at the The west coast of Svalbard, an area that according to the climate data record used to be covered by some ice, on average. For ice in the climatology but was completely ice—free during HALO (AC)<sup>3</sup>. In the northern and southern regions, the mean SIC for the entire campaign period did not differ more than 5% on average compared to from the climatological mean.

Note that uncertainties in the marginal ice zone are especially large due to weather related filters and as a result of temporal and spatial interpolations. This mainly affects the area of the central region where the estimated uncertainties provided with of the SIC product (total standard uncertainty) can reach up to 40% at the ice edge, mostly due to smearing uncertainty (gridding of the swaths, i.e., areas imaged on the surface, from several daily overflights), and different satellite footprints at different frequency channels.

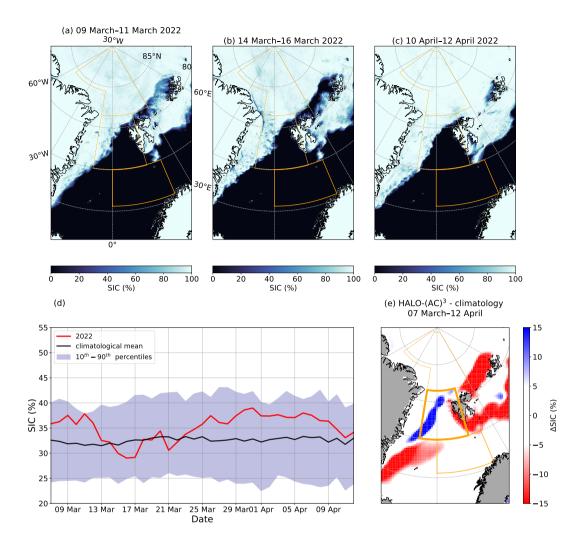

Figure 8. Average sea ice concentration (SIC) for two three-day time periods during from the HALO-MODIS-AMSR2 product at 1km grid resolution for (AC)<sup>3</sup> campaign: (a) 09–11 March (prior to the first AR event), (b) 14–16 March (during the second AR event), (c) 10–12 April (at the end of the campaign). Data is from the MODIS-AMSR2 product at 1km grid resolution. (d): SIC time series averaged over the central region for HALO-(AC)<sup>3</sup> the campaign period, as well as the mean, and 10–90<sup>th</sup> percentiles of the 1979–2022 climatology. (e): Time-averaged SIC anomalies from the climatological mean averaged over the entire campaign period. Note that here only differences larger 5% are considered due to the uncertainties of the satellite product in the marginal ice zone. Data for (d) and (e) is from the OSI–SAF sea ice concentration climate data record Copyright © 2018 EUMETSAT.

## 4 Specific events during HALO-(AC)<sup>3</sup>

590

605

610

## 4.1 Warm air intrusions and Atmospheric Rivers

The first two campaign weeks were warm period was characterized by four independent AR events (12–13 March, 14 March, 15 March, and 20 March) that were at least partly sampled by research aircraft in the three measurement regions. Back trajectory analyses with LAGRANTO (Sect. 2.4.5) revealed that the air masses of the 12–13 March event (Fig. B1a) originated from midlatitude regions of the North Atlantic and from central Europe (Fig. C1a). For the second AR event on 15 March (Fig. B1b), the air masses originated almost exclusively from the western part of the mid–latitude North Atlantic (Fig. C1b). Maximum IVT (meridional and zonal) exceeded 400 kg m<sup>-1</sup> s<sup>-1</sup> between 13 We neglect the ARs on 14 and 16 March in the central region (see Appendix B, Fig. B1).

Apart from these major MWAIs in conjunction with ARs, two more remarkable events of moisture transport were identified. The first one was associated with the Shapiro–Keyser cyclone (Sect. 3.1) and approached our region of interest on 20 March with a maximum IVT exceeding 500 kg m<sup>-1</sup> s<sup>-1</sup>. The Shapiro–Keyser cyclone, however, steered the AR away from the sea ice edge to the southeast of Svalbard and dissipated sufficiently before entering the southern or central region. The second moisture transport event, associated with the low pressure complex over Scandinavia from 08 to as they did not enter the central region, but either propagated northwards to the west of it or dissipated before reaching it. The moist air advection event on 10 April, was confined to the southern region and much more zonally oriented but (Fig. C1c) was too weak to be detected as AR but was relevant for the formation of cirrus clouds over sea ice.

We compare the strength of AR events during HALO-(AC)<sup>3</sup> by analysing them with respect to the relation between IVT and latitude over the North Atlantic and Arctic Ocean (50–90° N, 60° W–40° E) (Fig. 9). Note that a different region was selected to extend the view on the North Atlantic, one of the major pathways of ARs (Guan and Waliser, 2017; Nash et al., 2018). Along their northward propagation, ARs generally decline in intensity. If otherwise ARs start to form in the Arctic, their moisture supply is reduced so that their intensification is limited (Papritz et al., 2021). Therefore the number of strong AR events decreases meridionally –(Fig. 9).

North of 70.6° N (southern boundary of the southern region), only few ARs exceed an IVT of  $250 \,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$  when averaged over the detected AR area (Fig. 9). In the climatology, the majority has mean values around  $150 \,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$ . The AR events on 12–13, and 15 March represent strong cases in terms of mean IVT for all time steps as they lie outside the  $25^{th}$  percentile in latitude–IVT space (Fig. 9). On 15 March at 18 UTC, the AR averaged IVT even exceeded the  $10^{th}$  percentile while being centered at  $76^{\circ}$  N. While the AR centre from the event on 12–13 March was located most northerly before it dissipated, the AR from 15 March was characterized by the most intense moisture transport with mean IVT of around  $250 \,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$  when centered at  $70^{\circ}$  N, decreasing to  $200 \,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$  at  $75^{\circ}$  N. Maximum IVT (meridional and zonal) slightly exceeded  $400 \,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$  between 13 and 16 March in the central region (see Appendix B, Fig. B1). HALO's dropsonde measurements showed a maximum IVT of  $490 \,\mathrm{kg}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$  on 15 March, suggesting that ERA5 underestimates the moisture flux. As these AR events had meridionally elongated structures, the outflow region reached up to the central Arctic while their centres were

located at 70–78° N (Fig. 9). During their poleward propagation, the moisture transport decreased so that they no longer fulfilled the detection requirements.

