## Abstract.

Centered around the High Altitude and Long Range (HALO) research aircraft and the collaborative research project on Arctic Amplification (AC)<sup>3</sup>, the airborne field campaign HALO–(AC)<sup>3</sup> took place from 07 March to 12 April 2022. Its major goal was to observe the transformation of air masses during their meridional transport in the North Atlantic sector of the Arctic.

5 We evaluate the meteorological and sea ice conditions during the campaign based on the European Centre for Medium–Range Weather Forecasts (ECMWF) Reanalysis v5 (ERA5), satellite data, and atmospheric soundings with respect to climatology. HALO–(AC)<sup>3</sup> started with a warm period (11–20 March) where strong southerly winds prevailed that caused moist and warm air intrusions (MWAI). Two MWAI were detected as Atmospheric Rivers (ARs). Compared to the ERA5 climatology (1979–

10 found. These warm and moist air masses caused the highest rainfall rates over the sea ice northwest of Svalbard since the beginning of the ERA5 climatology. During the subsequent cold period, starting after the passage of a strong cyclone on 21 March, northerly winds advected colder air into the Fram Strait. Marine cold air outbreaks (MCAOs) prevailed until 08 April, interrupted by short periods of aged subpolar warm air. On average, the entire campaign period was warmer than the climatological mean due to the strong influence of the ARs. In the Fram Strait, the sea ice concentration (SIC) was well within

15 the climatological variability, staying within the 10–90<sup>th</sup> percentiles over the entire campaign duration. However, during the warm period, an atypically large polynya opened north of Svalbard. For potential future studies, we describe the environmental conditions of the most significant weather events (ARs, MCAOs, Polar Low, and Arctic cirrus) during HALO–(AC)<sup>3</sup> in detail. Comparing atmospheric conditions over the Fram Strait with Ny–Ålesund (Svalbard), temporal shifts up to one day have been identified. The temporal shift and orographic effects must be taken into account when combining airborne HALO–(AC)<sup>3</sup>

20 measurements with ground based observations at Ny-Ålesund. Compared to previous airborne field campaigns focusing on the evolution of (mixed-phase) clouds, a larger variety of MCAO conditions were observed during HALO-(AC)<sup>3</sup>. Our study may serve as basis for future analyses of the data collected during the campaign.

## 1 Introduction

The Arctic experiences a drastic temperature increase almost 4 times stronger compared to the rest of the globe (Rantanen et al., 2022). This enhanced warming is known as Arctic Amplification and is caused by several feedback mechanisms (Serreze et al., 2009; Screen and Simmonds, 2010; Serreze and Barry, 2011). While the contribution of some feedback mechanisms to Arctic Amplification can be regarded as scientific consensus (e.g., sea ice–albedo feedback, Serreze et al., 2009), others are not yet sufficiently explored and their contribution is uncertain (e.g., influence of clouds, lapse rate feedback, linkages between Arctic and mid–latitudes, Wendisch et al., 2023). As the Arctic warms faster than the mid–latitudes, the meridional temperature gradient decreases in most heights of the troposphere, likely resulting in a weaker jet stream and possibly enhancing the tendency to meander (Francis and Vavrus, 2015). A more meandering jet would result in an increasing number of poleward moist and warm air intrusions (MWAI) and southward cold air outbreaks (CAOs). However, the tropical upper troposphere warms while the Arctic lower stratosphere cools, enhancing meridional temperature gradients at higher altitudes (Lee et al., 2019; Stendel et al., 2021). The frequency of meridional transport through the North Atlantic has increased during the last decades while it stayed constant or even decreased in other regions (Mewes and Jacobi, 2019). You et al. (2022) found a positive trend in the frequency and duration of atmospheric blocking over the Barents Sea especially in winter, supporting the statement of an enhanced North Atlantic pathway for meridional transport.

MWAI frequently transport large amounts of heat and moisture into the Arctic through the Atlantic sector (Woods and Caballero, 2016). When the warm air is pushed upwards over cold Arctic air masses, deep cloud systems including mixed–phase clouds may form. During MWAI, cirrus clouds, whose radiative effect is not well explored over sea ice (Hong and Liu, 2015; Marsing et al., 2023), can be formed or advected to the Arctic. Woods et al. (2013) and Woods and Caballero (2016) stress that intense MWAI have a large effect on the downward terrestrial radiation at the surface, contributing to the warming of the Arctic. Such MWAI precondition the sea ice for the melting season, resulting in lower sea ice extent at the end of the summer (Kapsch et al., 2013, 2019). Numerical models still struggle to accurately represent the mixed–phase clouds and the transformation processes of the air masses (Pithan et al., 2014; Cohen et al., 2020). MWAI can often be linked with filamentary bands of strong moisture transport, known as Atmospheric Rivers (ARs, Newell et al., 1992). ARs are responsible for over 90% of the poleward moisture transport across the mid–latitudes and are frequently accompanied by strong winds and precipitation (Nash et al., 2018). While the precipitation can cause snow accumulation during ARs in the Arctic, the enhanced emission of downward terrestrial radiation by the clouds can lead to melting of snow and sea ice (Neff et al., 2014; Komatsu et al., 2018; Mattingly et al., 2018, 2020; Bresson et al., 2022; Viceto et al., 2022). In a warming climate, ARs are expected to shift polewards and intensify due to the increased moisture load (Ma et al., 2020).

CAOs are often responsible for severe weather events in the high– and mid–latitudes and mainly occur in winter and spring (Fletcher et al., 2016; Pithan et al., 2018). Here, we focus on marine CAOs (MCAOs) where cold and dry air is advected southwards from the sea ice to the ice–free (open) ocean. Over the open ocean, the strong temperature contrast between the surface and the lower tropospheric air leads to intense fluxes of sensible and latent heat, responsible for 60–80% of the oceanic heat losses in that region (Papritz and Spengler, 2017). This heat and moisture transfer into the atmosphere destabilizes the

boundary layer and leads to the formation of cloud streets, which later develop into open cells. This cloud evolution is not well represented in models but an important feature (Pithan et al., 2018). MCAOs can also cause the formation of Arctic mesoscale cyclones (Polar Lows, Rasmussen and Turner, 2003; Zahn and von Storch, 2008), which may locally lead to heavy precipitation and strong winds. The formation processes of Polar Lows and their relation to MCAOs are still not fully understood, partly due to the sparsity of measurements in the Arctic (Moreno-Ibáñez et al., 2021).

So far, observations of air mass transformations in the Arctic have mostly been conducted from a fixed local position (Eulerian view). Only a few aircraft based samplings of air mass properties over a limited regional area have been reported (e.g., Wendisch et al., 2019; Mech et al., 2022). To observe air mass transformation processes along their meridional pathway in a Eulerian view, multiple stations that are aligned with the wind direction would be needed. Therefore, Pithan et al. (2018) proposed a quasi-Lagrange approach following air masses to and from the Arctic, which motivated the field campaign HALO-(AC)<sup>3</sup> within the Transregional Collaborative Research Center TRR 172 (TRR 172) "Arctic Amplification: Climate Relevant Atmospheric and Surface Processes and Feedback Mechanisms (AC)<sup>3</sup>". The campaign was designed to obtain quasi-Lagrange observational data of air mass transformations during MWAI and MCAOs to gain process understanding and evaluate the performance of weather and climate models (Wendisch et al., 2021).

During HALO-(AC)<sup>3</sup>, extensive remote sensing and in situ measurements of surface, cloud and thermodynamic properties have been performed between the Norwegian Sea and the North Pole from 11 March to 12 April 2022 with three research aircraft (HALO, Polar 5, and Polar 6). The High Altitude and LONG-range research aircraft (HALO) operated by the German Aerospace Center (DLR, Ziereis and Gläßer, 2006; Stevens et al., 2019) is a modified Gulfstream G550, which has a sufficient operating range (9000 km in altitudes up to 15 km) for quasi-Lagrange air mass observations and was based in Kiruna during HALO-(AC)<sup>3</sup>. For HALO-(AC)<sup>3</sup>, it was equipped with a similar instrumental payload as during the EUREC4A campaign (Stevens et al., 2019; Konow et al., 2021). Polar 5 and Polar 6 (P5 and P6) were based in Longyearbyen and operated by the Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI, Wesche et al., 2016) in a similar coordinated way as during the ALOUD campaign (Wendisch et al., 2019).

This study focuses on the environmental conditions during HALO-(AC)<sup>3</sup> and their climatological context to serve as comprehensive reference in future studies. After introducing the data basis and methods in Sect. 2, we describe the synoptic development during two dominating periods in Sect. 3.1. We also provide a view on the conditions at Ny-Ålesund (Sect. 3.2), where future studies will use the extensive measurements from the French-German Atmospheric Observatory AWIPEV. Sea ice conditions in the North Atlantic sector of the Arctic are presented in Sect. 3.3. We further analyse the origin and strength of the MWAI and ARs (Sect. 4.1), the conditions during the MCAO periods (Sect. 4.2), the formation and environmental characteristics of the Polar Low (Sect. 4.3), and Arctic cirrus clouds (Sect. 4.4), before concluding our study in Sect. 5.

## 2 Data and Methods

### 2.1 Study domain

HALO-(AC)<sup>3</sup> flight tracks cover the North Atlantic sector of the Arctic, the major pathway of MWAI (Johansson et al., 2017; You et al., 2022). Based on the flight tracks, we selected three domains for our synoptic analysis as shown in Fig. 1. The exact geographical coordinates of the domains are listed in Appendix A, Table A1. From north to south the domains are referred to as northern region (central Arctic north of Svalbard and Greenland), central region (Fram Strait and Greenland Sea), and southern region (Greenland and Norwegian Seas between Svalbard and Norway). A particular focus lies on the central region, where measurements were performed with all three aircraft.

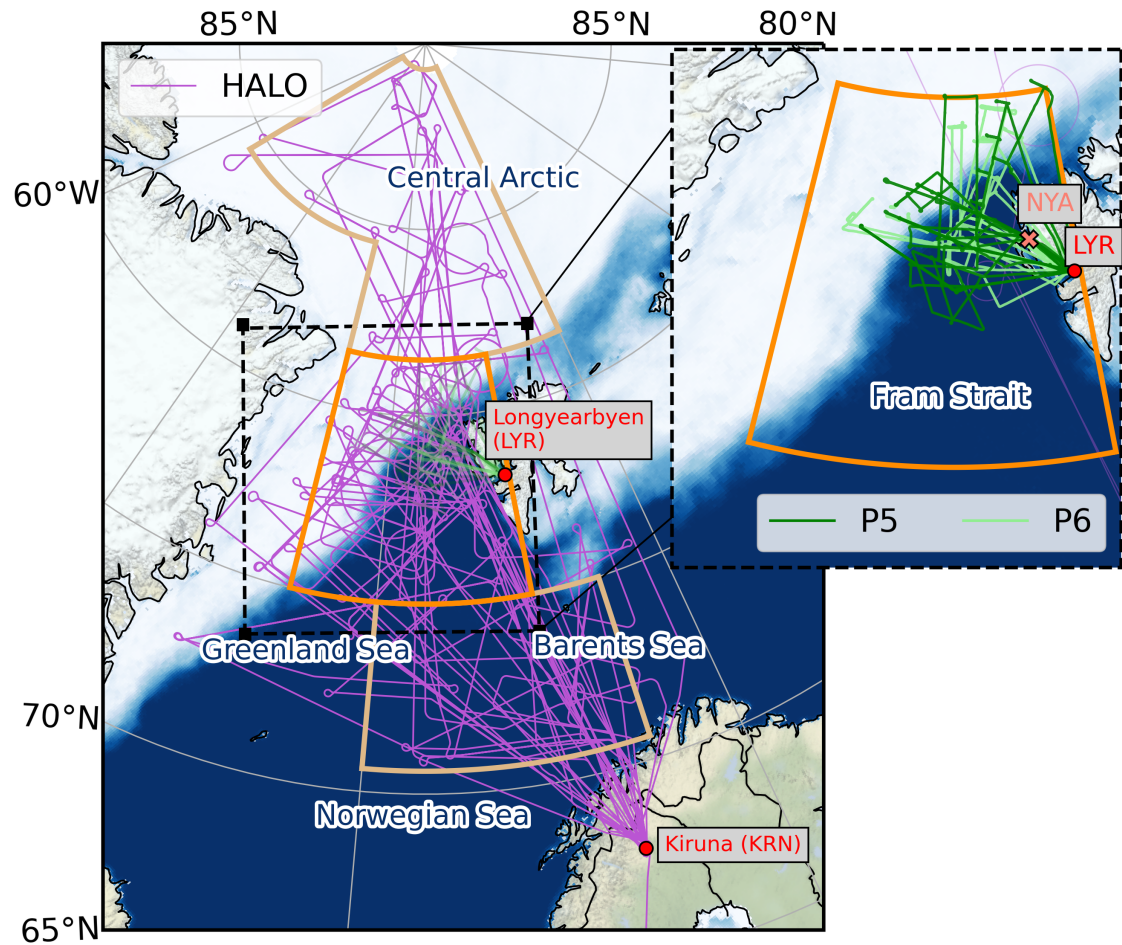

### 2.2 Atmospheric conditions observed from HALO and at Ny-Ålesund

Vertical profiles of temperature, relative humidity, pressure and wind were recorded with RD94 dropsondes launched from HALO (Hock and Franklin, 1999; George et al., 2021) and radiosondes launched at the Atmospheric Observatory of the French-German AWIPEV research base in Ny-Ålesund (Svalbard) every 6 hours (Vaisala RS41, Maturilli, 2020b). From the radiosonde profiles, we identified the thermal tropopause according to the WMO definition as the lowest level at which the temperature lapse rate falls below  $2\text{K km}^{-1}$  and does not exceed this value for the next 2 km. The integrated water vapour (IWV) was calculated from profiles of air pressure and specific humidity, which was derived from the temperature and relative humidity measurements. Ground based meteorological measurements gathered at AWIPEV provide an additional view on the environmental conditions during HALO-(AC)<sup>3</sup> in the central region (Maturilli et al., 2013; Maturilli, 2020a). Additionally, we used data from the CL-51 ceilometer to assess the cloud conditions at Ny-Ålesund (Maturilli and Ebell, 2018; Maturilli, 2022).

### 2.3 Satellite observations of sea ice

We focused on sea ice concentration (SIC), i.e., the percentage of a satellite pixel (grid cell in ERA5) covered by sea ice, derived from satellite measurements to describe the sea ice conditions during HALO-(AC)<sup>3</sup>. In general, we separated observations for areas with and without sea ice (latter is also termed open water) through the threshold of 15% SIC. Satellite based passive microwave radiometers provide a long-term observation of sea ice (Spreen and Kern, 2016). Here, we used the OSI SAF Global Sea Ice Concentration Climate Data Record (SIC CDR v2.0), namely the product OSI-450 from 1979 to 2015, and the complementary Interim Climate Data Record OSI-430-b from 2016 onwards (OSI SAF, 2017; Copernicus Climate Change Service (C3S), 2020). The product is based on low-frequency passive microwave satellite data and is described in Lavergne et al. (2019). The datasets are available daily with a grid spacing of  $25\text{ km} \times 25\text{ km}$ .

