Abstract

Few studies have investigated the impact of new particle formation (NPF) on cloud condensation nuclei (CCN) in remote Antarctica, and none has elucidated the relationship between NPF and CCN production. To address that knowledge gap, we continuously measured the number size distribution of 2.5–300 nm particles and CCN number concentrations at King Sejong Station in the Antarctic Peninsula from January 1 to December 31, 2018. Ninety-seven new particle formation (NPF) events were detected throughout the year. Clear annual and seasonal patterns of NPF were observed: high concentration and frequency of nucleation-mode particles in summer (December–February: 53 NPF cases) and undetected nucleation-mode particles in winter (June–August: no NPF cases). The estimated median spatial scale of NPF around Antarctic peninsula was found to be approximately 155 km, indicating the large-scale of NPF events. Air back-trajectory analysis revealed that 80 cases of NPF events were associated with air masses originating over the ocean, followed by sea-ice (12 cases), multiple (3 cases), and land (2 cases) regions. We present and discuss three major NPF categories: (1) marine NPF (2) sea-ice NPF, and (3) multiple NPF. Satellite-estimates for sea surface dimethylsulfoniopropionate (DMSP; a precursor of gaseous dimethyl sulfide) data showed that the production of oceanic biogenic precursors could be a key component in marine NPF events~~Our results showed that the photo-oxidation of oceanic biogenic~~

30 ~~precursors such as dimethyl sulfide (DMS) could be a key component in marine NPF events~~, whereas
31 halogen compounds released from ice-covered areas could contribute to sea-ice NPF events. Terrestrial
32 sources (wild life colonies, vegetation, and meltwater ponds) from Antarctica could affect aerosol
33 production in multiple air masses. Out of 97 observed NPF events, 83 cases were characterized by the
34 simultaneous increase in the CCN concentration by 2–270% (median 44%) in the following 1 to 36 hours
35 (median 8 hours) after NPF events. Overall, Antarctic NPF events were found to be a significant source
36 of particles with different physical characteristics and related to biogenic sources in and around the
37 Antarctic Peninsula, which subsequently grew to cloud condensation nuclei.

39 **1. Introduction**

40 Antarctic peninsula is warming more rapidly than Earth’s global mean rate (Chen et al., 2009;
41 Vaughan et al., 2003), leading to shrinking sea-ice coverage and consequent sea-level rise (Pritchard et
42 al., 2009). In the Antarctic region, ambient aerosols play a crucial role in governing radiative transfer,
43 directly by the scattering and absorption of solar radiation and indirectly by acting as cloud condensation
44 nuclei (CCN) (IPCC, 2013). The magnitude of the radiative forcing caused by the interactions between
45 aerosols and CCN remains highly uncertain due to a poor understanding of pristine natural aerosols
46 (Carslaw et al., 2013). To reduce this uncertainty, the physicochemical properties of aerosol particles (e.g.,
47 number concentrations, size distributions, chemical compositions, and hygroscopicity) have been studied
48 at several Antarctic stations including King Sejong Station (Kim et al., 2019), Aboa (Asmi et al., 2010;
49 Virkkula et al., 2006), Dome C (Järvinen et al., 2013), Halley (Lachlan-Cope et al., 2020; O’Dowd et al.,
50 1997), Kohn (Weller et al., 2018), McMurdo (Giordano et al., 2018; Liu et al., 2018), Neumayer (Teinilä
51 et al., 2014; Weller et al., 2015), Princess Elisabeth (Herenz et al., 2019) and Syowa (Hara et al., 2011;
52 Ito, 1993), ~~as well as from shipborne observations (Fossum et al., 2018; Humphries et al., 2015;
53 Humphries et al., 2016)~~. Furthermore, open ocean and coastal Antarctic expeditions such as SIPEXII (Sea
54 Ice Physics and Ecosystems eXperiment, 2012; Humphries et al., 2015; Humphries et al., 2016),
55 PEGASO (Plankton-derived Emissions of trace Gases and Aerosols in the Southern Ocean, 2015;

56 [Dall'Osto et al., 2017; Decesari et al., 2020; Fossum et al., 2018](#)), [ACE-SPACE \(Antarctic](#)
57 [Circumnavigation Expedition – Study of Preindustrial-like Aerosol Climate Effects, 2017; Schmale et al.,](#)
58 [2019; Walton and Thomas, 2018\)](#), [PCAN \(Polar Cell Aerosol Nucleation, 2017; Simmons et al., 2021\)](#);
59 [PI-ICE \(Polar atmosphere-ice-ocean Interactions: Impact on Climate and Ecology, 2019; Brean et al.,](#)
60 [2021; Dall'Osto et al., 2022\)](#) studies on the influences of marine aerosols on climate and ecology. Overall,
61 aerosol particle number concentrations follow a clear annual trend, being much higher in austral summer
62 than in other seasons (Järvinen et al., 2013; Kerminen et al., 2018; Weller et al., 2011). For instance, Kim
63 et al. (2017) found that summertime concentrations in the Antarctic Peninsula were ~20 times higher than
64 in winter. This pattern can be largely explained by new particle formation (NPF) events.