The AR events in the warm period were associated with anomalous amounts of precipitation. In Fig. 10, we show the hourly averaged precipitation rate from 11 to 20 March 2022 as well as for the same days of the climatology. Further, the fraction of the precipitation rate in 2022 to that in the climatology is illustrated climatology of these days. Along the east coast of Greenland, the total precipitation and snowfall rate partly exceeded  $1 \, \mathrm{mm} \, \mathrm{h}^{-1}$  (Fig. 10a, d), around six times higher compared to climatology (Fig. 10c, f). Over the North Atlantic, Fram Strait, and central Arctic Ocean, total precipitation and snowfall rates exceeded the climatology by a factor of 3. In parts of the Norwegian and Barents Seas, total precipitation and snowfall rates were below the climatological mean. Record breaking rainfall rates were found northwest of Svalbard, exceeding the climatology up to a factor of 36 (Fig. 10i). However, the actual rainfall rate in this area was below 0.25 mm h<sup>-1</sup> and the high deviation is caused by even lower rainfall rates in the climatology. Liquid precipitation over sea ice was also observed by the cloud radar onboard HALO during research flights.

In summary, the ARs observed during HALO–(AC)<sup>3</sup> featured uncommonly high AR–averaged IVT values, higher than 90% of all ARs in the climatology. Additionally, record breaking rainfall rates occurred over the sea ice northwest of Svalbard.

## 4.2 Marine cold air outbreaks

620

625

630

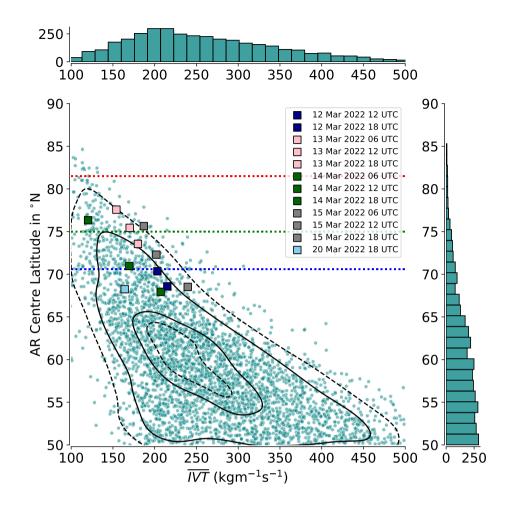

635

640

The cold period included several MCAO events (21 March–07 April), which are analysed in detail specifically for the central region. Figure 11 shows the time series of atmospheric conditions as described in Sect. 2.4.3. To highlight the conditions in the MCAOs' source region, we also include the temporal evolution of the parameters averaged over the northern region (without extension to the west) eastern part of the northern region in Appendix D (Fig. D1). The corresponding temporal development over the southern region is shown in Fig. D2 in Appendix D.

After the Shapiro–Keyser cyclone, which caused multi–layered clouds and intense snowfall on 21 March at the west coast of Svalbard (Fig. 11d–g), MCAO conditions were established. From 22 to 26 March, the contribution of convective to total snowfall increased over open water and mid– and high–level cloud cover decreased. Over sea ice, the total snowfall was low and almost exclusively stratiform. Liquid precipitation was not present except for 21 March. Low–level cloud cover remained high until 07 April, reflecting the presence of the atmospheric boundary layer clouds typically associated with MCAOs (Fig. 11d). However, some parts of the open water regions of the central region were not fully covered by low–level clouds as the 5% percentile was mostly between 0.2–0.4.

The strong MCAO events (21–26 March and 01–02 April) were characterized by the strongest northerly lower tropospheric winds and high values of domain–averaged turbulent fluxes of sensible and latent heat flux (Fig. 11a, h). The maximum values of sensible and latent heat coincided with the highest wind speeds and low temperatures (21–22 March, Fig. 11a, b, h). Note that over the southern region the sensible heat fluxes were slightly lower, whereas, on average, latent heat fluxes were higher than over the central region (Fig. D2). One possible explanation is that the lower tropospheric air temperature Near–surface air temperatures increased towards the south. Hence, resulting in smaller sensible heat fluxes would become smaller while the while latent heat fluxes would increase were increased due to a rising saturation water vapour pressure at the air–sea interface

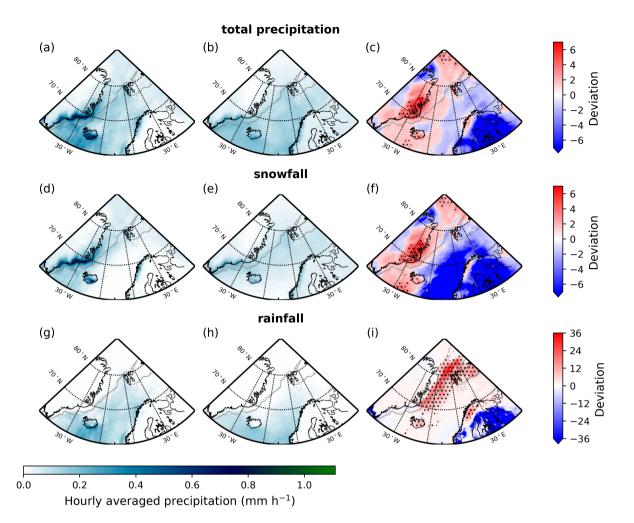

**Figure 9.** Six hourly climatological (1979–2022) distribution of central latitudes of Atmospheric Rivers (ARs) as a function of mean AR IVT using an ERA5 based AR catalogue modified from Guan and Waliser (2015). Cases categorized as ARs during HALO–(AC)<sup>3</sup> are illustrated by coloured boxes for 06, 12, and 18 UTC of respective flight days. Black (dashed) lines indicate the 25<sup>th</sup> and 75<sup>th</sup> (10<sup>th</sup> and 90<sup>th</sup>) percentiles of a kernel density estimation to visualize the shape of the histogram. Horizontal dotted **grey**-lines indicate the latitude boundaries of the three measurement regions (Table A1Fig. 1) in the same colours as in Fig. 3.

645 (e.g., Hartmann et al., 1997). We found that larger differences between the specific humidity of the air and specific humidity at saturation in the southern compared to the central region were responsible for the increased latent heat fluxes (not shown).