To study the evolution of SIC during HALO-(AC)<sup>3</sup> at a higher spatial resolution, we used the merged MODIS-AMSR2 SIC dataset, available daily at 1 km resolution. The merged MODIS-AMSR2 product (Ludwig et al., 2020) takes advantage of the

**Figure 1.** Flight tracks of HALO (purple), as well as P5 and P6 (dark and light green, zoomed domain in the right panel) during HALO–(AC)<sup>3</sup>. For orientation, the mean sea ice concentration from 07 March to 12 April 2022 based on AMSR2 satellite data (Spreen et al., 2008) is shown as filled contours. The three measurement domains (southern region, central region, and northern region) are marked as yellow and orange boxes. The central region is highlighted. The orange label NYA in the zoomed domain marks the location of Ny-Ålesund.

high spatial resolution of thermal infrared (Drüe and Heinemann, 2004), and of the independence of cloud cover of microwaves (Spreen et al., 2008).

## 2.4 Reanalysis data

120 To analyse the weather development, we used the ERA5 reanalysis from the European Centre for Medium-Range Weather Forecasts (ECMWF). ERA5 offers hourly data output since 1950 with a horizontal resolution of 31 km and 137 vertical model levels (Hersbach et al., 2018a, b, 2020). ERA5 represents clouds and precipitation in the Arctic better than other reanalyses

(Graham et al., 2019a; Avila-Diaz et al., 2021). Additionally, ERA5 features a higher vertical resolution than other reanalyses, which leads to more accurate wind fields and, thus, to improved water vapour transport estimates (Graham et al., 2019b).  
 125 However, ERA5 shows higher warm biases over sea ice of near surface temperatures than other reanalyses due to the misrepresentation of the stable stratification (Wang et al., 2019; Yu et al., 2021). During HALO-(AC)<sup>3</sup>, dropsonde measurements launched from HALO were assimilated into ERA5. The climatological comparisons presented here are based on the years 1979–2022 unless specified differently. Grid points with a land fraction  $> 0$  have been excluded from our analysis according to the ERA5 land–sea–mask. Domain averages of the regularly gridded ERA5 quantities were calculated as area averages  
 130 weighted by the cosine of the latitude to respect the increasing data point density with increasing latitudes. In the following, we describe the processing of ERA5 data and derivation of indices calculated for our analysis.

#### 2.4.1 Detection of Atmospheric Rivers and moist and warm air intrusions

Woods and Caballero (2016) detect moist air intrusions into the Arctic when the vertically integrated meridional moisture flux ( $IVT_{\text{north}}$ ) at  $70^\circ$  N exceeds  $200 \text{ Tg d}^{-1} \text{ deg}^{-1}$  ( $60.6 \text{ kg m}^{-1} \text{ s}^{-1}$ ) over a duration of at least 1.5 days and a zonal extent of  
 135 at least  $9^\circ$ . For our purpose, we adapted this detection and defined MWAI with positive daily means of  $IVT_{\text{north}}$  averaged over the central region. An MWAI is considered weak (strong) when  $IVT_{\text{north}}$  is below (equal or above)  $100 \text{ kg m}^{-1} \text{ s}^{-1}$ . Additionally, we computed the temporal mean, 25–75<sup>th</sup> and 10–90<sup>th</sup> percentiles over the climatology period. In this study, ARs were identified with a global algorithm by Guan and Waliser (2015) in its revised version (Guan et al., 2018), adapted to the lower moisture content of the Arctic (Lauer et al., 2023).

#### 140 2.4.2 Marine cold air outbreak index

A key feature of MCAOs are strong temperature decreases with increasing height especially in the lower troposphere over open ocean. This forms the basis for the MCAO index  $M$  to identify them and to quantify their strength. The MCAO index  $M$  was calculated following Papritz and Spengler (2017) and Dahlke et al. (2022):

$$M = \theta_{\text{SKT}} - \theta_{850} \tag{1}$$

145 with  $\theta_{\text{SKT}}$  ( $\theta_{850}$ ) as the potential skin temperature (potential temperature at 850 hPa). Grid points with skin temperatures below 271.5 K (i.e., over sea ice) were excluded from further processing as in Dahlke et al. (2022). We averaged over the central region and computed the climatology as for  $IVT_{\text{north}}$ . Following Papritz and Spengler (2017), MCAO conditions are present when  $M > 0 \text{ K}$  and its strength can be classified as weak ( $0 \text{ K} < M \leq 4 \text{ K}$ ), moderate ( $4 \text{ K} < M \leq 8 \text{ K}$ ), strong ( $8 \text{ K} < M \leq 12 \text{ K}$ ) or very strong ( $M > 12 \text{ K}$ ).

#### 150 2.4.3 Lower tropospheric parameters for marine cold air outbreak analysis

For a detailed analysis of the MCAO conditions over the campaign (Sect. 4.2), we used hourly ERA5 data of wind, temperature, and relative humidity at 850, 925, and 1000 hPa, as well as cloud cover, precipitation and surface turbulent heat fluxes (sensible and latent). All variables were temporally averaged over 6 hour intervals and spatially averaged over the central region. Cloud

cover was confined to open water surfaces only as ERA5 tends to overestimate especially low-level cloud cover over sea ice  
155 (Di Biagio et al., 2021). Details can be found in Appendix A.

#### 2.4.4 Environmental conditions of Polar Lows

We analyse the environment for Polar Low formation with a set of conditions (C1–C6) suggested by Radovan et al. (2019) and  
Terpstra et al. (2016) in a 200 km radius around the Polar Low's centre (pressure minimum): C1: sea surface temperature (SST)  
– 500 hPa temperature, C2: SST – 2 m temperature, C3: mean lapse rate below 850 hPa, C4<sub>i</sub>: mean relative humidity below  
160 950 hPa, C4<sub>ii</sub>: mean relative humidity between 850 and 950 hPa, C5: 10 m wind speed (here, gust), C6: 500 hPa geopotential  
height anomaly. Condition C3 is evaluated as the vertical mean of the vertical potential temperature gradient between the  
surface and the 850 hPa pressure level. The meaning of each condition is summarized in Appendix A.

For conditions C1–C4, the 75<sup>th</sup> percentile, for C5, the maximum, and for C6, the mean were computed. Wahl et al. (2017)  
found that scales of multiples of the grid cell spacing are required to realistically represent the energy spectrum of a wind field.  
165 We decided to use the maximum 10 m wind gust instead of mean wind to get a better estimate of the near-surface wind field  
of this small-scale phenomenon that might be hidden due to the coarse resolution of ERA5. The climatology of the 500 hPa  
geopotential height for C6 consists of all days of April between 1979 and 2022 for each grid point within the 200 km radius.  
Subsequently, the geopotential height anomaly was computed as the difference between the conditions during HALO-(AC)<sup>3</sup>  
and the climatology, and C6 was obtained by averaging over the 200 km circle.

170 Furthermore, we calculated vorticity from 10 dropsonde measurements taken within 1 hour arranged on a circular pattern.  
Following Lenschow et al. (2007) and Bony and Stevens (2019), we assumed horizontal variations in the wind field to be linear  
and expanded the wind vector with Taylor expansion around the centre of the circle in spherical coordinates.

#### 2.4.5 Trajectory calculations

Trajectory calculations were performed using LAGRANTO (Sprenger and Wernli, 2015) and wind fields from ERA5. To assess  
175 the origin of sampled cirrus air masses, 72 hour back-trajectories for the northernmost sections of the flights on 11 and 12 April  
were computed. Trajectories were initialized at the pressure levels 350–550 hPa in 50 hPa steps, where the single-layer cirrus  
had been observed by HALO (Sect. 4.4). Furthermore, 72 hour back- and 48 hour forward-trajectories were computed to  
identify the pathways of the MWAI (ARs) on 13 and 15 March (Appendix C). These trajectories were initialized along the  
77.5° N latitude with 1° zonal spacing between 20° W and 13° E at 18:00 UTC on the respective days at the pressure levels  
180 700, 850, and 925 hPa.

### 3 Meteorological and sea ice conditions during HALO–(AC)<sup>3</sup>

#### 3.1 Analysis and identification of synoptic events

In this section, we characterize weather events during HALO–(AC)<sup>3</sup> and assess their strength in the climatological context. At first, we separate the campaign into two major periods based on  $IVT_{\text{north}}$  and the MCAO index ( $M$ ) in the central region (see Fig. 2). The campaign started with a warm and humid period with positive  $IVT_{\text{north}}$  and negative values of  $M$ , coinciding with enhanced static stability, from 11 to 20 March 2022. The warm period was followed by a cold and dry period from 21 March to 12 April 2022, where  $IVT_{\text{north}}$  ( $M$ ) was almost exclusively negative (positive).

Within the warm and cold periods, we classified a large variety of weather events based on  $IVT_{\text{north}}$  and  $M$ , the large scale pressure constellation, and regional averages of meteorological variables from ERA5 (Fig. 3 and 4). In Fig. 5, we show latitude–averages of  $IVT_{\text{north}}$  and the vertically integrated meridional heat flux  $IHT_{\text{north}}$  over the central region to spatially and temporally localize meridional heat and moisture transport corresponding with MWAI and MCAOs. Negative values of  $IHT_{\text{north}}$  and  $IVT_{\text{north}}$  indicate southward fluxes. To put the weather conditions into climatological context, anomalies of temperature at 850hPa and 2m above the surface, geopotential height at 500hPa, and IWV were computed for the warm, cold and the entire campaign period. Positive (negative) anomalies correspond to values above (below) the long–term mean. Evaluating the temperature anomalies at these two levels reveals the vertical extent of the temperature anomalies in the lower troposphere.

##### 3.1.1 Warm period

During the warm period, the corresponding general circulation pattern was characterized by a high surface pressure system extending from the North Sea to Baltic Sea and Scandinavia (Fig. 4a, b). The surface high was connected to a ridge in the 500hPa geopotential height. Low surface pressure and low 500hPa geopotential height were located over Greenland and the North Atlantic. This pressure constellation resulted in a consistent southerly and southwesterly flow with only a few short–lived interruptions in the three measurement regions. The interruptions can be seen as near–surface temperature drops and wind direction change (e.g., 11 March, Fig. 3c, d).

On 11–13 and 15–16 March, the pressure gradients between Greenland and Scandinavia were intensified and blocking (Omega Block) was established over most of Europe. Intense MWAI are connected to blocking situations over the eastern border of a large basin (here, North Atlantic), redirecting cyclones northward as the typical eastward propagation is blocked (Woods et al., 2013). Consequently, warm and moist air masses originating from the North Atlantic were transported towards our three main measurement areas, driven by several low pressure systems that formed between Iceland and eastern Greenland.

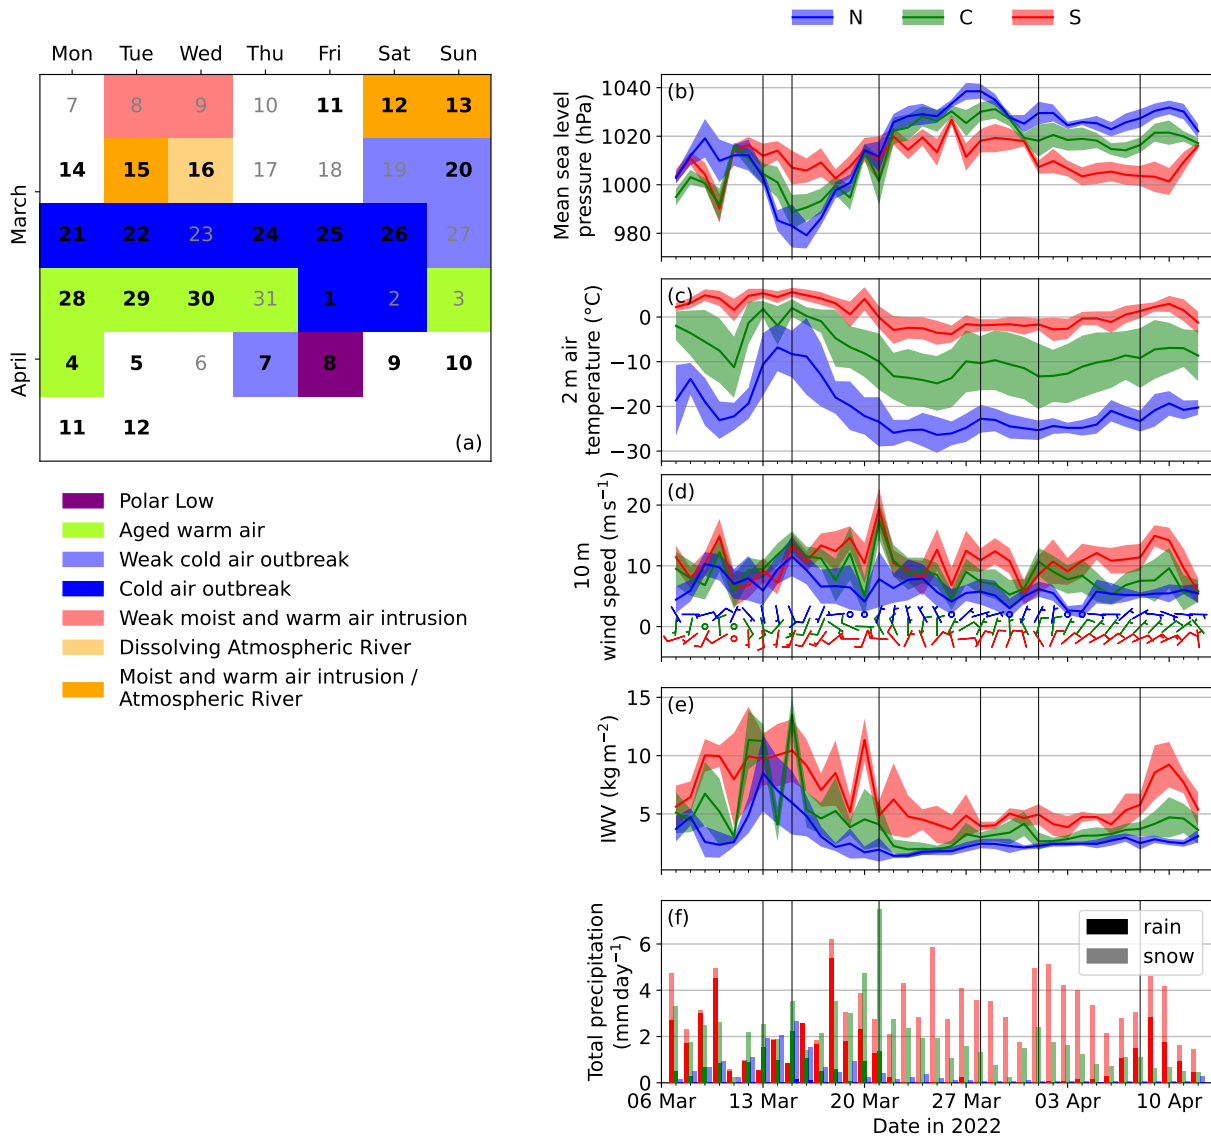

We identified a strong MWAI event during the first week of the campaign (Fig. 3a) with area–averaged  $IVT_{\text{north}}$  up to  $160\text{kg m}^{-1}\text{s}^{-1}$  (Fig. 2a). The event was detected as AR and passed through the measurement regions on 12–13 March (Fig. 4a). In the northern region, IWV reached its campaign maximum ( $8\text{kg m}^{-2}$ ) on 13 March and declined afterwards while the 2m temperature in the northern region continued to increase until the following day (Fig. 3d, e).