65 Precursor gases for NPF in this region can originate from the ocean, sea-ice, meltwater ponds,
66 terrestrial animal colonies, [anthropogenic activity and continental ecosystem](#). Oceanic emissions of
67 dimethyl sulfide (DMS) represent the largest natural sulfur source in the Antarctic atmosphere (Simó,
68 2001), and its photooxidation is a key process contributing to NPF (Giordano et al., 2017; Jang et al.,
69 2019 and 2022). For instance, in situ (Saiz-Lopez et al., 2007) and satellite (Schönhardt et al., 2008)
70 measurements have shown Antarctica to be an iodine emission hotspot, particularly from the sea-ice in
71 the Weddell Sea during spring (Atkinson et al., 2012). [Indeed, Sipilä et al. \(2016\) measured iodic acid](#)
72 [\(HIO₃\) in Antarctica and found that the Antarctic oceanic regions may be strong sources of molecular](#)
73 [iodine, which is then converted to HIO₃ in gas-phase reactions.](#) Dall'Osto et al. (2017) reported that
74 microbiota in sea-ice were associated with atmospheric organic nitrogen formation in the Southern Ocean
75 near Antarctica. According to Kyrö et al. (2013), the precursor vapors responsible for NPF and subsequent
76 growth could originate from the cyanobacteria, which are abundant in Antarctic meltwater ponds. In
77 addition, continental Antarctica is a habitat for various types of seabirds and penguins, with guano species
78 acting as a crucial source of ammonia and organic compounds and may contribute to NPF in coastal
79 Antarctic areas (Schmale et al., 2013; Weber et al., 1998; Zhu et al., 2011). [At continental South Pole NPF](#)
80 [event are commonly associated with the local anthropogenic pollution during calm weather conditions](#)
81 [\(Park et al., 2004\). In addition, the biomass burning aerosol from South American continental outflow has](#)

82 been observed at Troll Research Station (Fiebig et al., 2009). During the daytime, higher radiation
83 enhances photo-active emissions from land ecosystems (mosses, grasses, and lichens) of the Antarctic
84 Peninsula and can lead to NPF and aerosol growth (Decesari et al., 2020; Quéléver et al., 2022; Schmale
85 et al., 2013). However, land sources are rather unlikely due to a small footprint of emerging land and the
86 associated short overpass over the sparse vegetation.

87 In recent years, long-term records of aerosol size distribution have become an important aspect of
88 investigations into the sources and dynamical processes of NPF. The majority of Antarctic field studies
89 have focused on the annual and spatial patterns of the number size distribution of particles > 10 nm (Belosi
90 et al., 2012; Järvinen et al., 2013; Kim et al., 2019; Kyrö et al., 2013; Lachlan-Cope et al., 2020). Although
91 NPF events are typically characterized by a rapid increase in the number concentration of cluster from 1–
92 3 nm (Kulmala et al., 2004), datasets for these types of aerosol size distribution remain rare. To date,
93 number size distribution of particles > 3 nm has been reported by Asmi et al. (2010) at Aboa during from
94 December 29, 2006 to January 29, 2007; by Pant et al. (2011) at Maitri from January 1 to February 28,
95 2015; by Weller et al. (2015) at Neumayer from January 20 to March 26, 2012; by Jokinen et al. (2018)
96 at Aboa from November 2014 to February 2015; by Weller et al. (2018) at Kohnen during January 2015
97 and 2016; by Quéléver et al. (2022) at Marambio during the austral summer between January 15 and
98 February 25, 2018; and by Brean et al. (2021) during the PI-ICE cruise from January 25 to February 4,
99 2019. However, all of these measurements were made during the Antarctic summer due to restricted
100 access and, therefore, limited information on seasonal cycles.

101 Newly formed particles can grow into larger sizes that act as CCN, becoming relevant for cloud
102 formation (O’Dowd, 2002; Williamson et al., 2019). In a highly pristine atmosphere such as Antarctica,
103 where CCN concentration is extremely low (Kim et al., 2017), NPF may be a significant phenomenon
104 controlling the CCN budget (Kyrö et al., 2013). For instance, Herenz et al. (2019) showed that an elevated
105 CN_{2.5} (total number concentration of particles > 2.5 nm) during NPF events was accompanied by an
106 increase in CCN concentrations at Princess Elisabeth during austral summer (December to February,
107 2013–2016). Ship-based observations during the ACE-SPACE found that the fraction of particle serving

108 as CCN was higher near the coast of Antarctica compared to open ocean, resulting from multiple
109 processing cycles of dissipating and condensing clouds and/or the higher availability condensable gases
110 originating from marine microbial activity (Schmale et al., 2019). In addition, seasonal variability in
111 CN_{2.5–10} (number concentration of particles within the 2.5 nm and 10 nm range and attributed to NPF)
112 and CCN concentrations at King Sejong Station from March 2009 to December 2016 were investigated
113 by Kim et al. (2019), who concluded that CCN concentrations during NPF events increased by ~11%
114 compared to the background concentration. However, to date, only one study (Kim et al., 2019) has
115 reported the contribution of NPF to CCN in the Antarctic Peninsula, and that study did not consider
116 aerosol number size distribution.