During the weak MCAOs and aged warm air periods, northeasterly winds dominated (Fig. 11a). Compared to strong MCAO conditions, sensible heat fluxes were reduced by a factor of 2 while latent heat fluxes decreased to a lesser extent. Between 27–30 March and 03–05 April, when aged warm air was advected to the central region, precipitation decreased as the air mass dried and temperatures increased (Fig. 11b, c, g). Also, foehn effects due to the easterly winds over Svalbard might have contributed to drier and warmer conditions over parts of the Fram Strait as this effect can influence the atmospheric conditions

650

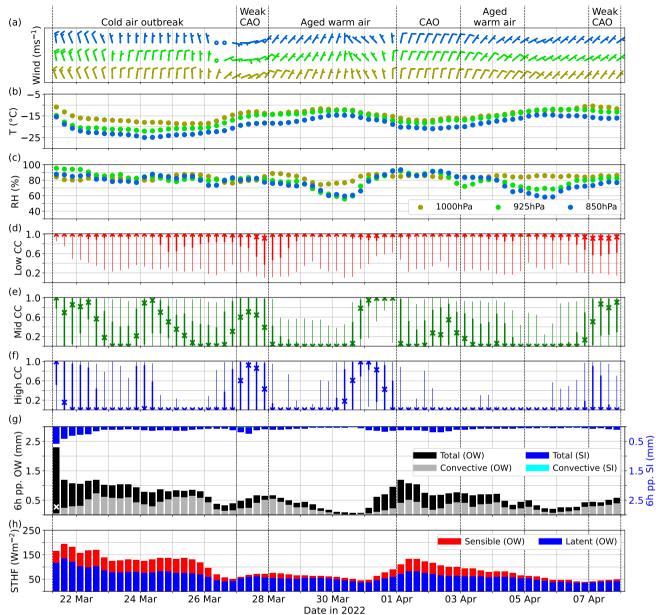

**Figure 10.** Hourly averaged precipitation, snowfall and rain rate  $(mmh^{-1})$  derived from ERA5 for (a, d, g) 11–20 March 2022, and (b, e, h) the climatology. In (c, f, i), we show the deviation from the climatology. Note that the rainfall over sea ice is barely visible in both (g) and (h). Positive deviations of precipitation rates are illustrated as the fraction of the average rate in 2022 to the rate of the climatology while negative deviations are given as its inverse.

more than 100 km off the coast (Shestakova et al., 2022). The eastern parts of the central region close to Svalbard were not fully covered by low–level clouds as the 5% percentile was mostly between 0.2–0.4. For the first aged warm air period, the southward advection of the air masses from the sea ice covered ocean took about one day. This can be seen when comparing the temporal evolution of the lower tropospheric temperature and relative humidity over the northern and central regions (e.g.i.e., low relative humidity from 29 to 30 March, Fig. D1a–c vs. 11a–c).

655

From 05 April on, the mean wind speed decreased and turned to northeast. Hence, more convergent regions developed in the lee of Svalbard with a rather diffuse low–level cloud structure (not shown). These converging winds in combination with a

**Figure 11.** Temporal evolution of (a) wind, (b) air temperature (T), and (c) relative humidity (RH) on the 1000, 925, and 850 hPa pressure levels, and of (d) low–, (e) mid–, and (f) high–level cloud cover (CC), (g) precipitation, and (h) surface turbulent heat fluxes (STHF, upward is positive) over the central region for 21 March – 07 April 2022 derived from ERA5. For cloud cover, we show the median, the 25 and 75<sup>th</sup> percentiles, and the 5 and 95<sup>th</sup> percentiles of a 6 hour interval over open–water surfaces only as crosses, thick vertical lines, and thin vertical lines, respectively. In (g), we display area–averaged values of the accumulated 6 hour snowfall distinguished between convective and total precipitation, and open water (OW) and sea ice (SI). White crosses show the accumulated mean rainfall with more than  $0.05 \, \text{mm} \, (6 \, \text{h})^{-1}$ .

weak MCAO promoted the formation of a mesoscale eyelone Polar Low in the following days, which is explained in greater detail in the next section.

During HALO-(AC)<sup>3</sup>Hence, different wind regimes and strengths of MCAOs were observed. MCAO strength lied partly outside the 90<sup>th</sup> percentile, partly well within the interquartile range of the climatology. Wind regimes ranged from northwest to northeast with different intensity, ranging from northwest to northeast and MCAO strengths were observed during HALO-(AC)<sup>3</sup>. The large variety of MCAO conditions provides great opportunities for detailed cloud evolution and air mass transformation studies.

## 4.3 Polar low

660

665

675

680

685

690

The Polar Low formed on 07 April close to the west coast of Svalbard at a baroclinic zone where cold air transported by north to northeasterly winds converged with warmer North Atlantic air from south to southeasterly windson 07 April, forming a baroclinic zone. During the development phase of the Polar Low, the mean sea level pressure showed closed isobars from 08 April 2022 00 UTC on (Fig. 4f). We examine which environmental conditions for the Polar Low formation set by Radovan et al. (2019) were fulfilled. The conditions whether the environmental conditions C1–C6 explained in (see Sect. 2.4.4and Table 1 are checked) were fulfilled in a 200 km radius around the mean sea level pressure minimum of the Polar Low at that time (Fig. 12):

The vertical temperature gradient conditions C1 and C2 are fulfilled with 44 K and 8.5 K, respectively, while the lapse rate condition (C3) was not fulfilled with 4.2 K km<sup>-1</sup>. Conditions C4<sub>i</sub> and C4<sub>ii</sub>, which are a measure for the availability of moisture for latent heat release, exceed the thresholds of 75% and 82% with 92.7% and 93.9%. Near surface wind gusts reached 16.6 ms<sup>-1</sup> during the development phase of the Polar Low (00 UTC), which was sufficient to fulfill condition C5. They and increased to 18.8 ms<sup>-1</sup> 9 hours later when the Polar Low was in its at the mature stage. In both stages, condition C5 was fulfilled. If we considered the maximum of the 10m wind speed instead of the gust from ERA5in the 200 km circle, the condition would not have been fulfilled. However, using the Copernicus Arctic Regional Reanalysis (CARRA) from ECMWF with a 2.5 km×2.5 km resolution, we fond found maximum wind speeds of more than 16 ms<sup>-1</sup> (19 ms<sup>-1</sup>) at 00 UTC (09 UTC). The trough connected to the Polar Low was not sufficiently strong with respect to the climatology as the geopotential height anomaly (C6) was only -80 gpm. Anomalously high geopotential around Svalbard and the central Arctic during that time might have obscured the strength of the trough, resulting in the failure of condition C6.

Some of the conditions had a large regional variability within the 200 km circle. Condition C2 ranged from below the threshold of 6K in the southern part of the Polar Low to 10K in the northern half. As the northwestern part of the circle lied lay over sea ice, the vertically averaged lower tropospheric lapse rate (C3) indicated stable stratification and reached values up to  $10 \, \mathrm{K \, km^{-1}}$ . These high values of the lapse rate dominated the computation of the 75th percentile although the lapse rate was below the threshold in most parts of the circle.