**Figure 2.** Daily means of (a) northwards component of integrated water vapour transport ( $IVT_{north}$ ), (b) Marine Cold Air Outbreak (MCAO) index ( $M$ ) based on ERA5 and averaged over the central region for HALO–(AC)<sup>3</sup> (black line). The mean, as well as the 10–90<sup>th</sup> and 25–75<sup>th</sup> percentiles of the climatology (1979–2022) are illustrated as grey line, light and dark grey shadings. The red (blue) box indicates the warm (cold) period dominated by MWAI (MCAOs). Vertical dashed black lines mark the days shown in Fig. 4.

A second AR followed on 15 and 16 March (Fig. 3a), which had a more distinct confluent tropospheric southwesterly flow between the Greenland low and the Scandinavian high (Fig. 4b). In the central Arctic Ocean, the strongest warming occurred on 16 March and resulted in the highest 2 m temperature in March averaged over all ERA5 grid points north of 80° N (latitude-weighted) since 1979 (not shown). Simultaneously, the latitude-averaged  $IHT_{north}$  and  $IVT_{north}$  exceeded the previous maxima from 1996 ( $9.44 \cdot 10^{10} \text{ W m}^{-1}$  vs.  $9.32 \cdot 10^{10} \text{ W m}^{-1}$ , and  $388 \text{ kg m}^{-1} \text{ s}^{-1}$  vs.  $384 \text{ kg m}^{-1} \text{ s}^{-1}$ , Fig. 5). In some parts of the northern region, near-surface temperatures were above freezing and even liquid precipitation was documented over the sea ice (Fig. 3c, f, analysed in greater detail in Sect. 4.1). The AR on 15–16 March also caused the highest daily precipitation of the northern region over the campaign period. In the central region, the area-averaged 2 m temperature was above freezing and a high fraction of rainfall to the total daily precipitation was found.

After the AR, much drier but still relatively warm air followed, leading to a strong reduction in  $IVT_{north}$  and a slight reduction in  $IHT_{north}$  (Fig. 5). As a surface based high pressure system formed over Greenland, the large-scale pressure constellation started to change. However, at upper levels, low geopotential persisted, promoting the formation of a strong low pressure

**Figure 3.** Left column: (a) Calendar of March and April 2022 showing the categorized and colour-coded weather conditions. Bold font indicates days when research flights were performed. Right column: Regional averages (lines) and standard deviation (shading) of ERA5 based time series of (b) mean sea level pressure, (c) 2m temperature, (d) 10m wind (lines indicate speed, barbs indicate direction and speed), (e) integrated water vapour (IWV), and (f) daily accumulated precipitation, separated into rain (no transparency) and snow (partly transparent). Regional averages are performed for the southern (S, red), central (C, green), and northern (N, blue) region shown in Fig. 1. Vertical black lines indicate days shown in Fig. 4.

225 system near Iceland on 20 March. The low quickly propagated towards the northeast and was characterized by rapid deepening ( $> 25$  hPa core pressure decrease in 24 hours) and a frontal structure representative of a Shapiro–Keyser cyclone (Shapiro and Keyser, 1990). On the eastern flank of the Shapiro–Keyser cyclone,  $IHT_{\text{north}}$  and  $IVT_{\text{north}}$  indicate similarly strong fluxes as on 12 March (Fig. 5).

In the climatological perspective, the prevailing pressure gradient between Scandinavia and Greenland is reflected in the 230 extremely strong gradient of the 500 hPa geopotential height anomalies ( $> 10$  gpdm over Scandinavia,  $< -10$  gpdm over Greenland, Fig. 6h) and was responsible for the associated warming. Moreover, we found positive temperature anomalies at 850 hPa of more than 7 K over the Fram Strait and up to 9 K over Scandinavia and around Franz Josef Land (northeast of Svalbard, Fig. 6b). At 2 m, the warming was amplified to more than 16 K above climatology over Franz Josef Land and more than 10 K over the Greenland Sea and Fram Strait (Fig. 6e). The bottom–amplified warming is consistent to the findings of 235 Woods and Caballero (2016), confirming the reduction of the Arctic boundary layer inversion strength through intense MWAI. Additionally, the high amounts of moisture carried by the ARs resulted in positive IWV anomalies of more than  $2 \text{ kg m}^{-2}$  over the southern, central, and parts of the northern region (up to  $4 \text{ kg m}^{-2}$  in the Norwegian and Greenland Seas, Fig. 6k).

### 3.1.2 Cold period

On 21 March 2022, the Shapiro–Keyser cyclone, together with a strong high pressure system over Greenland, marked a turning 240 point in the circulation pattern (Fig. 4c). Compared to the warm period, the zonal pressure gradient across the North Atlantic has been inverted. The resulting northerly winds caused negative  $IHT_{\text{north}}$  and  $IVT_{\text{north}}$  after the cyclone passed (Fig. 3d and 5). Although the sign of the pressure gradient remained until the end of the campaign (12 April), the position and strength of the synoptic– and meso–scale circulations changed over time. As Kolstad et al. (2009) showed, there is a connection between such a circulation pattern and the onset of MCAOs in that region. In all three measurement regions, the area–averaged 2 m 245 temperature remained below  $0^\circ\text{C}$  until 07 April (Fig. 3c).

As the Shapiro–Keyser cyclone stayed over the Barents Sea while dissipating, IWV dropped to the lowest area–averaged values in the northern region ( $1.4$ – $2.4 \text{ kg m}^{-2}$ , Fig. 3e). Two strong MCAO events were observed during the cold period. The first one lasted for almost the entire third campaign week with a maximum  $M$  of 10 K, which exceeded the 90<sup>th</sup> percentile of the climatology (Fig. 2b). The second MCAO event occurred on 01–02 April and exceeded the 75<sup>th</sup> percentile with  $M$  up 250 to 9 K. This event showed the minimum latitude–averaged  $IHT_{\text{north}}$  of the campaign ( $-5.32 \cdot 10^{10} \text{ W m}^{-1}$ , Fig. 5) and did not reach the 0.02<sup>th</sup> percentile of the climatology.

Between the two strong MCAO events and after the second one, the MCAO conditions weakened (decreasing  $M$ ) in the western Fram Strait due to decreasing pressure gradients and calming winds, which turned more towards easterlies (Fig. 3d). Especially in the central region, the near–surface temperature increase (Fig. 3c) indicated the advection of relatively warm air 255 from several subpolar regions across the central Arctic. We classified these events as aged warm air periods (Fig. 3a) during which we observed mainly three recurring patterns. First, the easterly winds resulted in cloud–free areas in the lee of Svalbard. Second, converging winds over the central Fram Strait led to increased convective cloud formation. Third, some cloud streets developed over the western Fram Strait due to a less disturbed off–ice flow. Both position and intensity of these patterns varied

**Figure 4.** Maps of mean sea level pressure (white contour lines), 500 hPa geopotential height (black contour lines), and 850 hPa equivalent-potential temperature (shading and grey contours) from ERA5 data for representative days of the main weather conditions at 12 UTC. 13 March (a) and 15 March (b) represent the moist and warm air intrusions with AR characteristics, (c) shows the Shapiro–Keyser cyclone on 21 March that marked the beginning of the cold air outbreak period, 28 March (d) and 01 April (e) represent the persistent northeasterlies with varying cold air advection strength, and (f) features the Polar Low west of Svalbard on 08 April. The 15% sea ice concentration from AMSR2 (Spreen et al., 2008) is displayed as blue contour line.

**Figure 5.** Hovmöller diagram of hourly vertically integrated meridional fluxes of (a) heat ( $IHT_{\text{north}}$ ), and (b) moisture ( $IVT_{\text{north}}$ ) during HALO-(AC)<sup>3</sup>, averaged over the central region latitudes. Positive (negative) values indicate northward (southward) fluxes. Orange vertical lines indicate the longitude boundaries of the central region. Important synoptic events shown in Fig. 4 are marked by horizontal dashed lines. Data is based on ERA5.

from day to day. On 05–06 April, the relatively warm air was still present in the measurement regions, but the advection was weaker due to reduced horizontal pressure gradients. Therefore, we did not attribute these days to one of the weather classes defined in Fig. 3.

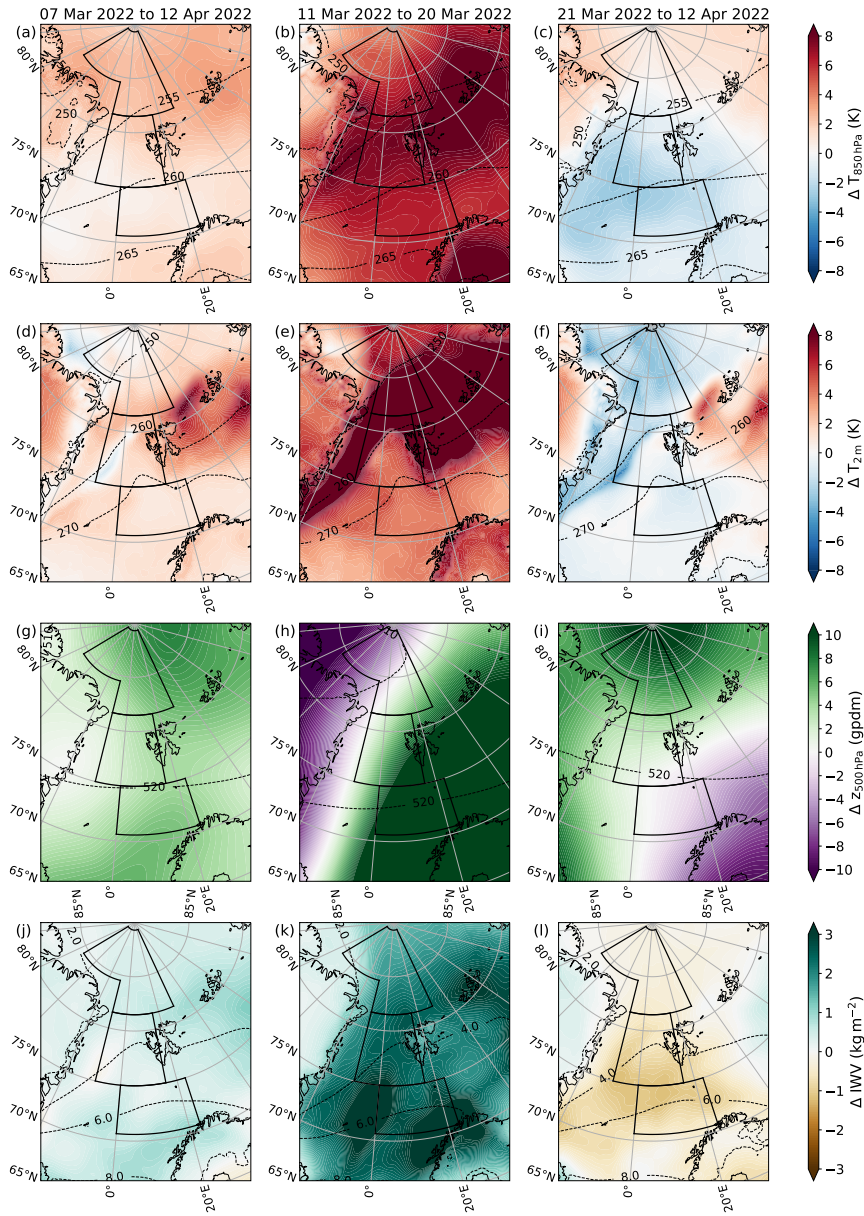

On 07 April, another weak MCAO (Fig. 2b) and the positive vorticity of an upper-level trough reaching Fram Strait promoted the formation of a mesoscale cyclone with features of a Polar Low (Fig. 4f, details in Sect. 4.3). In the following two days, the Polar Low moved to the northwest and dissipated over the sea ice northeast of Greenland. In parallel, a low pressure complex over Scandinavia advected warm and moist air from Siberia towards the Norwegian Sea. This air mass caused an increase of IWV above  $10 \text{ kg m}^{-2}$  over parts of the southern region (Fig. 3e) and was advected northwards with a southerly upper-level flow in the following days (10–12 April). The elevated moist air led to the formation of cirrus clouds over the western Fram Strait (see Sect. 4.4).

Overall, the period of pronounced MCAO activity lasting from 21 March to 12 April much better reflects the typical state  
270 of the central region than the preceding warm period. Climatologically, the entire campaign period is characterized by weak  
MCAO conditions ( $M$  between 1 and 3K). With a duration of 5–6 days, the first HALO–(AC)<sup>3</sup> MCAO period (21–26 March)  
was slightly longer than the mean duration of MCAO events (3–4 days, Terpstra et al., 2021). During the cold period, the  
500hPa geopotential height anomalies were negative over Scandinavia and northwestern Russia (coinciding with low surface  
pressure), and positive over the central Arctic and Greenland (coinciding with high surface pressure, Fig. 6i). The persistence  
275 of the northerly winds due to this anomalous pressure constellation explains the longevity of the MCAO conditions. Negative  
temperature anomalies at 2m and at 850hPa were most prominent in the central Fram Strait, Norwegian Sea and parts of the  
Greenland Sea, which were affected by the cold air advection (Fig. 6c, f). Reduced IWV compared to the climatology overlaps  
well with the negative 850hPa temperature anomalies (Fig. 6l). Positive temperature anomalies at 850hPa were restricted  
to regions that were not affected by cold air advection (central Arctic, eastern Barents Sea). Interestingly, the central Arctic  
280 Ocean showed negative temperature anomalies at 2m and positive anomalies at 850hPa, suggesting enhanced static stability  
compared to the climatological mean (Fig. 6c, f). This area also shows slightly positive subsidence anomalies at 850hPa (not  
shown). In contrast, the static stability is reduced in the area between Svalbard and Franz Josef Land with positive anomalies  
at the surface and negative anomalies at 850hPa.