117 In this study, we continuously recorded the number size distribution of 2.5–300 nm particles and
118 CCN number concentrations at King Sejong Station in the Antarctic Peninsula from January 1, 2018, to
119 December 31, 2018. Our primary goals were to (1) characterize the seasonal variation and occurrence of
120 NPF events from the perspective of aerosol physical properties (total number concentration, number size
121 distribution, formation and growth rates, and condensation sink); (2) improve our understanding of the
122 major sources (including open ocean, sea-ice, and land) and processes influencing NPF and particle
123 growth; and (3) estimate the contribution of atmospheric NPF to CCN activity in this pristine environment.
124 To our knowledge, this is the first study to present direct evidence of CCN production associated with
125 NPF and growth events in the Antarctic Peninsula, using simultaneous measurements of particle number
126 size distributions (down to 3 nm) and CCN properties for a full year.

127

128 **2. Experimental methods**

129 **2.1. Sampling site and instrumentation**

130 Continuous measurements of the physical properties of aerosol particles were conducted from
131 January 2018 to December 2018 at King Sejong Station in the Antarctic Peninsula (62.22° S, 58.78° W).
132 Full details of the sampling site and measurement setup are given in Kim et al. (2017). In brief, a
133 cylindrical stainless inlet (0.1 m diameter and 5.2 m length; total flow rate of the sampled air was 150 L

134 min⁻¹) was placed on the observatory roof following Global Atmosphere Watch aerosol measurement
135 guidelines and recommendations. Two condensation particle counters (TSI model 3776 CPC and TSI
136 model 3772 CPC) were used to measure the total number concentration of particles larger than 2.5
137 (corresponding data CN_{2.5}) and 10 nm (corresponding data CN₁₀) every 1 s, respectively. The aerosol
138 sample flow rates of TSI model 3776 CPC and TSI model 3772 CPC were 1.5 and 1.0 L min⁻¹, respectively.
139 ~~Two condensation particle counters (TSI model 3776 CPC and TSI model 3772 CPC) were used to~~
140 ~~measure the total number concentration of particles every 1 second, with aerosol sample flow rates of 1.5~~
141 ~~and 1.0 L min⁻¹, respectively.~~ A nano-scanning mobility particle sizer (nano-SMPS) consisting of a nano-
142 differential mobility analyzer (nano-DMA) (TSI model 3085, USA) and an ultrafine condensation particle
143 counter (TSI model 3776, USA) was used to measure the number size distribution of particles from 2.5–
144 64 nm every 3 minutes. The aerosol flow rate was 1.5 L min⁻¹ and the sheath flow rate was 15 L min⁻¹
145 inside the nano-DMA.

146 The particle number size distribution (from 10–300 nm every 3 min) was measured with a standard-
147 SMPS consisting of a long DMA (TSI model 3081, USA) and a CPC (TSI model 3772, USA). The aerosol
148 flow rate was 1.0 L min⁻¹, and the sheath flow rate was 10 L min⁻¹ inside the long DMA. To obtain the
149 number size distribution of particles from 2.5–300 nm, the nano-SMPS and standard-SMPS were merged.
150 For particle diameters 2.5–20 nm, nano-SMPS data were chosen because this was optimized to operate
151 with a smaller particle diameter. In the nano-DMA, the aerosol residence time can be reduced by
152 shortening the inlet transport passage (5.0 cm) and increasing the inlet flow (up to 16.5 L min⁻¹) (< 10 nm)
153 (Chen et al., 1998). Hence, the number size distribution data from both nano-SMPS and standard-SMPS
154 were merged at a diameter of 20 nm. Furthermore, three-point median filter and five point moving average
155 were performed on merging the number size distribution data to remove nano-SMPS noise, as suggested
156 by Kulmala et al. (2012).

157 The black carbon (BC) concentration was measured using an aethalometer (AE22, Magee Scientific
158 Co., USA) every 5 min to examine long-range polluted aerosol transport from other continents and to
159 assess the influence of local pollution from the station. The flow rate through a sharp-cut 2.5 µm cyclone

160 (BGI, Inc., USA) was set to 5 L min⁻¹. The CCN counter (CCNC: CCN-100, Droplet Measurement
161 Technologies, USA) measured CCN number concentrations ~~at five different supersaturations (0.2%, 0.4%,~~
162 ~~0.6%, 0.8%, and 1.0%)~~ at five different supersaturation levels of 0.2% 0.4%, 0.6%, 0.8%, and 1% every
163 30 minute. The total flow rate in the CCN counter was 0.5 L min⁻¹. The sample and sheath flow rates of
164 the CCN counter were 0.05 and 0.45 L min⁻¹, respectively. In addition, basic meteorological parameters
165 (temperature, pressure, relative humidity (RH), wind speed, wind direction, and solar radiation intensity)
166 were measured using an automatic weather station (Vaisala HMP45).