At the mature stage (08 April 06–09 UTC), the region of maximum SST –  $T_{500\,hPa}$  difference coincided well with the observed convective clouds during the research flight with HALO in the eastern part of the Polar Low (see Appendix E, Fig. E1). It also overlapped with the maximum precipitation rate indicated by ERA5 with (1.2 mm h<sup>-1</sup> (not shown). Wind gusts

**Table 1.** Criteria to evaluate environmental conditions of a Polar Low in a 200 km radius around its pressure minimum according to Radovan et al. (2019). An "X" in the right column indicates that the condition is fulfilled.

Condition	Meaning	How evaluated	Threshold	Fulfilled
<u>C1</u>	Sea surface temperature — 500 hPa temperature	75 <sup>th</sup> percentile	≥43 K	X
<u>C2</u>	Sea surface temperature — 2 m temperature	75 <sup>th</sup> percentile	<u>≥6K</u>	X
<u>C3</u>	Mean lapse rate below 850 hPa	75 <sup>th</sup> percentile	$\leq 3 \text{K km}^{-1}$	
$\underbrace{\mathbf{C4_{i}}}$	Mean relative humidity below 950 hPa	75 <sup>th</sup> percentile	≥75%	X
$\underbrace{C4}_{ii}$	Mean relative humidity between 850 and 950 hPa	75 <sup>th</sup> percentile	≥82%	X
<u>C5</u>	10 m wind gust	maximum	$\geq 15 \mathrm{ms}^{-1}$	$X_{\sim}$
<u>C6</u>	500 hPa geopotential height anomaly	mean	<u>≤ −160 gpm</u>	

peaked at 18.8 ms<sup>-1</sup> and were therefore stronger than during the development phase. ERA5 data also show updrafts of and strongest updrafts (-1.75 Pa s<sup>-1</sup> at 850 hPain the northeastern half of the Polar Low (northwest to southeast) and slight descending motion in the centre) indicated by ERA5 (not shown). It is likely that higher precipitation rates and updrafts occurred that were smoothed out by the relatively coarse ERA5 data.

Dropsonde measurements between 06:55 and 07:53 UTC show high values of relative vorticity in the lowest 2 km and above 6 km, indicating cyclonic rotation. When averaging ERA5 vorticity over the grid points closest to the dropsonde positions, we find a disagreement to the dropsonde measurements below and good agreement above 4 km height. While the lower tropospheric relative vorticity is related to the Polar Low, the upper tropospheric value is associated with the trough in the geopotential height. The disagreement between ERA5 and the dropsondes could be due to a misrepresentation of the Polar Low's wind field in the reanalysis or due to spatio–temporal mismatches of its position. Measured relative vorticity at 850 hPa (1.5 km height) was about  $3.5 \cdot 10^{-5} \text{ s}^{-1}$  and therefore did not exceed the threshold suggested by Stoll (2022) (>  $20 \cdot 10^{-5} \text{ s}^{-1}$ ). However, the flight track did not perfectly align was not perfectly aligned with the Polar Low's centre and but extended too far to the south and east of the Polar Low where the mean sea level pressure isobars do not suggest a closed circulation (Fig. 13b). Negative relative vorticity to the east of the Polar Low, which is related to lee effects, also influenced the calculation from the dropsonde measurements. ERA5 data shows a maximum of  $22 \cdot 10^{-5} \text{ s}^{-1}$  at 850 hPa within the Polar Low on 08 April at 09 UTC.

As soon as the Polar Low drifted over sea ice, it started to dissipate due to the loss of atmospheric instability and strongly reduced upward sensible and latent heat fluxes. The Polar Low observed during HALO–(AC)<sup>3</sup> fulfilled four of the six conditions (see Table 1). However, Polar Lows can also form without fulfilling all conditions. According to Considering the climatology of Polar Lows in Zahn and von Storch (2008), which covers the years 1949–2005, our Polar Low was located unusually far in the north. Also Radovan et al. (2019) investigated 33 Polar Lows with the Arctic System Reanalysis, of which 32 were centered further to the south than our case. Despite its northerly position, the 10m wind speed of our Polar Low was larger than the average over the 33 Polar Lows investigated in their study.

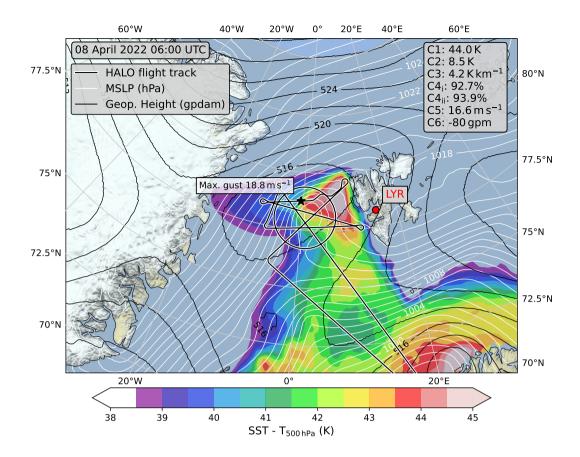

Figure 12. Mean sea level pressure (MSLP, white contour lines),  $500\,\mathrm{hPa}$  geopotential height (black contour lines), and the difference between sea surface temperature (SST) and  $500\,\mathrm{hPa}$  temperature during the mature stage of the Polar Low on 08 April 2022 06:00 UTC. Additionally, the maximum  $10\,\mathrm{m}$  wind gust at 09:00 UTC (black star and text label) and the HALO flight track (black line with white outline) are included. The Polar Low conditions C1 (SST  $-500\,\mathrm{hPa}$  temperature), C2 (SST  $-\mathrm{T_{2\,m}}$ ), C3 (vertical mean of the vertical potential temperature gradient below  $850\,\mathrm{hPa}$ ), C4 (i: mean relative humidity below  $950\,\mathrm{hPa}$ , ii: mean relative humidity between  $850\,\mathrm{and}$   $950\,\mathrm{hPa}$ ), C5 (maximum  $10\,\mathrm{m}$  wind speed), and C6 ( $500\,\mathrm{hPa}$  geopotential height anomaly) analysed by Radovan et al. (2019) are given for  $08\,\mathrm{April}$  2022  $00:00\,\mathrm{UTC}$ . Data is based on ERA5.