### 3.1.3 Climatological assessment of the full HALO–(AC)<sup>3</sup> period

285 The 2m temperature anomalies for the entire HALO–(AC)<sup>3</sup> period (07 March–12 April) were positive in most regions shown  
in Fig. 6d. Only in the central Fram Strait and north of Greenland negative 2m temperature anomalies down to  $-1.2\text{K}$  and  
 $-2.4\text{K}$ , respectively, were found, coinciding with the regions of strongest negative 2m temperature anomalies during the  
cold period. Slightly positive 2m temperature anomalies over the sea ice in the western Fram Strait indicate that the extremely  
positive anomalies of  $> 8\text{K}$  during the warm period were not completely balanced by negative anomalies during the longer cold  
290 period (Fig. 6d–f). Temperature anomalies at 850hPa were positive in all regions shown in Fig. 6. The strongest anomalies with  
2–3.5K were found over the central Arctic Ocean and northern Barents Sea, coinciding with the regions of positive 850hPa  
temperature anomalies during the cold period (Fig. 6a, c). Positive temperature anomalies combined with high surface pressure  
over Scandinavia (central Arctic) in the warm (cold) period resulted in overall positive 500hPa geopotential height anomalies  
over these regions (Fig. 6g). The lowest 500hPa geopotential height anomalies were located over the east coast of Greenland,  
295 where low geopotential also remained during the first part of the cold period.

Over the central region, we found small northward heat fluxes ( $\text{IHT}_{\text{north}}$  of  $5.4 \cdot 10^8 \text{W m}^{-1}$ ) and moisture fluxes ( $\text{IVT}_{\text{north}}$   
of  $18 \text{kg m}^{-1} \text{s}^{-1}$ ). Consequently, the thermal energy input into the Arctic through this pathway was slightly positive and the  
brief but intense MWAI / ARs overcompensated the long MCAO period. In previous years,  $\text{IHT}_{\text{north}}$  and  $\text{IVT}_{\text{north}}$  were often  
smaller or even negative over the campaign days and the central region.

**Figure 6.** Anomaly maps of (a–c) temperature at 850 hPa ( $\Delta T_{850\text{hPa}}$ ), (d–f) 2 m temperature ( $\Delta T_{2\text{m}}$ ), (g–i) geopotential height at 500 hPa ( $\Delta Z_{500\text{hPa}}$ ), and (j–l) vertically integrated water vapour ( $\Delta \text{IWV}$ ) based on ERA5 for the entire campaign, the warm, and the cold period in the left, middle, and right column. The coloured contours show the long–term mean subtracted from the mean of the time period in 2022 so that positive (negative) values correspond to anomalies above (below) the long–term mean. The dashed black isolines describe the long–term climatology in each panel. The three measurement regions (shown in Fig. 1) are illustrated as black boxes.

## 300 3.2 Ny-Ålesund

The extensive remote sensing observations at Ny-Ålesund may complement the airborne observations during HALO-(AC)<sup>3</sup>. However, Ny-Ålesund is located at the eastern edge of the central region and measurements may be influenced by the local orography. Based on the temperature profiles (Fig. 7a), the atmospheric conditions at Ny-Ålesund can also be divided into a warm (11–21 March) and a colder period (22 March–12 April). Compared to the full central region, this indicates a temporal shift of one day.

The warm air advection related to the first AR led to an increase of 2m temperature from about  $-14^{\circ}\text{C}$  to  $+2^{\circ}\text{C}$  within 19 hours (meteorological tower measurements, not shown). Vertical advection of heat and moisture lifted the tropopause to 12.9 km (measured by the 12 UTC radiosonde on 12 March, Fig. 7a). The 2m temperature remained above freezing for five days and even reached a new maximum for March on 15 March ( $5.5^{\circ}\text{C}$ ). On this day, also the highest IWV was observed (14.5  $\text{kg m}^{-2}$ , Fig. 7b).

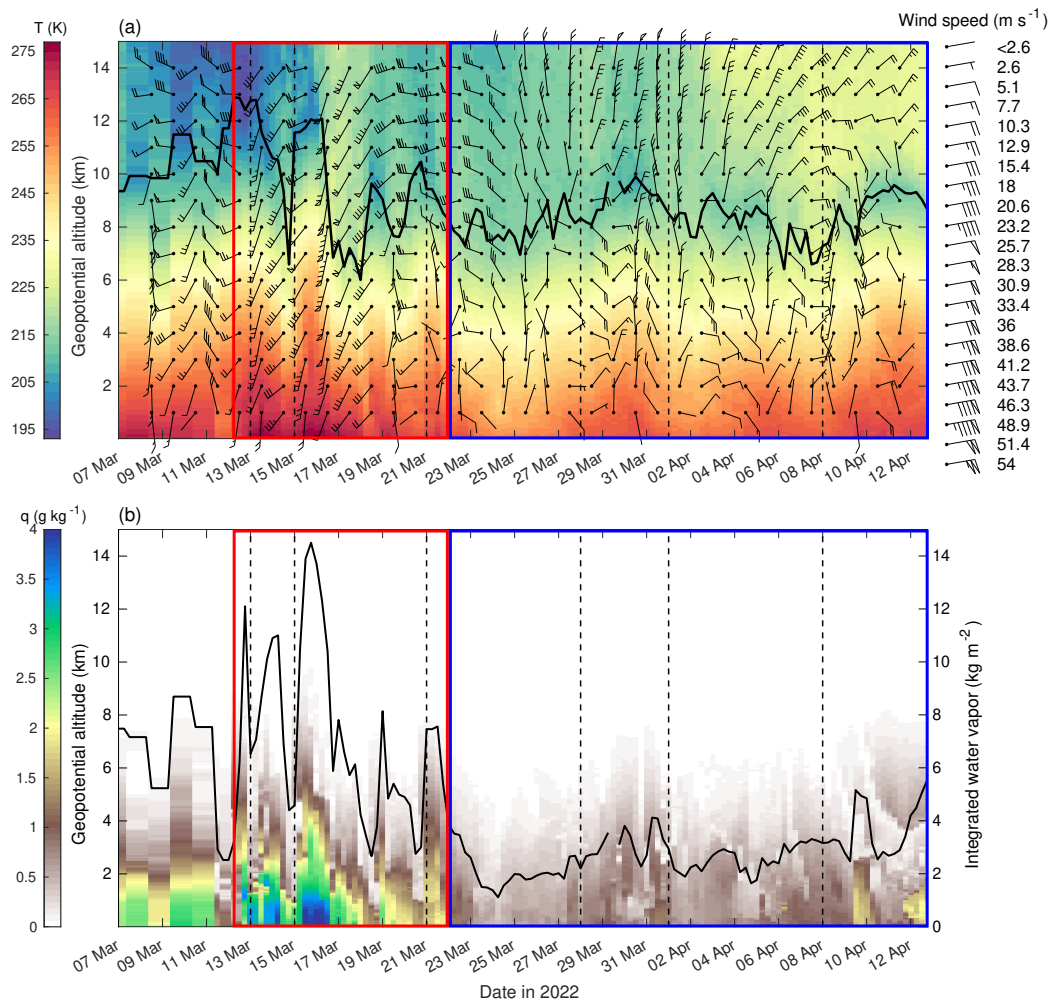

The warm period was characterized by constant low-level cloud cover over Ny-Ålesund detected by the ceilometer, interrupted only by a few hours of high-level cloud occurrence in connection with a high pressure ridge passing the site in the night of 14–15 March (not shown). The situation changed during the course of 17 March, when the cloud deck started to dissolve and the 2m temperature dropped below  $0^{\circ}\text{C}$ .

The influence of the Shapiro–Keyser cyclone (see Sect. 3.1) delayed the beginning of the cold period over Svalbard compared to the central region by about one day. Northerly winds corresponding to the MCAO period led to extremely dry conditions with IWV down to  $1.1 \text{ kg m}^{-2}$  (closest grid point in ERA5 with land-fraction  $< 0.25$ :  $1.5 \text{ kg m}^{-2}$ ) on 24 March at 06 UTC (Fig. 7b). This IWV is below the 3<sup>rd</sup> percentile of all radiosondes between 07 March and 12 April 1993–2022 (Maturilli and Kayser, 2016, 2017; Maturilli, 2020b). At Ny-Ålesund, the MCAO conditions on 23–30 March, and on 01–05 April were mostly associated with clear sky and 2m temperatures below  $-12^{\circ}\text{C}$ . Aged warm air reached Ny-Ålesund on 28–29 March with more humidity, with slightly higher temperatures and IWV increasing to  $4 \text{ kg m}^{-2}$ .

Especially during the cold period, cloud conditions at Ny-Ålesund are not representative for the central region because of lee effects as visible on MODIS images (e.g., NASA Worldview, not shown). Additionally, the temporal delay related to the propagation of synoptic systems during the warm period must be kept in mind when combining Ny-Ålesund with HALO-(AC)<sup>3</sup> observations.

## 3.3 Sea ice conditions

The different synoptic patterns affected the sea ice conditions in the measurement areas. In Fig. 8a–c, we present the spatial distribution of SIC before (09–11 March) and during (14–16 March) the MWAI, as well as after the MCAO period (10–12 April). SIC was  $> 90\%$  in almost the entire northern region in the first period (Fig. 8a). In the central region, the sea ice covered 30–40% of the area with a southwest–northeast oriented edge. The southern region was almost completely ice-free over the entire campaign duration (Fig. 8a–c). A time series of SIC for the central region compared to the climatology is shown in Fig. 8d.

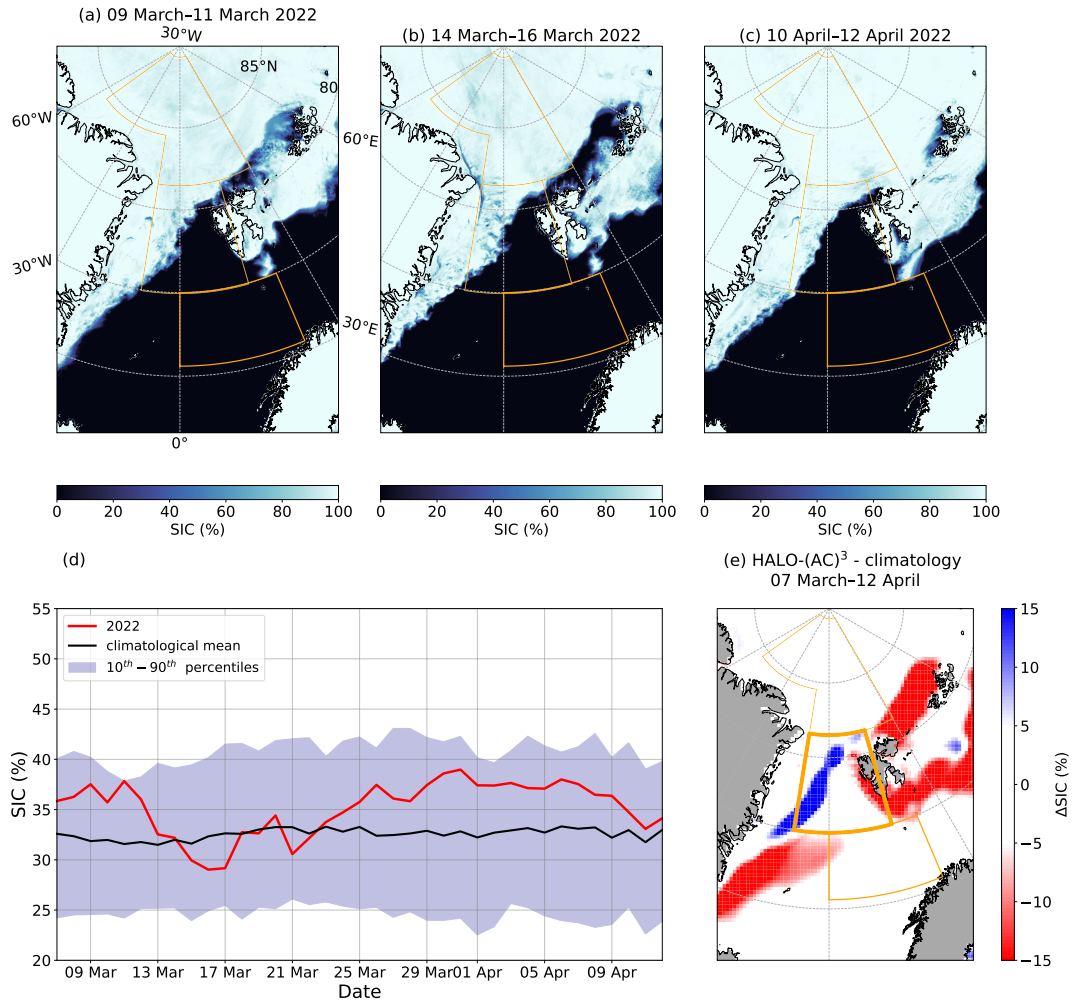

**Figure 7.** Time series of Ny-Ålesund radiosondes of (a) temperature profiles (shading), height of thermal tropopause (black line), and wind barbs in selected levels, and (b) specific humidity profiles (shading) and resulting IWV (black line, right axis). Vertical dashed black lines indicate the days shown in Fig. 4. The red (blue) box indicates the shifted warm (cold) period.

The MWAI / AR events on 12–13 and 15 March caused a reduction of SIC in the northwestern part of the central region, resulting in the lowest values of the entire campaign period (Fig. 8b, d). SIC was below the climatological mean but within the 10–90<sup>th</sup> percentiles. Furthermore, an unusually large polynya opened from north of Svalbard to Franz Josef Land, which resulted in the below-average static stability during the cold period in this region (Fig. 8b). We assume that ice dynamics related to strong winds caused the SIC decrease, but ice melt cannot be excluded as well because temperatures were above freezing and liquid precipitation was observed over sea ice. Rapid ice melt has been attributed to warm air advections and induced increases of heat flux in summer (Tjernström et al., 2015; Woods and Caballero, 2016). Although the liquid precipitation on snow alters

340 the signal of the microwave radiometry and might have increased the uncertainty of the SIC product (Stroeve et al., 2022; Rückert et al., 2023), that SIC reduction was obvious in visual satellite images as well (e.g., NASA Worldview, not shown). After the AR events, the sea ice conditions recovered and the polynya closed again (Fig. 8c, d) mostly due to sea ice transport from the central Arctic. This southward transport can be attributed to the winds during the high MCAO activity between 21 March and 07 April.

345 For most of the campaign period, the average SIC in the central region was above the climatological mean (Fig. 8d). A map of SIC anomalies compared to the climatological mean is illustrated in Fig. 8e. Southwest of 75° N and 0° E as well as northeast and southeast of Svalbard, SIC anomalies were negative. In contrast, a positive SIC anomaly was found in the central and western Fram Strait, which overlaps well with the negative 2m temperature anomalies shown in Fig. 6d, f. The west coast of Svalbard used to be covered by ice in the climatology but was completely ice-free during HALO-(AC)<sup>3</sup>. In the northern  
350 and southern regions, the mean SIC for the entire campaign period did not differ more than 5% from the climatological mean.