167

168 2.2. Data evaluation

169 As the observatory is located ~400 m southwest of the main station buildings and several kilometers
170 away from other research stations, measurement data were impacted by local emissions from station
171 activities (e.g., power generators and incineration) or anthropogenic pollutions near the observatory (e.g.,
172 plumes from other research station about several kilometers, vessels providing research station supply,
173 and commercial cruise vessels).~~As the observatory is located ~400 m southwest of the main station~~
174 ~~buildings, measurement data were impacted by local emissions from station activities (e.g., power~~
175 ~~generators and incineration).~~ To obtain an unperturbed aerosol population of pristine Antarctic
176 environment, contaminated measurements were removed manually based on wind direction, wind speed,
177 BC concentration, and total particle number concentration. The following data elimination procedure was
178 applied: (1) the measurements taken within wind sector of 355° and 55° were discarded as directly
179 impacted by local pollution sources; (2) relative wind speed below 2.0 m s⁻¹, as stagnant conditions would
180 have facilitated contaminated particle propagation to the measurement location; (3) equivalent BC mass
181 concentrations exceeding 50 ng m⁻³, because elevated BC concentration unambiguously pointed at
182 polluted particles; and (4) a sharp increase in the total number concentration over the entire particle
183 diameter range in a short time scale of less than an hour, as such abrupt peaks and spikes are related to
184 potential contamination or instrumental malfunctions. For instance, CPC and SMPS data were removed
185 for time periods when particle number concentrations suddenly increased to more than twice the

186 background values.

187 Based on a four-year (2016-2019) BC dataset, six types of Antarctic Peninsula air-pollution levels
188 were identified (Grigas et al., 2017): (1) pristine air with BC concentrations $< 15 \text{ ng m}^{-3}$, (2) clean air with
189 BC levels $15\text{--}50 \text{ ng m}^{-3}$, (3) slightly polluted air with BC levels $50\text{--}100 \text{ ng m}^{-3}$, (4) moderately polluted
190 air with BC levels $100\text{--}300 \text{ ng m}^{-3}$, (5) polluted air with BC levels $300\text{--}1000 \text{ ng m}^{-3}$, and (6) extremely
191 polluted air with BC concentrations $> 1000 \text{ ng m}^{-3}$ (Figure 1). Previously, BC data were used as indicators
192 for local contamination in Antarctica when BC concentration level exceeded 50 ng m^{-3} (Herenz et al.,
193 2019) or 100 ng m^{-3} (Jang et al., 2018; Kim et al., 2017; Kim et al., 2019; Weller et al., 2011; Weller et
194 al., 2015). Hara et al. (2019) measured BC concentration at Syowa station Antarctica from February 2005
195 until December 2016. They found that the daily median BC concentrations were below the detection limit
196 (0.2 ng m^{-3}) to 63.8 ng m^{-3} at Syowa Station (median, 1.8 ng m^{-3} ; mean, 2.7 ng m^{-3} during the measurement
197 period). During the ACE-SPACE expedition, BC concentration reach its background levels of 19.2 ng m^{-3}
198 (Schmale et al., 2019). Arctic shipborne-observations measured BC concentration throughout the Arctic
199 Ocean and Pacific Ocean during the summer of 2017, all pointing to pristine clean marine air masses with
200 BC values of approximately $20 \pm 10 \text{ ng m}^{-3}$. (Park et al., 2020). Several studies have also reported that BC
201 concentrations not exceeding 15 ng m^{-3} were used to reliably exclude anthropogenically impacted air
202 masses over the Northeast Atlantic (Grigas et al., 2017; O'Dowd et al., 2015; Ovadnevaite et al., 2014).

203 Of the total time period assessed, pristine air conditions represented 30% (mean value of BC: 6.00
204 $\pm 6.35 \text{ ng m}^{-3}$), clean for 44% (mean value of BC: $29.85 \pm 9.81 \text{ ng m}^{-3}$), lightly polluted 19% (mean value
205 of BC: $68.78 \pm 13.57 \text{ ng m}^{-3}$), moderately polluted 6% (mean value of BC: $150.43 \pm 47.12 \text{ ng m}^{-3}$),
206 polluted 1% (mean value of BC: $498.74 \pm 173.87 \text{ ng m}^{-3}$), and extremely polluted less than 1% (mean
207 value of BC: $1537.41 \pm 595.47 \text{ ng m}^{-3}$). Together, pristine and clean air conditions accounted for $\sim 72\%$
208 of the time with the remaining 28% ($\text{BC} > 50 \text{ ng m}^{-3}$) removed prior to data analysis. ~~For comparison,~~
209 ~~mean BC measured at the Mace Head Research Station on the Irish coast from 2009–2014 (Grigas et al.,~~
210 ~~2017) ranged from 8 ng m^{-3} (pristine) to 1700 ng m^{-3} (extreme), where clean and pristine air conditions~~
211 ~~accounted for 63% of the total time.~~