## 4.4 Arctic cirrus over sea ice

720

The sequence of HALO flights between 10 - 12 April  $\frac{2022}{2022}$  aimed to characterize a pronounced field of Arctic cirrus, which entered the central Arctic through the Fram Strait and was finally located close to the North Pole. The initial synoptic state of this period was dominated by a low pressure system, which was centered over Scandinavia on 09 April, advecting warm and moist air westwards (see Sect. 3.1). Along approximately the  $5^{\circ}$  W meridian the westward flow converged with a cold air mass that formed over the Greenland ice sheet and flowed eastwards into the Fram Strait. Due to the convergence, a strong

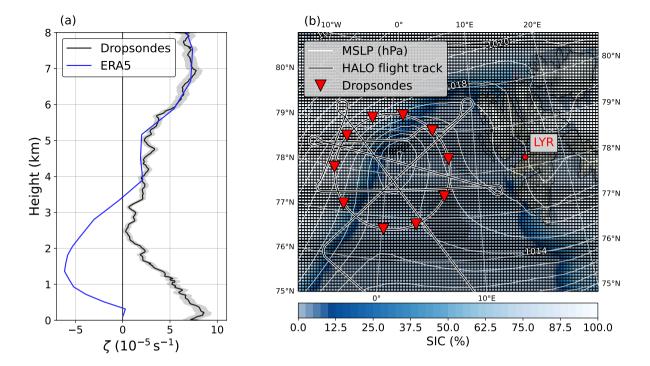

Figure 13. (a) Relative vorticity  $\zeta$  computed from 10 dropsondes (black) and as model output from ERA5 averaged over the grid points nearest to the dropsondes (blue). (b) Location of the dropsondes (red triangles) launched from HALO while flying in a circle around the Polar Low. ERA5 based mean sea level pressure (white contour lines) and sea ice concentration (coloured filled contours) is shown for 08 April 2022 09 UTC. The HALO flight track is displayed as black line with white outline. Horizontal (horizontal and vertical) hatching indicates areas where ERA5 based 850 hPa relative vorticity is below  $-10 \cdot 10^{-5} \, \mathrm{s}^{-1}$  (above  $20 \cdot 10^{-5} \, \mathrm{s}^{-1}$ ).

vertical wind shear developed south of Greenland with low-level northeasterly winds and southeasterly winds at levels above 700 hPa along the east coast of Greenland. The southerly upper-level flow generated a poleward moisture transport, which was accompanied by cirrus and mid-level clouds west of Svalbard and north of Greenland. This upper-level flow continued during the sequence of three research flights conducted by HALO and roughly connected the air masses sampled during the three consecutive days.

725

730

The trajectories of the air masses sampled on 11–12 April are shown in Fig. 14a, c. While on 11 April two branches, one southerly and one easterly, merged into the area of observations, the trajectories of 12 April first followed the westward moist air transport south of Svalbard and then turned northwards into the central Arctic. Figure 14b and d show illustrate the relative humidity over ice from all dropsondes launched in the central Arctic during the HALO flights on 11–12 April. The mean profile shows an enhanced moisture layer between 4 km and 8 km. This layer is associated with higher wind speeds up to  $25 \, \mathrm{m \, s^{-1}}$  and a shift in wind direction from a an easterly flow in the lower 3 km to a southerly flow in the upper troposphere. Below 4 km altitude, the air mass was rather dry with relative humidity below 50 %. In these lower altitudes, the stable cold and dry

air mass in the central Arctic was supported by the outflow of cold and dry air from northern Greenland and prohibited the formation of clouds below the cirrus. The airborne measurements during this constellation of isolated, widespread cirrus over the sea ice in the central Arctic are well suited to investigate the evolution and radiative effect of Arctic cirrus over sea ice, which is not well explored and of which only few observations exist(Hong and Liu, 2015; Marsing et al., 2023).

#### 5 Conclusions

735

750

755

760

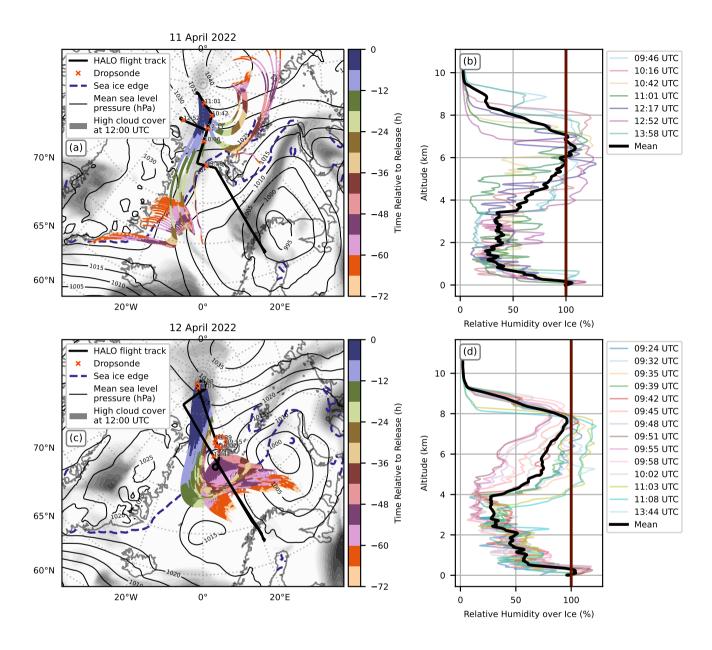

765

In this study, we described the weather and sea ice conditions during the HALO-(AC)<sup>3</sup> aircraft campaign carried out from 07

March to 12 April 2022 in the North Atlantic sector of the Arctic. Our analysis focused on the three different The analysis is based on the ERA5 reanalysis, dropsondes, satellite based sea ice products, and atmospheric measurements at Ny-Ålesund. We focus on three measurement regions of the campaign: the sea ice covered Arctic Ocean north of Svalbard and Greenland (northern region), the Fram Strait (central region), and the Greenland and Norwegian Seas between Svalbard and Scandinavia (southern region). Descriptions of the weather pattern were based on the ERA5 reanalysis and climatological context was The climatological context is given with respect to the years 1979–2022. Ny-Ålesund radiosondes and near-surface measurements allowed us to compare the conditions in the flight regions to those at the AWIPEV research base. We described the sea ice concentration (SIC) during HALO-(AC)<sup>3</sup> with a high resolution satellite product combining infrared and microwave observations. Climatological context of the SIC was presented with microwave satellite observations only.

The Based on the vertically integrated meridional water vapour transport (IVT<sub>north</sub>) and the MCAO index M, the campaign was separated into a warm period (11–20 March), and a cold period (21 March–12 April). Vertically integrated meridional water vapour transport (IVTDuring the warm (cold) phase, IVT<sub>north</sub>) and the MCAO index M averaged over the central region were used to classify the events of HALO–(AC)  $^3$  with highly was positive (negative) IVT<sub>north</sub> and while M was negative (positive)M during the warm (cold) phase. Within the respective periods, IVT<sub>north</sub> and MCAO index M exceeded the 90<sup>th</sup> percentile of the climatology on five and four consecutive days, respectively.