Note that uncertainties in the marginal ice zone are especially large due to weather related filters and as a result of temporal and spatial interpolations. This mainly affects the central region where the estimated uncertainties of the SIC product (total standard uncertainty) can reach up to 40% at the ice edge, mostly due to smearing uncertainty (gridding of the swaths, i.e., areas imaged on the surface, from several daily overflights), and different satellite footprints at different frequency channels.

**Figure 8.** Average sea ice concentration (SIC) from the MODIS-AMSR2 product at 1 km grid resolution for (a) 09–11 March (prior to the first AR event), (b) 14–16 March (during the second AR event), (c) 10–12 April (at the end of the campaign). Data is from the MODIS-AMSR2 product at 1 km grid resolution. (d): SIC time series averaged over the central region for the campaign period, as well as the mean, and 10<sup>th</sup>–90<sup>th</sup> percentiles of the 1979–2022 climatology. (e): SIC anomalies from the climatological mean averaged over the entire campaign period. Note that only differences larger 5% are considered due to the uncertainties of the satellite product in the marginal ice zone. Data for (d) and (e) is from the OSI-SAF sea ice concentration climate data record.

#### 4.1 Warm air intrusions and Atmospheric Rivers

The warm period was characterized by four independent AR events (12–13 March, 14 March, 15 March, and 20 March) that were at least partly sampled by research aircraft in the three measurement regions. Back trajectory analyses with LAGRANTO (Sect. 2.4.5) revealed that the air masses of the 12–13 March event (Fig. B1a) originated from mid–latitude regions of the North Atlantic and from central Europe (Fig. C1a). For the second AR event on 15 March (Fig. B1b), the air masses originated almost exclusively from the western part of the mid–latitude North Atlantic (Fig. C1b). We neglect the ARs on 14 and 20 March as they did not enter the central region, but either propagated northwards to the west of it or dissipated before reaching it. The moist air advection event on 10 April (Fig. C1c) was too weak to be identified as AR, but was relevant for the formation of cirrus clouds over sea ice.

We compare the strength of AR events during HALO–(AC)<sup>3</sup> by analysing them with respect to the relation between IVT and latitude over the North Atlantic and Arctic Ocean (50–90° N, 60° W–40° E) (Fig. 9). Note that a different region was selected to extend the view on the North Atlantic, one of the major pathways of ARs (Guan and Waliser, 2017; Nash et al., 2018). Along their northward propagation, ARs generally decline in intensity. If otherwise ARs start to form in the Arctic, their moisture supply is reduced so that their intensification is limited (Papritz et al., 2021). Therefore the number of strong AR events decreases meridionally (Fig. 9).

North of 70.6° N (southern boundary of the southern region), only few ARs exceed an IVT of  $250 \text{ kg m}^{-1} \text{ s}^{-1}$  when averaged over the detected AR area (Fig. 9). In the climatology, the majority has mean values around  $150 \text{ kg m}^{-1} \text{ s}^{-1}$ . The AR events on 12–13, and 15 March represent strong cases in terms of mean IVT for all time steps as they lie outside the 25<sup>th</sup> percentile in latitude–IVT space (Fig. 9). On 15 March at 18 UTC, the AR averaged IVT even exceeded the 10<sup>th</sup> percentile while being centered at 76° N. While the AR centre from the event on 12–13 March was located most northerly before it dissipated, the AR from 15 March was characterized by the most intense moisture transport with mean IVT of around  $250 \text{ kg m}^{-1} \text{ s}^{-1}$  when centered at 70° N, decreasing to  $200 \text{ kg m}^{-1} \text{ s}^{-1}$  at 75° N. Maximum IVT (meridional and zonal) slightly exceeded  $400 \text{ kg m}^{-1} \text{ s}^{-1}$  between 13 and 16 March in the central region (see Appendix B, Fig. B1). HALO’s dropsonde measurements showed a maximum IVT of  $490 \text{ kg m}^{-1} \text{ s}^{-1}$  on 15 March, suggesting that ERA5 underestimates the moisture flux. As these AR events had meridionally elongated structures, the outflow region reached up to the central Arctic while their centres were located at 70–78° N (Fig. 9). During their poleward propagation, the moisture transport decreased so that they no longer fulfilled the detection requirements.

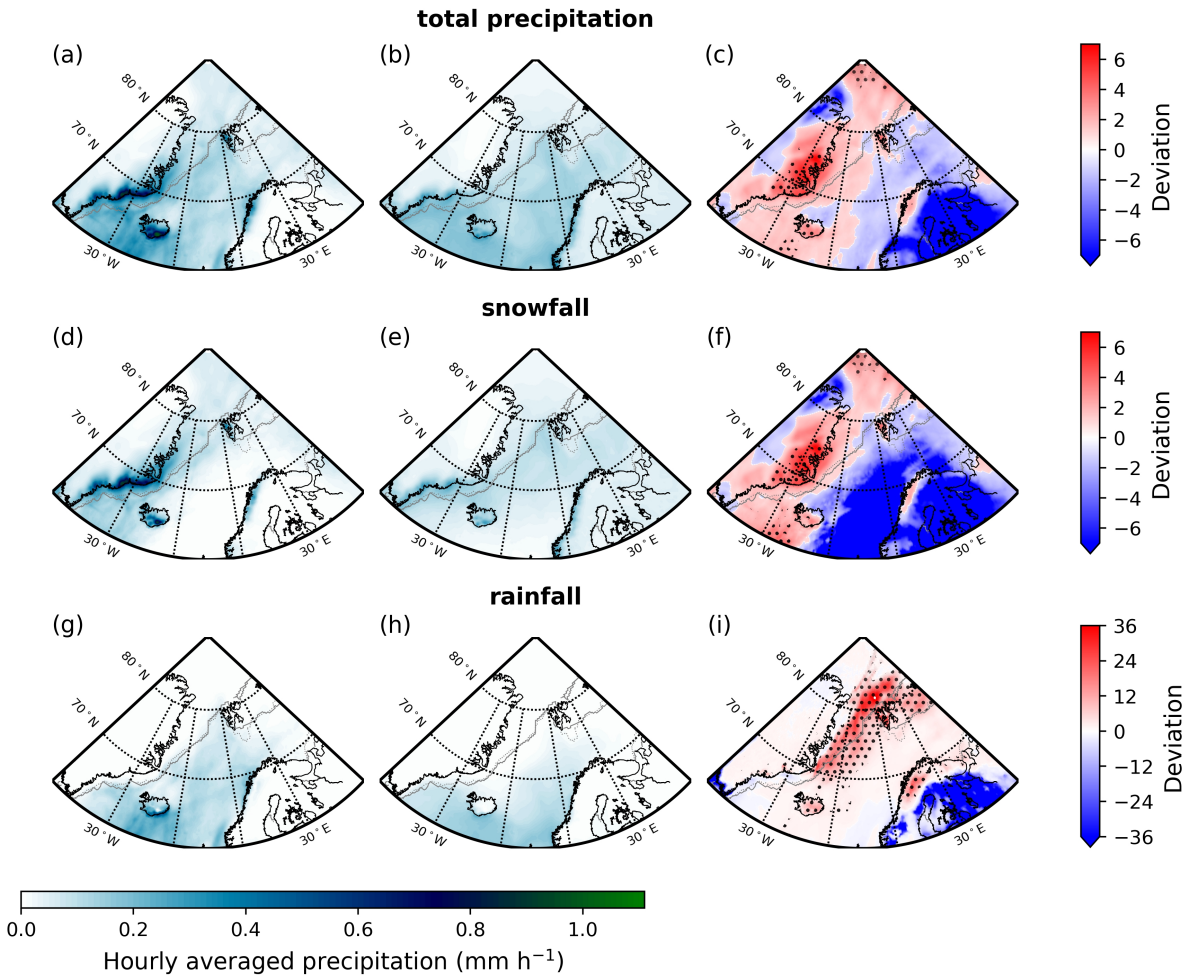

The AR events in the warm period were associated with anomalous amounts of precipitation. In Fig. 10, we show the hourly averaged precipitation rate from 11 to 20 March 2022 as well as for the climatology of these days. Along the east coast of Greenland, the total precipitation and snowfall rate partly exceeded  $1 \text{ mm h}^{-1}$  (Fig. 10a, d), around six times higher compared to climatology (Fig. 10c, f). Over the North Atlantic, Fram Strait, and central Arctic Ocean, total precipitation and snowfall rates exceeded the climatology by a factor of 3. Record breaking rainfall rates were found northwest of Svalbard, exceeding the climatology up to a factor of 36 (Fig. 10i). However, the actual rainfall rate in this area was below  $0.25 \text{ mm h}^{-1}$  and the

high deviation is caused by even lower rainfall rates in the climatology. Liquid precipitation over sea ice was also observed by  
 390 the cloud radar onboard HALO during research flights.

In summary, the ARs observed during HALO–(AC)<sup>3</sup> featured uncommonly high AR–averaged IVT values, higher than 90% of all ARs in the climatology. Additionally, record breaking rainfall rates occurred over the sea ice northwest of Svalbard.

**Figure 9.** Six hourly climatological (1979–2022) distribution of central latitudes of Atmospheric Rivers (ARs) as a function of mean AR IVT using an ERA5 based AR catalogue modified from Guan and Waliser (2015). Cases categorized as ARs during HALO–(AC)<sup>3</sup> are illustrated by coloured boxes for 06, 12, and 18 UTC of respective flight days. Black (dashed) lines indicate the 25<sup>th</sup> and 75<sup>th</sup> (10<sup>th</sup> and 90<sup>th</sup>) percentiles of a kernel density estimation to visualize the shape of the histogram. Horizontal dotted lines indicate the latitude boundaries of the three measurement regions (Fig. 1) in the same colours as in Fig. 3.

**Figure 10.** Hourly averaged precipitation, snowfall and rain rate ( $\text{mm h}^{-1}$ ) derived from ERA5 for (a, d, g) 11–20 March 2022, and (b, e, h) the climatology. In (c, f, i), we show the deviation from the climatology. Note that the rainfall over sea ice is barely visible in both (g) and (h). Positive deviations of precipitation rates are illustrated as the fraction of the average rate in 2022 to the rate of the climatology while negative deviations are given as its inverse.

## 4.2 Marine cold air outbreaks

The cold period included several MCAO events (21 March–07 April), which are analysed in detail specifically for the central region. Figure 11 shows the time series of atmospheric conditions as described in Sect. 2.4.3. To highlight the conditions in the MCAOs' source region, we also include the temporal evolution of the parameters averaged over the eastern part of the northern region in Appendix D (Fig. D1). The corresponding temporal development over the southern region is shown in Fig. D2 in Appendix D.

After the Shapiro–Keyser cyclone, which caused multi-layered clouds and intense snowfall on 21 March at the west coast  
400 of Svalbard (Fig. 11d–g), MCAO conditions were established. From 22 to 26 March, the contribution of convective to total  
snowfall increased over open water and mid- and high-level cloud cover decreased. Over sea ice, the total snowfall was low  
and almost exclusively stratiform. Liquid precipitation was not present except for 21 March. Low-level cloud cover remained  
high until 07 April, reflecting the presence of the atmospheric boundary layer clouds typically associated with MCAOs (Fig.  
11d).

405 The strong MCAO events (21–26 March and 01–02 April) were characterized by the strongest northerly lower tropospheric  
winds and high values of domain-averaged turbulent fluxes of sensible and latent heat flux (Fig. 11a, h). The maximum values  
of sensible and latent heat coincided with the highest wind speeds and low temperatures (21–22 March, Fig. 11a, b, h). Note  
that over the southern region the sensible heat fluxes were slightly lower, whereas, on average, latent heat fluxes were higher  
than over the central region (Fig. D2). Near-surface air temperatures increased towards the south, resulting in smaller sensible  
410 heat fluxes while latent heat fluxes were increased due to a rising saturation water vapour pressure at the air–sea interface  
(e.g., Hartmann et al., 1997). We found that larger differences between the specific humidity of the air and specific humidity at  
saturation in the southern compared to the central region were responsible for the increased latent heat fluxes (not shown).

During the weak MCAOs and aged warm air periods, northeasterly winds dominated (Fig. 11a). Compared to strong MCAO  
conditions, sensible heat fluxes were reduced by a factor of 2 while latent heat fluxes decreased to a lesser extent. Between  
415 27–30 March and 03–05 April, when aged warm air was advected to the central region, precipitation decreased as the air  
mass dried and temperatures increased (Fig. 11b, c, g). Also, foehn effects due to the easterly winds over Svalbard might have  
contributed to drier and warmer conditions over parts of the Fram Strait as this effect can influence the atmospheric conditions  
more than 100 km off the coast (Shestakova et al., 2022). The eastern parts of the central region close to Svalbard were not  
fully covered by low-level clouds as the 5% percentile was mostly between 0.2–0.4. For the first aged warm air period, the  
420 southward advection of the air masses from the sea ice covered ocean took about one day. This can be seen when comparing  
the temporal evolution of the lower tropospheric temperature and relative humidity over the northern and central regions (i.e.,  
low relative humidity from 29 to 30 March, Fig. D1a–c vs. 11a–c).

From 05 April on, the mean wind speed decreased and turned to northeast. Hence, more convergent regions developed in the  
lee of Svalbard with a rather diffuse low-level cloud structure (not shown). These converging winds in combination with a weak  
425 MCAO promoted the formation of a Polar Low in the following days, which is explained in greater detail in the next section.  
Hence, different wind regimes ranging from northwest to northeast and MCAO strengths were observed during HALO-(AC)<sup>3</sup>.  
The large variety of MCAO conditions provides great opportunities for detailed cloud evolution and air mass transformation  
studies.