212

213 **2.3. Definition of NPF and growth events**

214 NPF events were visually identified by the particle number size distribution based on the protocol
215 described by Dal Maso et al. (2005) and Kulmala et al. (2012). Here, these were defined when a distinct
216 new mode of particles (initially < 25 nm), appearing in the particle number size distribution at nucleation-
217 mode size (3–25 nm), prevailed for more than an hour. Using these criteria, the particle size distribution
218 data showed that in some cases, there was only a short burst of nucleation-mode particles without clearly
219 discernible particle growth, whereas in other cases, particle formation with subsequent particle growth
220 lasted for several hours, representing a regional-scale phenomenon (Ström et al., 2009). This enabled us
221 to determine the particle growth rate (GR), which is not possible during short bursts of nucleation-mode
222 particles.

223 The particle growth and formation rates along with the condensation sink were calculated from the
224 measured particle number size distribution. The GR was determined using the maximum concentration
225 and mode-fitting methods (Dal Maso et al., 2005; Yli-Juuti et al., 2009). GR was calculated by a linear fit
226 through the geometric mean diameter of the nucleation-mode particles as a function of time during NPF.
227 The formation rate (FR) of nucleation-mode particles (J_{3-25}) was calculated by taking into account the
228 time evolution of the particle number concentration in this size range and particle losses due to the
229 coagulation sink and condensational growth out of the size range (Kulmala et al., 2012). The surface area
230 of particles available for the condensation of gaseous molecules can be characterized by a condensation
231 sink (CS), which determines how rapidly vapor molecules condense onto pre-existing particles (Collins
232 et al., 2017; Dal Maso et al., 2002).

233

234 **2.4. Backward trajectory analysis and potential source regions**

235 Air mass back trajectories were obtained using the Hybrid Single-Particle Lagrangian Integrated
236 Trajectory (HYSPLIT) model to investigate their relationships with the physical characteristics of aerosol
237 particles (Draxler and Hess, 1998). The 2 days air mass back trajectories (48 hours) were determined at

238 hourly intervals and combined with satellite-derived geographical information to estimate the transport
239 history of the air masses arriving at the observation site (Jang et al., 2022 and Park et al., 2021). The
240 potential origins of the aerosols were divided into three categories based on the retention time of the 2
241 days back trajectories over three major domains: ocean (including the Weddell and Bellingshausen Seas),
242 sea-ice, and land (including the Antarctic Peninsula). Daily geographical information on ocean, sea-ice,
243 and land area was obtained from the Sea Ice Index (25 km resolution) provided by the National Snow and
244 Ice Data Center (NSIDC). The sea-ice zone was defined as the area with a sea-ice coverage >15% (Stroeve
245 et al., 2016). Air masses that passed over the Weddell and Bellingshausen Sea-regions were categorized
246 as originating from the ocean (i.e. > 50% retention over the ocean region). The air masses that frequently
247 advected over the sea-ice region were categorized as originated over the sea-ice (i.e. > 50% retention over
248 the sea-ice domain). Air masses that traveled through the Antarctic Peninsula were categorized as
249 originating from the land (i.e. > 50% retention over the land). Finally, the air masses which passed over
250 the ocean, sea-ice, and land regions simultaneously were categorized as originating from the multiple
251 regions (i.e., 20–40 % retention over each ocean, sea-ice, and land domain).

252 To evaluate the influence of oceanic biological characteristics on NPF properties, the phytoplankton
253 biomass of the ocean domains was estimated by calculating their chlorophyll concentration from the
254 Moderate Resolution Imaging Spectroradiometer on the Aqua (MODIS-Aqua) satellite at 4 km resolution
255 during the entire study period. Phytoplankton produces dimethylsulfoniopropionate (DMSP, a precursor
256 of gaseous DMS) and other organic vapors all of which are potential precursors to new particle formation.
257 Thus, the spatiotemporal distribution of sea-surface DMSP could be an indicator of contemporary DMS
258 emissions. The total DMSP concentration on the sea-surface was estimated using the algorithm developed
259 by Galí et al. (2015). The algorithm for the total DMSP concentration was based on the satellite-derived
260 chlorophyll concentration and photosynthetic radiation exposure. To calculate the air mass exposures to
261 ocean chlorophyll and DMSP (Jang et al., 2019), hourly back trajectory position was combined with
262 satellite-derived chlorophyll concentration and total DMSP concentration, providing a good measure for
263 quantitatively investigating the biological exposure history of sampled air over the several days before its

264 arrival at the observation site (Park et al., 2018 and 2021).

265

266 3. Results and discussion

267 3.1. General features and annual cycle

268 We investigated the overall seasonality of particle number size distributions focusing on NPF events.
269 In addition, local meteorological parameters (e.g., temperature, RH, wind speed, wind direction, pressure,
270 and solar radiation) and air mass back trajectories were used to support the interpretation of the seasonal
271 trends of the particle number size distribution and the dynamics of NPF events observed at the station.