The campaign started with-warm period at the beginning of the campaign was characterized by a consistent southerly flow, which led to a strong MWAI on 12–13 March that was detected as an Atmospheric River (AR) and reached the central Arctic. It was followed by an even stronger AR on 15–16 March. Compared to the climatology, both ARs denoted higher IVT and were centered further in the north than 75% (partly, 90%) of all ARs in the North Atlantic pathway within the ERA5 climatology. During the AR on 15–16 March, we found new records-maxima of vertically integrated meridional heat and water vapour fluxes (IHT<sub>north</sub> and IVT<sub>north</sub>) when averaged over for the central region latitudes. The heat and moisture transport of the warm period, dominated by the radiosondes at Ny-Ålesund detected unusually high tropopause altitudes up to 12.9 km. Although the MWAIs were relatively short-livedMWAIs / ARs, even surpassed the long period of southward transport during the , they caused a campaign average northward transport of heat and moisture, overcompensating the southward transport of the much longer cold period. We therefore stress the importance of MWAIs for the energy exchange between the mid-latitudes and the Arctic. Averaged over the warm period, record breaking new maximum rainfall rates were found over the sea ice northwest

**Figure 14.** (a, c) Three day back trajectories of air masses in which cirrus were sampled on 11 and 12 April 2022. All trajectories are based on ERA5 reanalysis and end at the HALO flight track in cirrus level between 350 and 550 hPa. Surface pressure (thin black lines) and cloud cover (black shading) above 550 hPa from ERA5 are shown for 12 UTC at both days. The thick black line indicates the HALO flight track, and red crosses the location of dropsonde releases. In (b, d) we show the average profile and all individual profiles of relative humidity over ice measured during the two flights by dropsondes.

of Svalbard, exceeding the climatology by a factor of 36. Not only is the high deviation intensity remarkable, but also the occurrence of rain over sea ice at this time of the year.

Starting on 18 March, the southerly flow became disrupted when a surface based high pressure system formed over Greenland. After the The cold period was initialized after the passage of a Shapiro-Keyser strong cyclone over Svalbard on 21 March, when a northerly flow was established in the central region, which marked the transition to the cold period. We identified two strong MCAO periods (21–26 March and 01–02 April), where M partly exceeded the 90<sup>th</sup> percentile. The strong MCAOs were associated with high upward fluxes of sensible and latent heat in the unstable atmospheric boundary layer, which stress the interaction between the warm ocean and cold atmosphere. The ocean–atmosphere interactions in the boundary layer resulted in the typical high fraction of low–level cloud cover (cloud streets) and convective precipitation. After each strong MCAO period, the northerly flow was replaced by weaker northeasterly flow and aged warm air was advected to the measurement regions (28–31 March, 03–04 April) by a weaker northeasterly flow. During the aged warm air period, precipitation faded in the central region due to warming and drying. West of Svalbard, cloud–free conditions prevailed because of orographic lee effects (foehn).

An upper-level trough approached the central region with After a weak MCAOand led to the development of , a Polar Low formed in the Fram Strait on 07 April. We confirmed that four out of six criteria for Polar Low development were fulfilled by inspecting the environmental conditions. With the help of dropsondes launched along a circle, we found strong rotation confined to the lowest 2km despite negative relative vorticity in the eastern part related to lee effects. The Polar Low was located unusually far in the north. At the end of the cold period (10–12 April), warm and moist air was advected by a Scandinavian Low towards the southern region and diverted northwards through the Fram Strait. The high altitude southerly winds transported cirrus clouds over the sea ice with cold and dry air from the Greenland ice sheet below. This combination resulted in an isolated humidity layer including Arctic cirrus in the absence of low— and mid—level clouds.

780

785

795

800

With respect to the climatology, the entire campaign was slightly warmer considering both  $2\,\mathrm{m}$  and  $850\,\mathrm{hPa}$  temperatures, except for the central Fram Strait and north of Greenland. Here,  $2\,\mathrm{m}$  temperature anomalies were negative. The influence of the ARs was clearly visible in the warm period with  $850\,\mathrm{hPa}$  ( $2\,\mathrm{m}$ ) temperatures of up to  $9\,\mathrm{K}$  ( $16\,\mathrm{K}$ ), and IWV more than  $3\,\mathrm{kg}\,\mathrm{m}^{-2}$  above the climatological mean. During the MCAO period, slightly positive  $850\,\mathrm{hPa}$  temperature anomalies remained in the central Arctic, but the Fram Strait was up to  $5.5\,\mathrm{K}$  colder and  $1\,\mathrm{kg}\,\mathrm{m}^{-2}$  drier than the climatology.

SICs were well In the central region, SICs were within the 10–90<sup>th</sup> percentiles of the climatology during the HALO-(AC)<sup>3</sup> campaign. In the Fram Strait, there was a remarkable reduction of SIC after the first AR event on 12–13 March entire campaign period. The AR events caused remarkable reductions of SIC in the Fram Strait and northeast of Svalbard due to dynamical forcing by wind and ocean, and possibly melt. Especially north and northeast of Svalbard, the sea ice cover retreated far towards the north leaving a widely open polynya even until Franz Josef Land. Afterwards during the MCAO period, temperatures stayed below the freezing point and northerly winds increased SIC above the climatological mean in that regionthose regions. Only around Svalbard and at its southeastern coast, SICs were lower than the climatological mean values. We identified a strip of positive SIC anomaly in the central and western Fram Strait, indicating that the sea ice edge was further to the south at this location compared to the climatology. The area of positive SIC anomaly which coincides well with the negative 2 m temperature anomalies.

Upper atmospheric Atmospheric soundings and near-surface measurements at Ny-Ålesund generally represent the weather conditions observed in the HALO-(AC)<sup>3</sup> flight area of the central region well, when considering the temporal difference respecting the temporal delay of up to 1 day due to the propagation of synoptic systems—during the warm period. However, during the cold period, lee effects at the coast of Svalbard cause cloud conditions that are only representative for the eastern part of the central region. The additional measurements at the AWIPEV can be implemented into the data analysis of HALO-(AC)<sup>3</sup> and provide a long–term climatological context to the airborne measurements. The radiosondes detected unusually high tropopause altitudes up to 12.9 km during the warm period and extremely dry conditions during the first strong MCAO period with IWV below the 3<sup>rd</sup> percentile (1.1 kg m<sup>-2</sup>).