### 4.3 Polar low

430 The Polar Low formed on 07 April close to the west coast of Svalbard at a baroclinic zone where cold air transported by  
northeasterly winds converged with warmer North Atlantic air from south to southeasterly winds. During the development  
phase of the Polar Low, the mean sea level pressure showed closed isobars from 08 April 00 UTC on (Fig. 4f). We examine

**Figure 11.** Temporal evolution of (a) wind, (b) air temperature ( $T$ ), and (c) relative humidity (RH) on the 1000, 925, and 850hPa pressure levels, and of (d) low-, (e) mid-, and (f) high-level cloud cover (CC), (g) precipitation, and (h) surface turbulent heat fluxes (STHF, upward is positive) over the central region for 21 March – 07 April 2022 derived from ERA5. For cloud cover, we show the median, the 25 and 75<sup>th</sup> percentiles, and the 5 and 95<sup>th</sup> percentiles of a 6 hour interval over open-water surfaces only as crosses, thick vertical lines, and thin vertical lines, respectively. In (g), we display area-averaged values of the accumulated 6 hour snowfall distinguished between convective and total precipitation, and open water (OW) and sea ice (SI). White crosses show the accumulated mean rainfall with more than  $0.05 \text{ mm} (6\text{h})^{-1}$ .

whether the environmental conditions C1–C6 (see Sect. 2.4.4) were fulfilled in a 200km radius around the pressure minimum of the Polar Low at that time (Fig. 12):

435 The vertical temperature gradient conditions C1 and C2 are fulfilled with 44K and 8.5K, respectively, while the lapse rate condition (C3) was not fulfilled with  $4.2\text{K km}^{-1}$ . Conditions C4<sub>i</sub> and C4<sub>ii</sub>, which are a measure for the availability of moisture for latent heat release, exceed the thresholds of 75% and 82% with 92.7% and 93.9%. Near surface wind gusts reached  $16.6\text{ms}^{-1}$  during the development phase of the Polar Low (00 UTC) and increased to  $18.8\text{ms}^{-1}$  9 hours later at the mature stage. In both stages, condition C5 was fulfilled. If we considered the maximum of the 10m wind speed instead of the gust from  
440 ERA5, the condition would not have been fulfilled. However, using the Copernicus Arctic Regional Reanalysis (CARRA) from ECMWF with a  $2.5\text{km}\times 2.5\text{km}$  resolution, we found maximum wind speeds of more than  $16\text{ms}^{-1}$  ( $19\text{ms}^{-1}$ ) at 00 UTC (09 UTC). The trough connected to the Polar Low was not sufficiently strong with respect to the climatology as the geopotential height anomaly (C6) was only  $-80\text{gpm}$ . Anomalously high geopotential around Svalbard and the central Arctic during that time might have obscured the strength of the trough, resulting in the failure of condition C6.

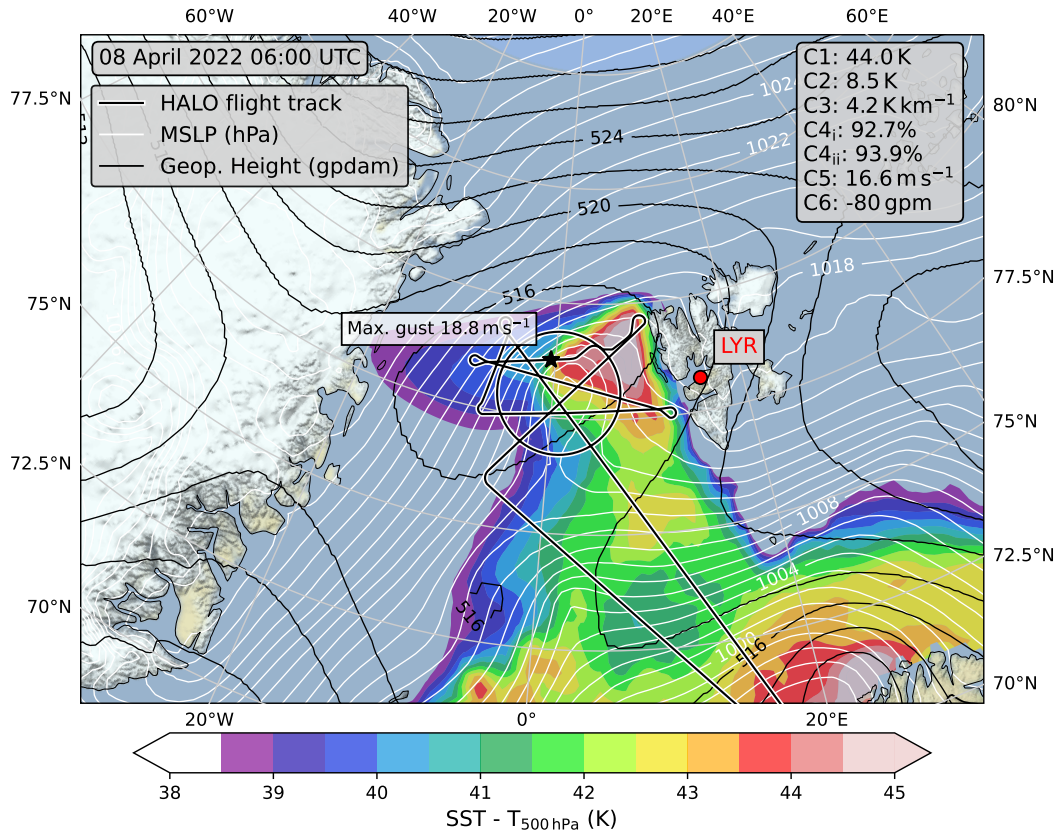

445 Some of the conditions had a large regional variability within the 200km circle. Condition C2 ranged from below the threshold of 6K in the southern part of the Polar Low to 10K in the northern half. As the northwestern part of the circle lay over sea ice, the vertically averaged lower tropospheric lapse rate (C3) indicated stable stratification and reached values up to  $10\text{K km}^{-1}$ . These high values of the lapse rate dominated the computation of the 75<sup>th</sup> percentile although the lapse rate was below the threshold in most parts of the circle.

450 At the mature stage (08 April 06–09 UTC), the region of maximum  $\text{SST} - T_{500\text{hPa}}$  difference coincided well with the observed convective clouds during the research flight with HALO in the eastern part of the Polar Low (see Appendix E, Fig. E1). It also overlapped with the maximum precipitation rate ( $1.2\text{mm h}^{-1}$ ) and strongest updrafts ( $-1.75\text{Pa s}^{-1}$  at 850 hPa) indicated by ERA5 (not shown). It is likely that higher precipitation rates and updrafts occurred that were smoothed out by the relatively coarse ERA5 data.

455 Dropsonde measurements between 06:55 and 07:53 UTC show high values of relative vorticity in the lowest 2km and above 6km, indicating cyclonic rotation. When averaging ERA5 vorticity over the grid points closest to the dropsonde positions, we find a disagreement to the dropsonde measurements below and good agreement above 4km height. While the lower tropospheric relative vorticity is related to the Polar Low, the upper tropospheric value is associated with the trough in the geopotential height. The disagreement between ERA5 and the dropsondes could be due to a misrepresentation of the Polar  
460 Low's wind field in the reanalysis or due to spatio-temporal mismatches of its position. Measured relative vorticity at 850 hPa (1.5 km height) was about  $3.5\cdot 10^{-5}\text{s}^{-1}$  and therefore did not exceed the threshold suggested by Stoll (2022) ( $> 20\cdot 10^{-5}\text{s}^{-1}$ ). However, the flight track was not perfectly aligned with the Polar Low's centre but extended too far to the south and east where the mean sea level pressure isobars do not suggest a closed circulation (Fig. 13b). Negative relative vorticity to the east of the Polar Low, which is related to lee effects, also influenced the calculation from the dropsonde measurements. ERA5 data shows  
465 a maximum of  $22\cdot 10^{-5}\text{s}^{-1}$  at 850 hPa within the Polar Low on 08 April at 09 UTC.

As soon as the Polar Low drifted over sea ice, it started to dissipate due to the loss of atmospheric instability and strongly reduced upward sensible and latent heat fluxes. The Polar Low observed during HALO-(AC)<sup>3</sup> fulfilled four of the six conditions

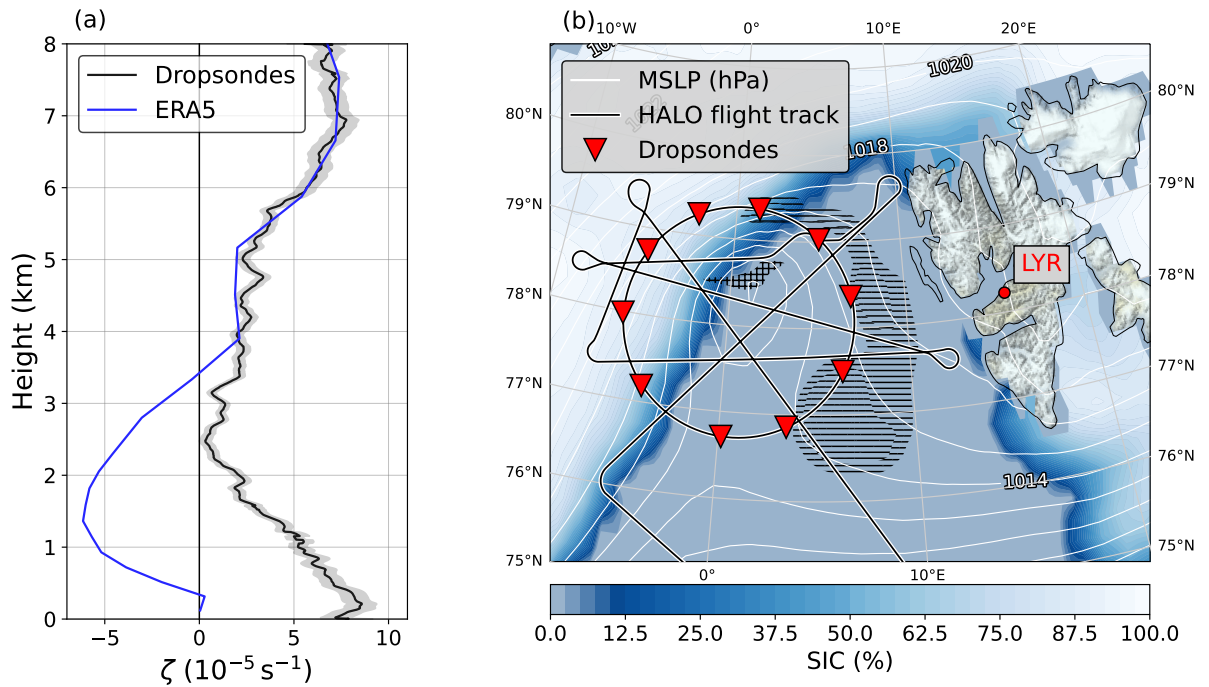

(see Table 1). However, Polar Lows can also form without fulfilling all conditions. Considering the climatology of Polar Lows in Zahn and von Storch (2008), which covers the years 1949–2005, our Polar Low was located unusually far in the north. Also  
 470 Radovan et al. (2019) investigated 33 Polar Lows with the Arctic System Reanalysis, of which 32 were centered further to the south than our case. Despite its northerly position, the 10m wind speed of our Polar Low was larger than the average over the 33 Polar Lows investigated in their study.

**Figure 12.** Mean sea level pressure (MSLP, white contour lines), 500hPa geopotential height (black contour lines), and the difference between sea surface temperature (SST) and 500hPa temperature during the mature stage of the Polar Low on 08 April 2022 06:00 UTC. Additionally, the maximum 10m wind gust at 09:00 UTC (black star and text label) and the HALO flight track (black line with white outline) are included. The Polar Low conditions C1 (SST – 500hPa temperature), C2 (SST – T<sub>2m</sub>), C3 (vertical mean of the vertical potential temperature gradient below 850hPa), C4 (i: mean relative humidity below 950hPa, ii: mean relative humidity between 850 and 950hPa), C5 (maximum 10m wind speed), and C6 (500hPa geopotential height anomaly) analysed by Radovan et al. (2019) are given for 08 April 2022 00:00 UTC. Data is based on ERA5.

**Table 1.** Criteria to evaluate environmental conditions of a Polar Low in a 200 km radius around its pressure minimum according to Radovan et al. (2019). An "X" in the right column indicates that the condition is fulfilled.

Condition	Meaning	How evaluated	Threshold	Fulfilled
C1	Sea surface temperature – 500 hPa temperature	75 <sup>th</sup> percentile	$\geq 43\text{ K}$	X
C2	Sea surface temperature – 2 m temperature	75 <sup>th</sup> percentile	$\geq 6\text{ K}$	X
C3	Mean lapse rate below 850 hPa	75 <sup>th</sup> percentile	$\leq 3\text{ K km}^{-1}$	
C4 <sub>i</sub>	Mean relative humidity below 950 hPa	75 <sup>th</sup> percentile	$\geq 75\%$	X
C4 <sub>ii</sub>	Mean relative humidity between 850 and 950 hPa	75 <sup>th</sup> percentile	$\geq 82\%$	X
C5	10m wind gust	maximum	$\geq 15\text{ ms}^{-1}$	X
C6	500hPa geopotential height anomaly	mean	$\leq -160\text{ gpm}$	

**Figure 13.** (a) Relative vorticity  $\zeta$  computed from 10 dropsondes (black) and as model output from ERA5 averaged over the grid points nearest to the dropsondes (blue). (b) Location of the dropsondes (red triangles) launched from HALO while flying in a circle around the Polar Low. ERA5 based mean sea level pressure (white contour lines) and sea ice concentration (coloured filled contours) is shown for 08 April 2022 09 UTC. The HALO flight track is displayed as black line with white outline. Horizontal (horizontal and vertical) hatching indicates areas where ERA5 based 850 hPa relative vorticity is below  $-10 \cdot 10^{-5} \text{ s}^{-1}$  (above  $20 \cdot 10^{-5} \text{ s}^{-1}$ ).

#### 4.4 Arctic cirrus over sea ice

The sequence of HALO flights between 10 – 12 April aimed to characterize a pronounced field of Arctic cirrus, which entered the central Arctic through the Fram Strait and was finally located close to the North Pole. The initial synoptic state of this period was dominated by a low pressure system, which was centered over Scandinavia on 09 April, advecting warm and moist air westwards (see Sect. 3.1). Along approximately the  $5^\circ$  W meridian the westward flow converged with a cold air mass that formed over the Greenland ice sheet and flowed eastwards into the Fram Strait. Due to the convergence, a strong vertical wind shear developed south of Greenland with low-level northeasterly winds and southeasterly winds at levels above 700 hPa along the east coast of Greenland. The southerly upper-level flow generated a poleward moisture transport, which was accompanied by cirrus and mid-level clouds west of Svalbard and north of Greenland. This upper-level flow continued during the sequence of three research flights conducted by HALO and roughly connected the air masses sampled during the three consecutive days.