272 3.1.1. Particle number concentrations and size distributions

273 Figure 2 shows a time series of the one-hour average total particle number concentration and size-
274 segregated particle number concentrations over the entire measurement period conforming to pristine (BC
275 $< 15 \text{ ng m}^{-3}$) and clean (BC: $15\text{--}50 \text{ ng m}^{-3}$) conditions. In addition, monthly medians for total number
276 concentration of particles, size-segregated particles number concentration, CCN number concentration at
277 supersaturation of 0.4%, and meteorological parameters are included in Table 1.~~The total particle number~~
278 ~~concentrations including ultrafine particles ($\text{CN}_{2.5}$; TSI 3776 CPC) and particles larger than 10 nm (CN_{10} ;~~
279 ~~TSI 3772 TSI) ranged from 60 to 4982 cm^{-3} and 30 to 3304 cm^{-3} , respectively.~~ The $\text{CN}_{2.5}$ and CN_{10} ranged
280 from 60 to 3982 cm^{-3} and 30 to 3304 cm^{-3} , respectively. The annual median number concentrations of
281 particles for the nucleation mode (N_{NUC} ; 2.5–25 nm in diameter), Aitken mode (N_{AIT} ; 25–100 nm in
282 diameter), and accumulation mode (N_{ACC} ; 100–300 nm in diameter) were 46.8 cm^{-3} , 53.5 cm^{-3} , and 21.7
283 cm^{-3} , respectively. The highest median N_{NUC} , N_{AIT} , and N_{ACC} values were recorded in December (193.5
284 cm^{-3}), December (227.6 cm^{-3}), and January (83.8 cm^{-3}), respectively (Table 1). The lowest N_{NUC} , N_{AIT} ,
285 and N_{ACC} values were recorded during austral winter in June – 12.2 cm^{-3} , 12.5 cm^{-3} and 9.2 cm^{-3} ,
286 respectively. Overall, clear annual and seasonal patterns of particle number concentrations in all size
287 classes were observed: high concentrations in summer (December–February) and low concentrations in
288 winter (June–August), similar to those observed at Marambio Station in the Antarctic Peninsula (Asmi et
289 al, 2018), at coastal Neumayer Station (Weller et al., 2011), at Concordia Station Dome C (Järvinen et al.,

290 2013), and at Troll Station (Fiebig et al., 2014). Furthermore, the hourly average CN₁₀ value was
291 positively correlated with the hourly average N_{NUC} ($R = 0.88$; not shown).~~Furthermore, the monthly~~
292 ~~median CN₁₀ value was positively correlated with the monthly median N_{NUC} ($R = 0.78$; not shown),~~
293 implying that the summer maximum of total particle number concentrations was largely influenced by
294 newly formed particles in the Antarctic atmosphere.

295 3.1.2. Influence of meteorological parameters on NPF events

296

297 The meteorological parameters after data filtering ($BC < 50 \text{ ng m}^{-3}$ indicating pristine and clean
298 conditions) were characterized by a solar radiation range of 0–919 W m^{-2} (median 10.7 W m^{-2}), a
299 temperature range of -20–6 °C (median -1.2 °C), an RH range of 52–98 % (median 88 %), a pressure
300 range of 950–1022 hPa (median 988 hPa), a wind speed range of 0.3–21 m sec^{-1} (median 7.4 m sec^{-1}),
301 and wind direction range of 3–357° (median 296°) (Figure S1). To understand impacts on the particle
302 number size distributions, we determined the relationships between the size-segregated particle number
303 concentrations and meteorological parameters (Figure S2). CN₁₀, N_{NUC}, N_{AIT}, and N_{ACC} were positively
304 correlated with both solar radiation intensity and temperature. In particular, N_{NUC} had the highest
305 correlation with solar radiation intensity ($R = 0.39$) of any meteorological condition, suggesting that solar
306 radiation is one of the most important factors influencing NPF events, as it can drive photochemical
307 reactions leading to the production and further reaction of precursor gases. In contrast, there was a weak
308 anticorrelation between RH and N_{NUC}, supporting the view that NPF occurs preferentially at low RH
309 (Dada et al., 2017; Hamed et al., 2011; Jeong et al., 2010; Laaksonen et al., 2008). Field observations
310 have reported that during NPF events, RH was negatively related to the number concentration of freshly
311 formed particles (Jeong et al., 2004; Lachlan-Cope et al., 2020; Weber et al., 1997) because of the
312 enhanced coagulation from scavenging effect of sub-3 nm nanoparticles at high RH and the diminished
313 solar radiation at high RH. Previously, some NPF events were associated with high wind speeds at various
314 Antarctic stations, such as Neumayer (Weller et al., 2015) and Aboa (Asmi et al., 2010; Virkkula et al.,
315 2007). These studies found an enhanced particle number concentration $< 10 \text{ nm}$ during stormy weather