Compared to previous aircraft campaigns in the Arctic within (AC)<sup>3</sup> that focused on the evolution of (mixed-phase) clouds (ACLOUD; AFLUX and MOSAiC-ACA, Wendisch et al., 2019; Mech et al., 2022), we observed a larger variety of MCAO conditions during HALO-(AC)<sup>3</sup>. The long phase of MCAOs with varying strength and different wind regimes provides opportunities for detailed MCAO studies making use of the airborne measurements. Also the sea ice edge was closer to Svalbard than during AFLUX (March-April 2019) so that ocean-ice transects could be performed more easily. We captured several MWAIs / ARs with unusual or even record breaking strength. With regard to the changing climate when exchanges between the mid-latitudes and the Arctic become more frequent and ARs are expected to shift poleward, the campaign provides a unique opportunity to study stronger than average MWAIs / ARs. We conclude that the weather conditions were well suited to achieve the objectives of the HALO-(AC)<sup>3</sup> campaign.

Code and data availability. All codes used for the analyses presented in this study have been uploaded to GITHUB and connected with ZENODO for public access (*in preparation*). Sea ice concentration climatology data is found on OSI SAF (2017) and Copernicus Climate Change Service (C3S) (2020). The high resolution sea ice concentration dataset used for 07 March–12 April 2022 is based on the product from the Institute of Environmental Physics, University of Bremen. The data is available at https://seaice.uni-bremen.de/data/modis\_amsr2. ERA5 data on single and pressure levels can be accessed through Hersbach et al. (2018b) and Hersbach et al. (2018a). Ny–Ålesund radiosondes and ceilometer data have been published on PANGAEA (Maturilli and Kayser, 2016, 2017; Maturilli, 2020b, 2022). Near–surface meteorology data from Ny–Ålesund is available on PANGAEA as well (Maturilli, 2020a). Dropsonde data from used in this study can be found on ZENODO (*in preparation*).

**Table A1.** Geographical coordinates for measurement regions as displayed in Fig. 1. Note that the northern part of the northern region in the central Arctic is extended to the west.

	Northern region	Northern region extension	Central region	Southern region
Northern limit in deg N	84.5	89.3	<u>81.5</u>	<u>75.0</u>
Southern limit in deg N	<u>81.5</u>	84.5	<u>75.0</u>	70.6
Western limit in deg E	-9.0	-54.0	-9.0	0.0
Eastern limit in deg E	30.0	30.0	16.0	23.0

## Appendix A: Methodology details

830

835

840

845

This part of the appendix includes additional details regarding the methods described in Sect. 2 that go beyond the necessary information to understand the study but help to reproduce the results.

For an exact computation of the regional averages over the southern, central and northern regions, we provide the geographical coordinates of the domains' boundaries in Table A1.

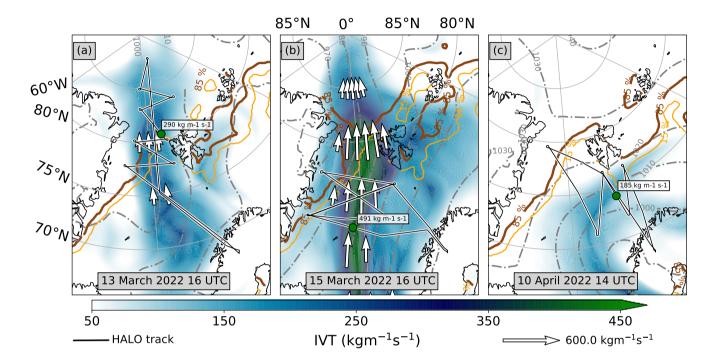

Here, we describe the processing of variables to analyse the MCAO conditions (Sect. 2.4.3) in greater detail for reproducibility. Turbulent flux data was confined to open water surfaces because our focus is on the intensity of the upward fluxes (positive sign) over open water during the MCAOs. We used the mean values over 1 hour at each grid point instead of the instantaneous values (Hersbach et al., 2020). For low, medium and high–level cloud cover, we computed the median value including 5, 25, 75, and 95<sup>th</sup> percentiles. Precipitation data was accumulated over 6 hour intervals and grouped into open water and sea ice covered surfaces. Snowfall is further separated into its large–scale and convective parts. The latter is defined in ERA5 as the frozen precipitation resulting from the convection scheme and thus from subgrid–scale convection. Total precipitation is then the sum of the convective and the large–scale part (Hersbach et al., 2020).

In the following, we summarize the meanings of the conditions tested for Polar Low formation (Sect. 2.4.4) for better understanding: Condition C1 is a measure of the convection potential as it evaluates the mean temperature gradient between the surface and the mid-troposphere. Large differences between the 2 m temperature and the SST (C2) promote strong sensible heat fluxes, stressing the air–sea interaction. Positive values of C3 represent an increase of potential temperature with height. At least conditionally unstable conditions (unstable (stable) for moisture–saturated (unsaturated) air parcels) should be present (C3  $\leq$  3 K km<sup>-1</sup>). The relative humidity conditions C4<sub>i</sub> and C4<sub>ii</sub> are an important measure for the availability of moisture for latent heat release, a major energy source of a Polar Low. Maximum 10 m wind speed (C5) is an indicator of the Polar Low's strength. The geopotential height condition (C6) is selected to ensure the presence of an upper level trough.

### Appendix B: Integrated water vapour transport for moist and warm air intrusions

850

For the MWAIs / ARs on 13 and 15 March, and for the weaker MWAI on 10 April, we show the total IVT in Fig. B1. While the former two events were meridionally aligned, the latter had a rather zonal orientation. The strongest total IVT is found on 15 March, exceeding  $400 \,\mathrm{kg} \,\mathrm{m}^{-1} \,\mathrm{s}^{-1}$ .

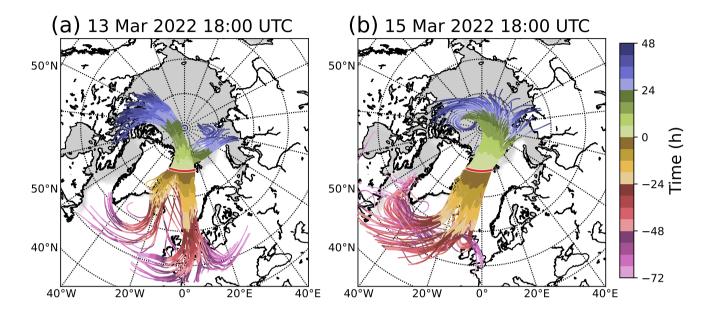

**Figure B1.** Total integrated water vapour transport (IVT, zonal and meridional component) from ERA5 (colours) and dropsondes (circular marker) for three moist and warm air intrusions / Atmospheric Rivers: (a) 13 March 2022 16 UTC, (b) 15 March 2022 16 UTC, (c) 10 April 2022 14 UTC. Quivers indicating the flow direction and strength, as well as the HALO flight track (black line with white outline) are also included. The orange (brown) line indicate the 15% (85%) sea ice concentration isoline. Grey dash–dotted contours show the mean sea level pressure. Data is based on ERA5.