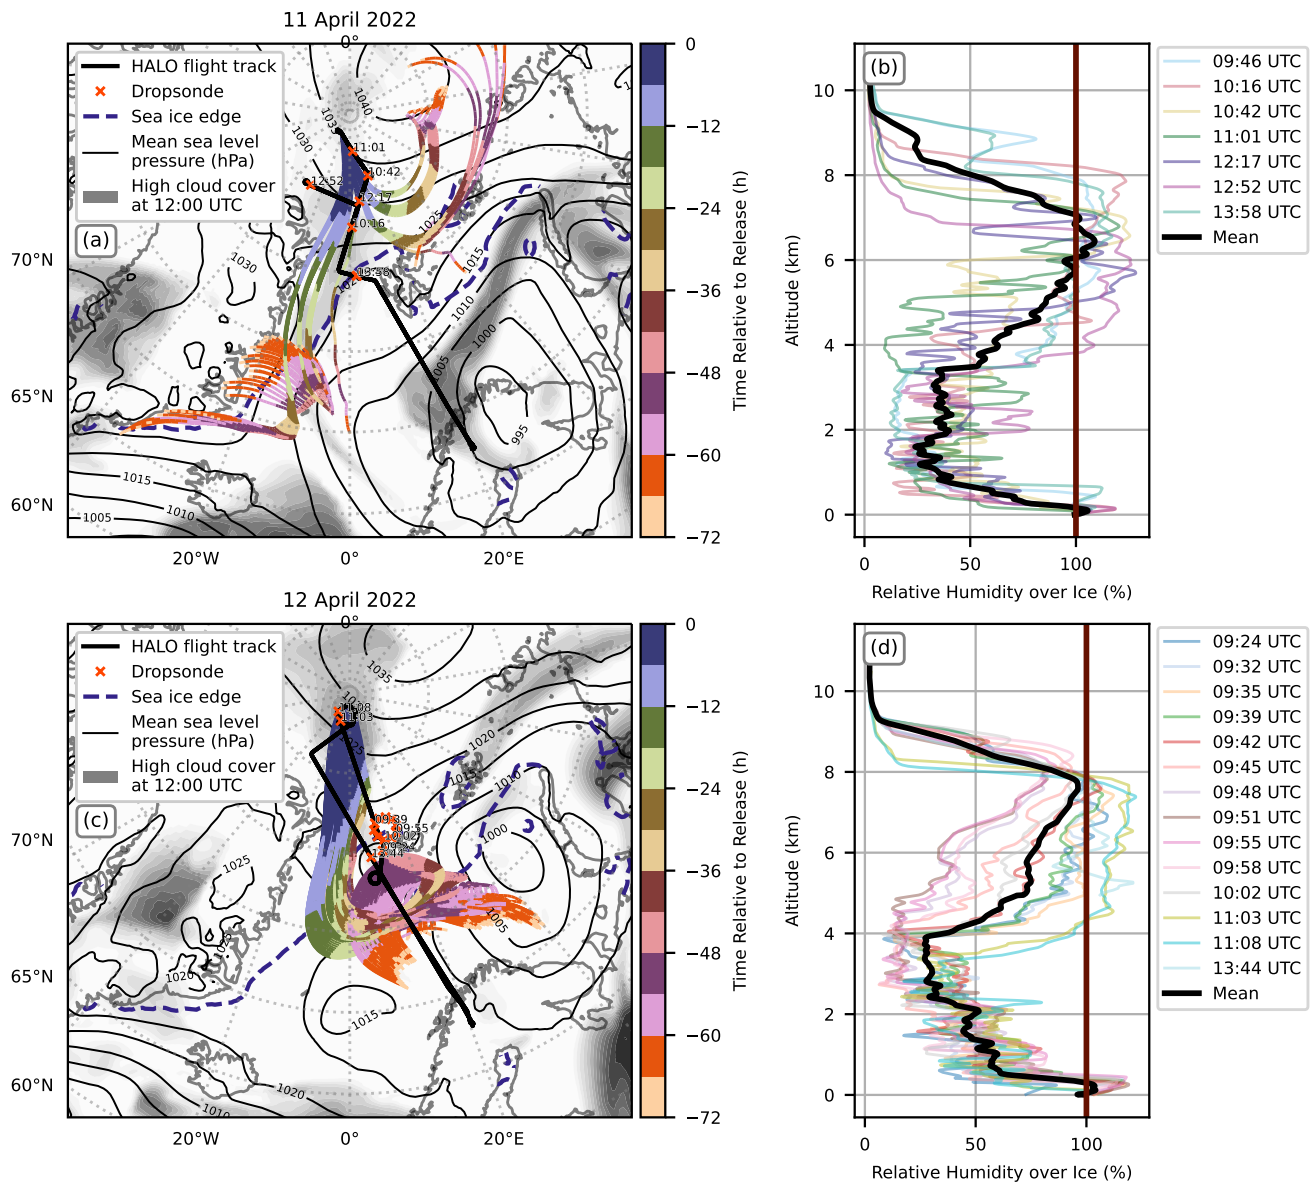

The trajectories of the air masses sampled on 11–12 April are shown in Fig. 14a, c. While on 11 April two branches, one southerly and one easterly, merged into the area of observations, the trajectories of 12 April first followed the westward moist air transport south of Svalbard and then turned northwards into the central Arctic. Figure 14b and d illustrate the relative humidity over ice from all dropsondes launched in the central Arctic during the HALO flights on 11–12 April. The mean profile shows an enhanced moisture layer between 4 km and 8 km. This layer is associated with higher wind speeds up to  $25 \text{ ms}^{-1}$  and a shift in wind direction from an easterly flow in the lower 3 km to a southerly flow in the upper troposphere. Below 4 km altitude, the air mass was rather dry with relative humidity below 50 %. In these lower altitudes, the stable cold and dry air mass in the central Arctic was supported by the outflow of cold and dry air from northern Greenland and prohibited the formation of clouds below the cirrus. The airborne measurements during this constellation of isolated, widespread cirrus over the sea ice in the central Arctic are well suited to investigate the evolution and radiative effect of Arctic cirrus over sea ice, of which only few observations exist.

## 5 Conclusions

In this study, we described the weather and sea ice conditions during the HALO–(AC)<sup>3</sup> aircraft campaign carried out from 07 March to 12 April 2022 in the North Atlantic sector of the Arctic. The analysis is based on the ERA5 reanalysis, dropsondes, satellite based sea ice products, and atmospheric measurements at Ny-Ålesund. We focus on three measurement regions of the campaign: the sea ice covered Arctic Ocean north of Svalbard and Greenland (northern region), the Fram Strait (central region), and the Greenland and Norwegian Seas between Svalbard and Scandinavia (southern region). The climatological context is given with respect to the years 1979–2022.

Based on the vertically integrated meridional water vapour transport ( $\text{IVT}_{\text{north}}$ ) and the MCAO index  $M$ , the campaign was separated into a warm period (11–20 March), and a cold period (21 March–12 April). During the warm (cold) phase,  $\text{IVT}_{\text{north}}$  was positive (negative) while  $M$  was negative (positive), respectively.

The warm period at the beginning of the campaign was characterized by a consistent southerly flow, which led to a strong MWAI on 12–13 March that was detected as an Atmospheric River (AR) and reached the central Arctic. It was followed by an

**Figure 14.** (a, c) Three day back trajectories of air masses in which cirrus were sampled on 11 and 12 April 2022. All trajectories are based on ERA5 reanalysis and end at the HALO flight track in cirrus level between 350 and 550 hPa. Surface pressure (thin black lines) and cloud cover (black shading) above 550 hPa from ERA5 are shown for 12 UTC at both days. The thick black line indicates the HALO flight track, and red crosses the location of dropsonde releases. In (b, d) we show the average profile and all individual profiles of relative humidity over ice measured during the two flights by dropsondes.

even stronger AR on 15–16 March. Compared to the climatology, both ARs denoted higher IVT and were centered further in the north than 75% (partly, 90%) of all ARs in the North Atlantic pathway within the ERA5 climatology. During the AR on 15–16 March, we found new maxima of vertically integrated meridional heat and water vapour fluxes ( $IHT_{\text{north}}$  and  $IVT_{\text{north}}$ ) for the central region latitudes. The radiosondes at Ny-Ålesund detected unusually high tropopause altitudes up to 12.9 km.

510 Although the MWAI s were relatively short-lived, they caused a campaign average northward transport of heat and moisture, overcompensating the southward transport of the much longer cold period. We therefore stress the importance of MWAI s for the energy exchange between the mid-latitudes and the Arctic. Averaged over the warm period, new maximum rainfall rates were found over the sea ice northwest of Svalbard, exceeding the climatology by a factor of 36. Not only is the intensity remarkable, but also the occurrence of rain over sea ice at this time of the year.

515 The cold period was initialized after the passage of a strong cyclone over Svalbard on 21 March, when a northerly flow was established in the central region. We identified two strong MCAO periods (21–26 March and 01–02 April), where  $M$  partly exceeded the 90<sup>th</sup> percentile. The strong MCAOs were associated with high upward fluxes of sensible and latent heat in the unstable atmospheric boundary layer, which stress the interaction between the warm ocean and cold atmosphere. The ocean-atmosphere interactions in the boundary layer resulted in the typical high fraction of low-level cloud cover (cloud streets) and convective precipitation.

520 After each strong MCAO period, aged warm air was advected to the measurement regions by a weaker northeasterly flow. During the aged warm air period, precipitation faded in the central region due to warming and drying. West of Svalbard, cloud-free conditions prevailed because of orographic lee effects (foehn).

After a weak MCAO, a Polar Low formed in the Fram Strait on 07 April. We confirmed that four out of six criteria for Polar Low development were fulfilled by inspecting the environmental conditions. With the help of dropsondes launched along a circle, we found strong rotation confined to the lowest 2 km despite negative relative vorticity in the eastern part related to lee effects. The Polar Low was located unusually far in the north. At the end of the cold period (10–12 April), warm and moist air was advected by a Scandinavian Low towards the southern region and diverted northwards through the Fram Strait. The high altitude southerly winds transported cirrus clouds over the sea ice with cold and dry air from the Greenland ice sheet below. This combination resulted in an isolated humidity layer including Arctic cirrus in the absence of low- and mid-level clouds.

525

530 With respect to the climatology, the entire campaign was slightly warmer considering both 2 m and 850 hPa temperatures, except for the central Fram Strait and north of Greenland. Here, 2 m temperature anomalies were negative. In the central region, SICs were within the 10–90<sup>th</sup> percentiles of the climatology during the entire campaign period. The AR events caused remarkable reductions of SIC in the Fram Strait and northeast of Svalbard due to dynamical forcing by wind and ocean, and possibly melt. Afterwards during the MCAO period, temperatures stayed below the freezing point and northerly winds increased SIC above the climatological mean in those regions. Only around Svalbard and at its southeastern coast, SICs were lower than the climatological mean values. We identified a strip of positive SIC anomaly in the central and western Fram Strait, which coincides well with negative 2 m temperature anomalies.

535

Atmospheric soundings and near-surface measurements at Ny-Ålesund generally represent the weather conditions of the central region well, when respecting the temporal delay of up to 1 day due to the propagation of synoptic systems during the warm period. However, during the cold period, lee effects at the coast of Svalbard cause cloud conditions that are only

540

representative for the eastern part of the central region. The additional measurements at the AWIPEV can be implemented into the data analysis of HALO-(AC)<sup>3</sup> and provide a long-term climatological context to the airborne measurements.

545 Compared to previous aircraft campaigns in the Arctic within (AC)<sup>3</sup> that focused on the evolution of (mixed-phase) clouds (ACLOUD; AFLUX and MOSAiC-ACA, Wendisch et al., 2019; Mech et al., 2022), we observed a larger variety of MCAO  
550 conditions during HALO-(AC)<sup>3</sup>. The long phase of MCAOs with varying strength and different wind regimes provides opportunities for detailed MCAO studies making use of the airborne measurements. Also the sea ice edge was closer to Svalbard than during AFLUX (March–April 2019) so that ocean–ice transects could be performed more easily. We captured several MWAI / ARs with unusual or even record breaking strength. With regard to the changing climate when exchanges between the mid-latitudes and the Arctic become more frequent and ARs are expected to shift poleward, the campaign provides a  
550 unique opportunity to study stronger than average MWAI / ARs. We conclude that the weather conditions were well suited to achieve the objectives of the HALO-(AC)<sup>3</sup> campaign.

*Code and data availability.* All codes used for the analyses presented in this study have been uploaded to GITHUB and connected with ZENODO for public access (*in preparation*). Sea ice concentration climatology data is found on OSI SAF (2017) and Copernicus Climate Change Service (C3S) (2020). The high resolution sea ice concentration dataset used for 07 March–12 April 2022 is based on the product from  
555 the Institute of Environmental Physics, University of Bremen. The data is available at [https://seaice.uni-bremen.de/data/modis\\_amr2](https://seaice.uni-bremen.de/data/modis_amr2). ERA5 data on single and pressure levels can be accessed through Hersbach et al. (2018b) and Hersbach et al. (2018a). Ny-Ålesund radiosondes and ceilometer data have been published on PANGAEA (Maturilli and Kayser, 2016, 2017; Maturilli, 2020b, 2022). Near-surface meteorology data from Ny-Ålesund is available on PANGAEA as well (Maturilli, 2020a). Dropsonde data from used in this study can be found on ZENODO (*in preparation*).

**Table A1.** Geographical coordinates for measurement regions as displayed in Fig. 1. Note that the northern part of the northern region in the central Arctic is extended to the west.

	Northern region	Northern region extension	Central region	Southern region
Northern limit in deg N	84.5	89.3	81.5	75.0
Southern limit in deg N	81.5	84.5	75.0	70.6
Western limit in deg E	-9.0	-54.0	-9.0	0.0
Eastern limit in deg E	30.0	30.0	16.0	23.0

## 560 Appendix A: Methodology details

This part of the appendix includes additional details regarding the methods described in Sect. 2 that go beyond the necessary information to understand the study but help to reproduce the results.

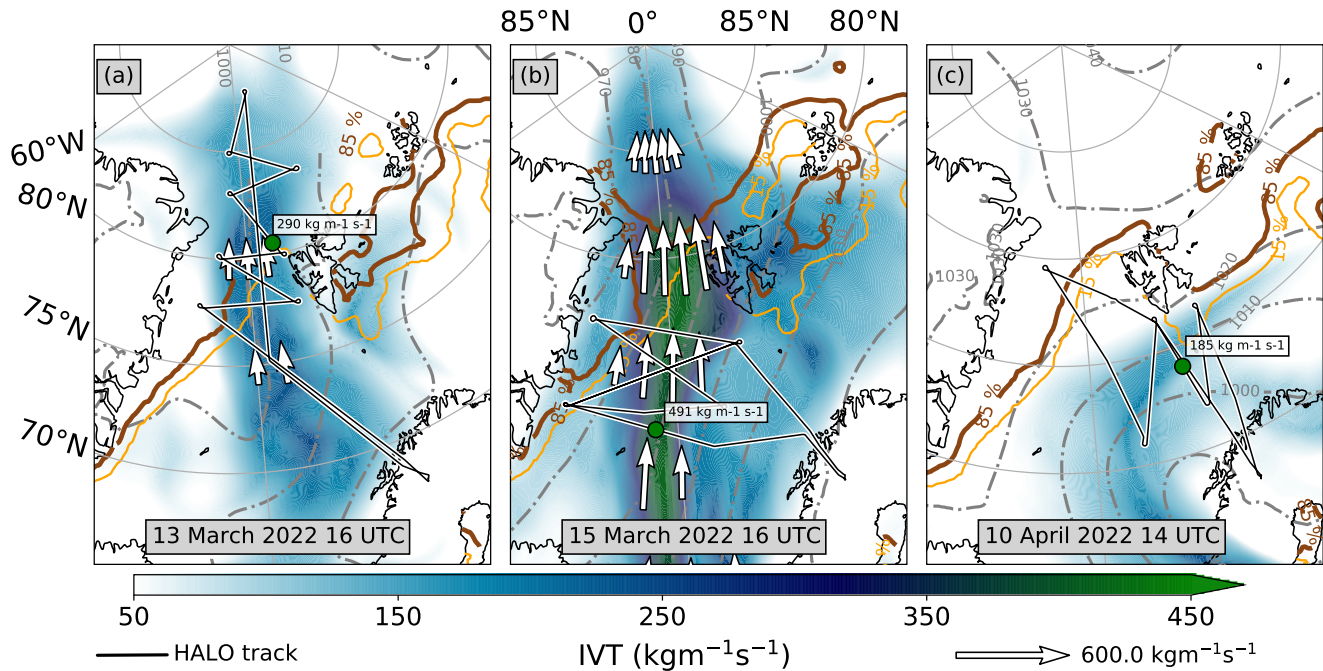

For an exact computation of the regional averages over the southern, central and northern regions, we provide the geographical coordinates of the domains' boundaries in Table A1.