316 and suggested ion production by frictional processes in fast-moving snow and ice crystals, followed by
317 subsequent ion-mediated nucleation during strong winds. However, in our study, wind speed was not
318 correlated with N_{NUC} ($R = -0.18$), N_{AIT} ($R = -0.04$), or N_{ACC} ($R = -0.05$), as recently suggested by Liu et
319 al. (2018). Our results indicated that wind speed did not affect NPF events. A possible explanation for the
320 wind speed independence is that an increase in wind speed contributes to the increase of cluster size ion
321 number concentrations by friction processes (Virkkula et al., 2007), but it was also accompanied by
322 cloudy conditions.~~A possible explanation for this wind speed independence is that an increase in wind~~
323 ~~speed contributes to the enhanced emissions of volatile organic compounds from the surface, but it was~~
324 ~~also accompanied by cloudy conditions.~~ In summary, the elevated N_{NUC} values (i.e., indicator of NPF
325 events) at King Sejong Station were more likely to be accompanied by high solar radiation, high
326 temperature, and low RH, regardless of wind speed. Recent studies concluded that Antarctic NPF
327 occurred under combined high solar radiation, high temperature and low RH conditions, similar to
328 previous study measured at the Marambio Antarctic research station (Quéléver et al., 2022). Quéléver et
329 al. (2022) found all NPF events were observed during the daytime with high solar radiation (clear-sky
330 conditions), mostly with above-freezing temperature and with low RH.

331 3.1.3. Characteristics of NPF events

332 NPF events in this study were identified based on the size distribution data measured using the
333 standard-SMPS (Figure 2e) and nano-SMPS (Figure 2f). During the pristine and clean periods
334 (comprising of 355 observation days and 169166 size distribution spectra for the standard-SMPS, and of
335 349 observation days and 165259 size distribution spectra for nano-SMPS), NPF events were frequently
336 observed at King Sejong Station, as shown by the size distribution data (Figure 2f). 97 events (26% of
337 observation days) with elevated N_{NUC} were observed when taking place in pristine ($\text{BC} < 15 \text{ ng m}^{-3}$) and
338 clean ($\text{BC}: 15\text{--}50 \text{ ng m}^{-3}$) conditions. Median value of BC concentrations during NPF events was 21.0 ng
339 m^{-3} , similar to that of whole measurement periods after data filtering (median BC value: 18.8 ng m^{-3})
340 (section 2.2). This indicated that NPF events are independent of occasional increases of BC during clean
341 periods. The NPF events were classified into: (1) burst event and (2) nucleation with growth event

342 according to the classification by Dal Maso et al. (2005) as seen in Figure S3. The burst events and
343 nucleation with growth events were observed on 1 January 2018 and 16 December 2018, respectively.
344 NPF events were more frequently observed in summer (~55%) than in any other season (Figure 4), with
345 the highest frequency in January (22%) and December (22%) followed by spring (September–November,
346 34%) and autumn (March–May, 11%). Similar results were reported by Järvinen et al. (2013) based on
347 observations from Dome C and Kim et al. (2019) based on observations from King Sejong Station.
348 Although Järvinen et al. (2013) reported winter events that occurred in the absence of sunlight, we did
349 not detect NPF events during austral winter from May through to August.

350 In order to investigate the seasonal characteristics of NPF event, we compared mean size
351 distributions of aerosol particles for summer, spring (transition period of the melting ocean), and autumn
352 (transition period of refreezing of the ocean) (Figure S4). Trimodal distributions were presented in all
353 seasons excepting winter when nucleation mode or particle formation was not observed. For instance, a
354 trimodal distribution was seen at 7 nm, 30 nm, 122 nm during summer months. The number concentration
355 of nucleation and Aitken modes were higher than the accumulation modes, indicating that NPF event
356 regulates the aerosol processes in Antarctic peninsula. The largest mode at 126 nm or 103 nm may be due
357 to a combination of primary (produced by bubble-bursting process) and secondary (produced by gas-to-
358 particle conversion process) aerosol components. Results are broadly in line with previous results
359 published from the Arctic and Antarctic regions. A ship-borne field campaign over Arctic Ocean found a
360 trimodal distribution at 18 nm, 53 nm and 150 nm for open-ocean marine Arctic NPF event (Park et al.,
361 2020). Lachlan-Cop et al. (2020) presented k-mean cluster analysis of particle size distribution measured
362 at Halley, Antarctica, showing a nucleation peak at 15 nm for “nucleation” ultrafine category and a
363 nucleation peak at 27 nm for “bursting” ultrafine category.