## Appendix C: Moist and warm air intrusion trajectories

855

The general air flow on two selected MWAI / AR days is investigated. Three day back and two day forward trajectories shown in Fig. C1 are initialized on 13 and 15 March each at 18:00 UTC. The trajectories reveal that the air masses of the first MWAI day mainly originated from central Europe and the second case from the North Atlantic. Forward trajectories show that both MWAIs / ARs reached the central Arctic.

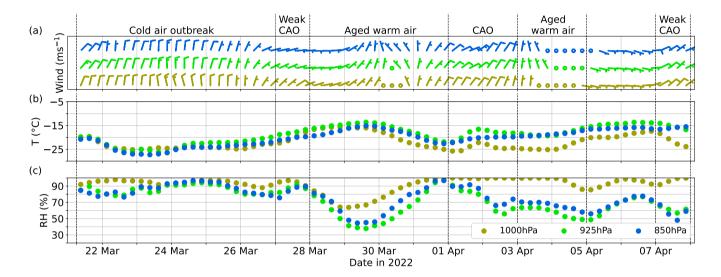

**Figure C1.** Three day backward and two day forward trajectories of the AR air masses observed in the central region on (a) 13 March 2022 18:00 UTC, and (b) 15 March 2022 18:00 UTC. at altitudes of 700, 850, and 925 hPa. Starting points are placed at 77.5° N between 20° W and 13° E with a zonal spacing of 1°. Both 72 hour back–trajectories as well as 48 hour forward–trajectories are computed. Grey shading indicates the sea ice concentration from ERA5.

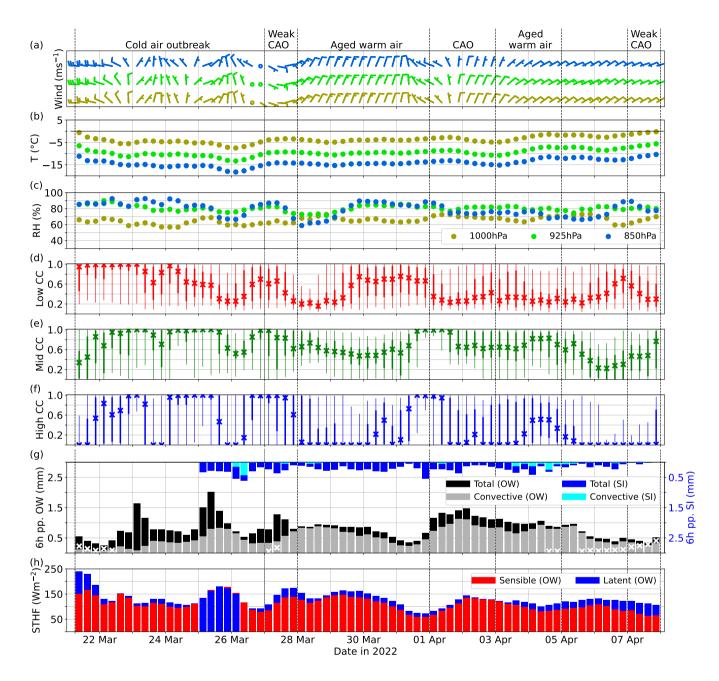

# Appendix D: Marine cold air outbreak

860

Figure D1 shows the ERA5 based temporal evolution of temperature, relative humidity and wind for the northern region. eastern part of the northern region (identical western longitude boundary as the central region). The data has been processed as described in Sect. 2.4.3 and Appendix A. During the stronger MCAOs in the central region with northerly winds, the airmasses air masses originated from the northern region. Due to the low occurrence of northwesterly winds, the western extension of the northern region is not included. For comparison of turbulent fluxes between the central and southern region, we include Fig. D2.

**Figure D1.** Temporal evolution of (a) wind, (b) air temperature (T), and (c) relative humidity (RH) on the 1000, 925, and 850 hPa pressure levels as in Fig. 11, but for the northern region (without western extension). Data is based on ERA5.

**Figure D2.** Temporal evolution of (a) wind, (b) air temperature (T), and (c) relative humidity (RH) on the 1000, 925, and 850 hPa pressure levels, and of (d) low-, (e) mid-, and (f) high-level cloud cover (CC), (g) precipitation, and (h) surface turbulent heat fluxes (STHF) as in Fig. 11 but for the southern region. Data is based on ERA5.

### Appendix E: Polar Low visual observations

865

870

Due to the relatively small extent of a Polar Low, we were able to see the entire structure during the HALO research flight on 08 April 2022. The photo was taken on one of the cross sections through the Polar Low, showing the relatively cloud free centre (eye) and the convective cloud band on its (north–)eastern side (Fig. E1).

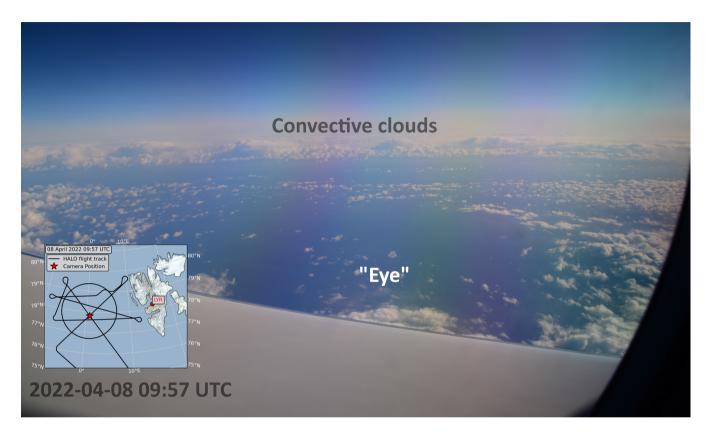

Figure E1. Photo of the Polar Low taken from HALO (portside) on 08 April 2022 at 09:57 UTC. The centre (eye) of the Polar Low can be seen in the foreground while the convective cloud band is visible in the background. The map indicates the flight track (black line) and the position of the aircraft at that time (red star). © Andreas Walbröl

Author contributions. SC, AE, IG, JanM, MW, and AW conceptualized the manuscript. MW and AW formulated the introduction with comments and input from AE, JanM, and SC. HD, BK, ML, NM, MM, JanR, and AW prepared the description of the data and methods chapter. SB, HD, BK, ML, JanM, HM, RN, FP, JohR, JanR, IS, NS, and AW provided visualisations and analysed figures. JohM and AW collected codes from co–authors and made them publicly available. AW is the main author of this manuscript and ensured validation. All co–authors reviewed the manuscript.