565 Here, we describe the processing of variables to analyse the MCAO conditions (Sect. 2.4.3) in greater detail for reproducibility. Turbulent flux data was confined to open water surfaces because our focus is on the intensity of the upward fluxes (positive sign) over open water during the MCAOs. We used the mean values over 1 hour at each grid point instead of the instantaneous values (Hersbach et al., 2020). For low, medium and high-level cloud cover, we computed the median value including 5, 25, 75, and 95<sup>th</sup> percentiles. Precipitation data was accumulated over 6 hour intervals and grouped into open water and sea ice  
570 covered surfaces. Snowfall is further separated into its large-scale and convective parts. The latter is defined in ERA5 as the frozen precipitation resulting from the convection scheme and thus from subgrid-scale convection. Total precipitation is then the sum of the convective and the large-scale part (Hersbach et al., 2020).

In the following, we summarize the meanings of the conditions tested for Polar Low formation (Sect. 2.4.4) for better understanding: Condition C1 is a measure of the convection potential as it evaluates the mean temperature gradient between  
575 the surface and the mid-troposphere. Large differences between the 2 m temperature and the SST (C2) promote strong sensible heat fluxes, stressing the air-sea interaction. Positive values of C3 represent an increase of potential temperature with height. At least conditionally unstable conditions (unstable (stable) for moisture-saturated (unsaturated) air parcels) should be present (C3  $\leq$  3 K km<sup>-1</sup>). The relative humidity conditions C4<sub>i</sub> and C4<sub>ii</sub> are an important measure for the availability of moisture for latent heat release, a major energy source of a Polar Low. Maximum 10m wind speed (C5) is an indicator of the Polar Low's  
580 strength. The geopotential height condition (C6) is selected to ensure the presence of an upper level trough.

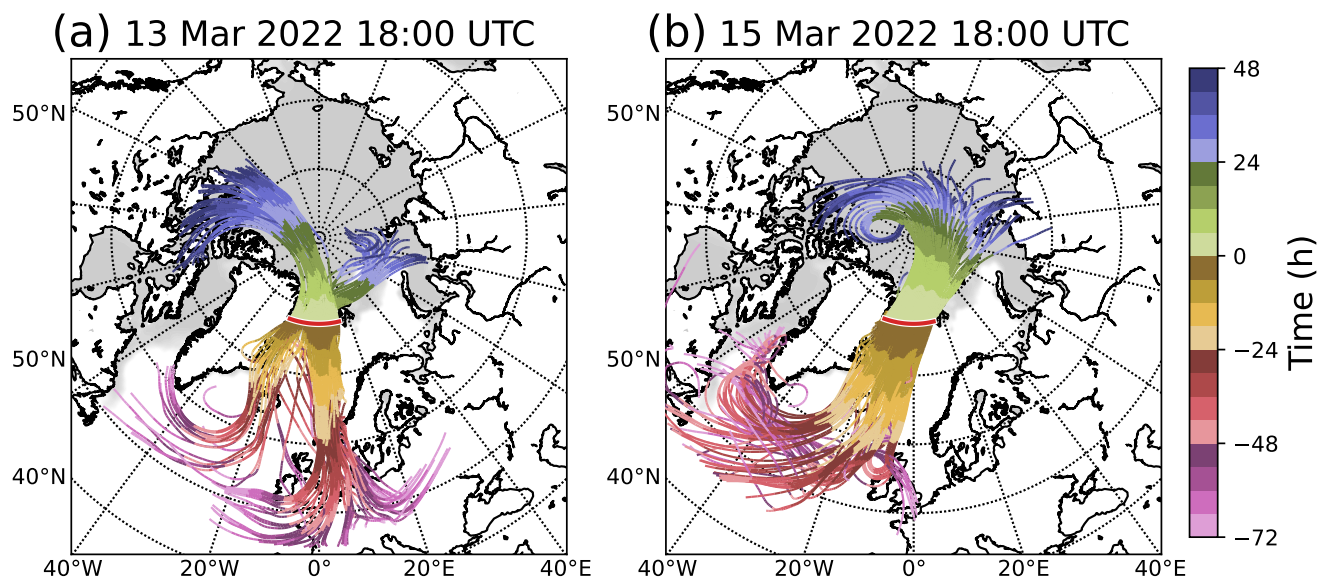

## Appendix B: Integrated water vapour transport for moist and warm air intrusions

For the MWAI / ARs on 13 and 15 March, and for the weaker MWAI on 10 April, we show the total IVT in Fig. B1. While the former two events were meridionally aligned, the latter had a rather zonal orientation. The strongest total IVT is found on 15 March, exceeding  $400 \text{ kg m}^{-1} \text{ s}^{-1}$ .

**Figure B1.** Total integrated water vapour transport (IVT, zonal and meridional component) from ERA5 (colours) and dropsondes (circular marker) for three moist and warm air intrusions / Atmospheric Rivers: (a) 13 March 2022 16 UTC, (b) 15 March 2022 16 UTC, (c) 10 April 2022 14 UTC. Quivers indicating the flow direction and strength, as well as the HALO flight track (black line with white outline) are also included. The orange (brown) line indicate the 15% (85%) sea ice concentration isoline. Grey dash-dotted contours show the mean sea level pressure. Data is based on ERA5.

The general air flow on two selected MWAI / AR days is investigated. Three day back and two day forward trajectories shown in Fig. C1 are initialized on 13 and 15 March each at 18:00 UTC. The trajectories reveal that the air masses of the first MWAI day mainly originated from central Europe and the second case from the North Atlantic. Forward trajectories show that both MWAI / ARs reached the central Arctic.

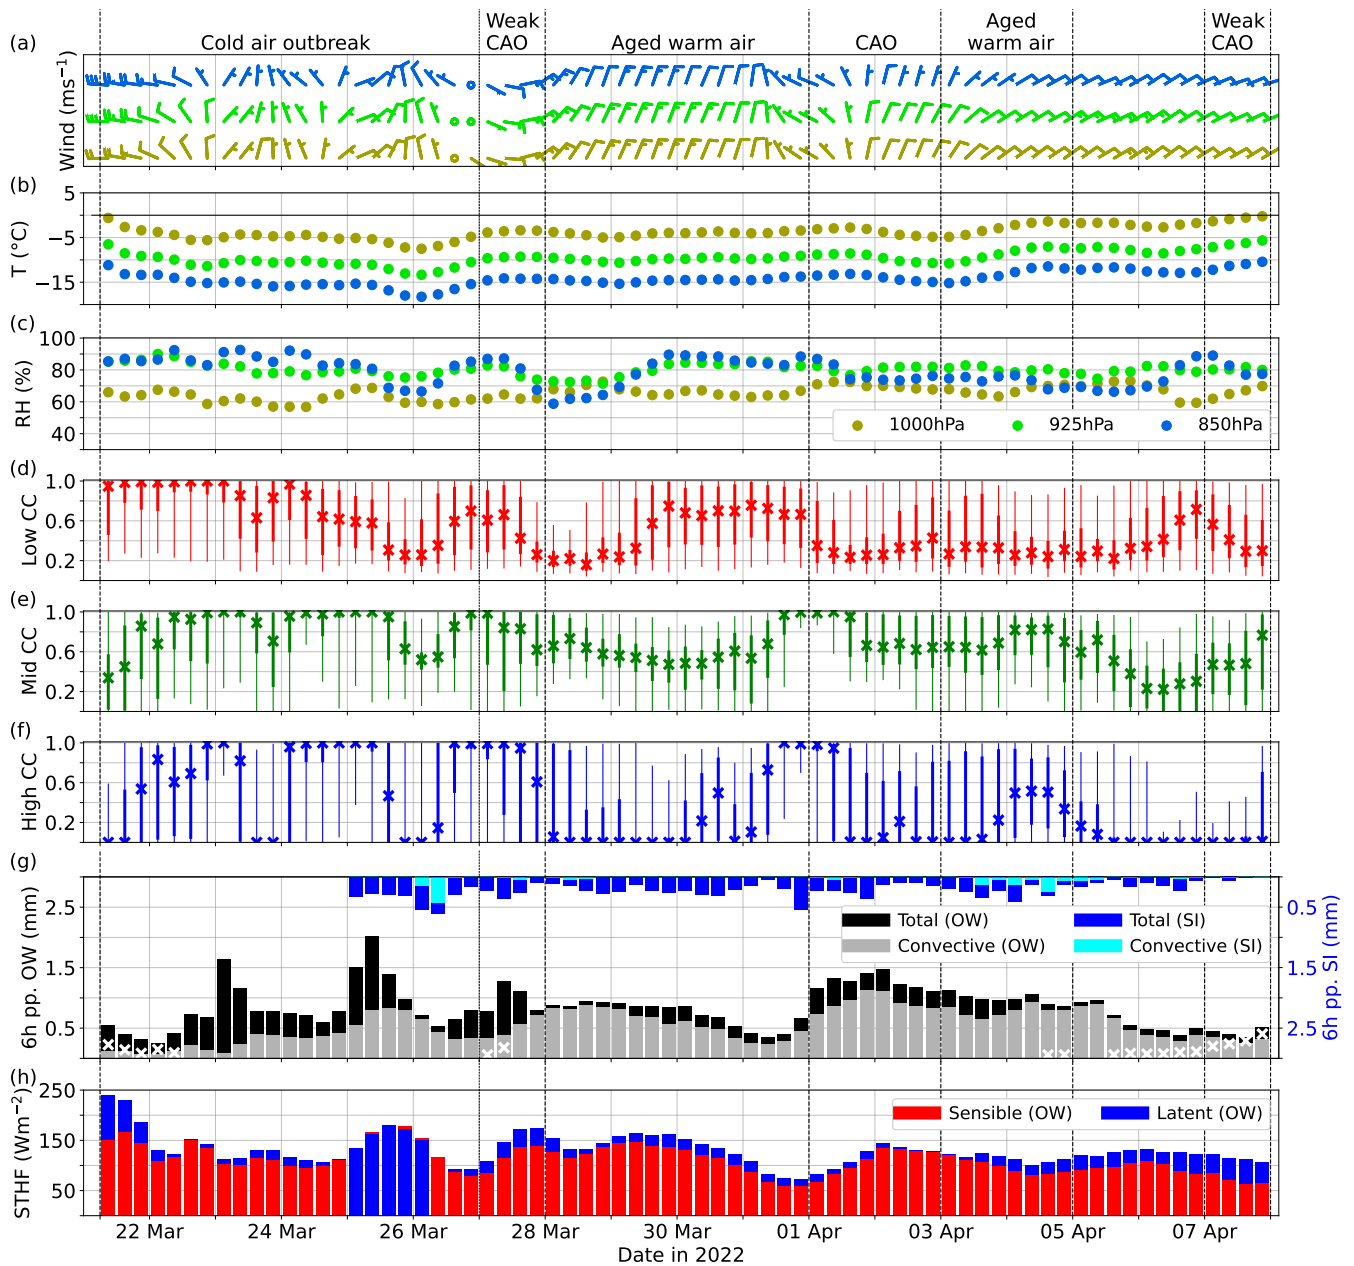

**Figure C1.** Three day backward and two day forward trajectories of the AR air masses observed in the central region on (a) 13 March 2022 18:00 UTC, and (b) 15 March 2022 18:00 UTC, at altitudes of 700, 850, and 925 hPa. Starting points are placed at 77.5° N between 20° W and 13° E with a zonal spacing of 1°. Both 72 hour back-trajectories as well as 48 hour forward-trajectories are computed. Grey shading indicates the sea ice concentration from ERA5.

Figure D1 shows the ERA5 based temporal evolution of temperature, relative humidity and wind for the eastern part of the northern region (identical western longitude boundary as the central region). The data has been processed as described in Sect. 2.4.3 and Appendix A. During the stronger MCAOs in the central region with northerly winds, the air masses originated from the northern region. Due to the low occurrence of northwesterly winds, the western extension of the northern region is not included. For comparison of turbulent fluxes between the central and southern region, we include Fig. D2.

**Figure D1.** Temporal evolution of (a) wind, (b) air temperature ( $T$ ), and (c) relative humidity ( $\text{RH}$ ) on the 1000, 925, and 850 hPa pressure levels as in Fig. 11, but for the northern region (without western extension). Data is based on ERA5.

**Figure D2.** Temporal evolution of (a) wind, (b) air temperature ( $T$ ), and (c) relative humidity (RH) on the 1000, 925, and 850hPa pressure levels, and of (d) low-, (e) mid-, and (f) high-level cloud cover (CC), (g) precipitation, and (h) surface turbulent heat fluxes (STHF) as in Fig. 11 but for the southern region. Data is based on ERA5.

## Appendix E: Polar Low visual observations

Due to the relatively small extent of a Polar Low, we were able to see the entire structure during the HALO research flight on 08 April 2022. The photo was taken on one of the cross sections through the Polar Low, showing the relatively cloud free centre (eye) and the convective cloud band on its (north-)eastern side (Fig. E1).

**Figure E1.** Photo of the Polar Low taken from HALO (portside) on 08 April 2022 at 09:57 UTC. The centre (eye) of the Polar Low can be seen in the foreground while the convective cloud band is visible in the background. The map indicates the flight track (black line) and the position of the aircraft at that time (red star). © Andreas Walbröl

600 *Author contributions.* SC, AE, IG, JanM, MW, and AW conceptualized the manuscript. MW and AW formulated the introduction with comments and input from AE, JanM, and SC. HD, BK, ML, NM, MM, JanR, and AW prepared the description of the data and methods chapter. SB, HD, BK, ML, JanM, HM, RN, FP, JohR, JanR, IS, NS, and AW provided visualisations and analysed figures. JohM and AW collected codes from co-authors and made them publicly available. AW is the main author of this manuscript and ensured validation. All co-authors reviewed the manuscript.