364 Air mass back trajectories were calculated at hourly intervals to investigate possible source regions
365 for the observed NPF events. Figure 2g shows the residence times of air masses over the three domains.
366 Based on 2-days air mass transport history analysis, air masses allocated to ocean, sea-ice and land
367 account for 83, 12 and 5%, respectively, during the study period. 97 cases were identified as NPF events,

80 of which were observed when the air mass originated over the ocean domain (Figure 4). 12 NPF events were observed in air masses originating over the sea-ice domain, while the remaining 5 events were associated with multi-regional origin (3 cases) and land origin (2 cases). Multi-regional origin indicated air masses simultaneously influenced by all three domains. Median BC concentration for ocean, sea-ice, and multiple air masses found to be 23.8 ng m⁻³, 12.7 ng m⁻³, 9.8 ng m⁻³, respectively, (Figure S5), indicating pristine clean air masses with minimum influence from anthropogenic pollutions during each NPF event case. Our results indicated that NPF events were more common in air masses originating over the ocean and sea-ice compared to those originating from the land. Precursors released by both ocean and sea-ice could play an important role in the formation of new particles in the Antarctic atmosphere.

3.1.4. Spatial extension of regional nucleation event ~~3.1.2. Spatial extension of regional nucleation event~~

~~NPF events were frequently observed at King Sejong Station, as shown by the size distribution data (Figure 2f).~~ Many previous studies have reported that key steps of the nucleation process (e.g., cluster stabilization) occur in the size range ~2 nm, in line with recent direct observations of atmospheric molecular clusters (Kerminen et al., 2018; Kulmala et al., 2013). However, during NPF events, we did not observe particle formation starting directly from the lower end of the particle size spectrum (2.5 nm), showing that the formation of freshly nucleated particles could not have actually taken place at the site. Indeed, the initial diameter of particles that arrived to the measurement site during the NPF ranged from 4 nm to 16 nm (Figure 3a). Median values of NPF event duration (Figure 3b) and growth rate (Figure 3c) were 4.0 hour and 0.83 nm hr⁻¹, respectively. We assumed that they were transported from elsewhere or produced aloft, and detected the appearance of an already grown mode. Consistent with these studies, NPF events can be a regional-scale phenomenon extending over spatial scales of tens to hundreds of kilometers in several regions, such as the remote marine boundary layer (Zheng et al., 2021), Canadian high Arctic (Eureka, Nunavut, on Ellesmere Island in the Canadian Arctic Archipelago) (Tremblay et al., 2019), and Arctic ship-based observations.

Assuming the region is characterized by homogenous meteorological conditions, we estimated the

394 spatial scale of NPF by multiplying the time during which a distinct nucleation mode can be observed at
395 the sampling site by the locally measured wind speed (Birmili et al., 2003; Crippa and Pryor, 2013). As
396 shown in Figure 3d, the spatial extend of NPF event associated with substantial particle growth can be
397 16–816 km (median value: 155 km), indicating the large-scale NPF events. Weller et al. (2015) measured
398 size distributions at the coastal Antarctic station Neumayer during two summer campaigns (from 20
399 January to 26 March 2012 and 1 February to 30 April 2014). They found that the spatial extend of NPF
400 event was estimated to be around 170 ± 85 km, taking into account the prevailing wind velocity (around
401 8 ± 4 m s⁻¹) and the confined NPF duration (around 6h).

402 **3.1.3. Characteristics of NPF events**

403 ~~NPF events in this study were identified based on the size distribution data measured using the~~
404 ~~standard SMPS (Figure 2e) and nano-SMPS (Figure 2f). During the pristine and clean periods~~
405 ~~(comprising of 355 observation days and 169166 size spectra for the standard SMPS, and of 349~~
406 ~~observation days and 165259 size spectra for nano-SMPS), NPF events were frequently observed at King~~
407 ~~Sejong Station, as shown by the size distribution data (Figure 2f). 97 events (26% of observation days)~~
408 ~~with elevated N_{NUC} were observed when taking place in pristine ($\text{BC} < 15$ ng m⁻³) and clean ($\text{BC}: 15$ – 50~~
409 ~~ng m⁻³) conditions. Median value of BC concentrations during NPF events was 21.0 ng m⁻³, similar to~~
410 ~~that of whole measurement periods after data filtering (median BC value: 18.8 ng m⁻³) (section 2.2). This~~
411 ~~indicated that NPF events are independent of occasional increases of BC during clean periods. NPF events~~
412 ~~were more frequently observed in summer (~55%) than in any other season (Figure 4), with the highest~~
413 ~~frequency in January (22%) and December (22%) followed by spring (September–November, 34%) and~~
414 ~~autumn (March–May, 11%). Similar results were reported by Järvinen et al. (2013) based on observations~~
415 ~~from Dome C and Kim et al. (2019) based on observations from King Sejong Station. Although Järvinen~~
416 ~~et al. (2013) reported winter events that occurred in the absence of sunlight, we did not detect NPF events~~
417 ~~during austral winter from May through to August.—~~

418 ~~Air mass back trajectories were calculated at hourly intervals to investigate possible source regions~~
419 ~~for the observed NPF events. Figure 2g shows the residence times of air masses over the three domains.~~

420 ~~Based on 2-days air mass transport history analysis, air masses allocated to ocean, sea ice and land~~
421 ~~account for 83, 12 and 5%, respectively, during the study period. 97 cases were identified as NPF events,~~
422 ~~80 of which were observed when the air mass originated over the ocean domain (Figure 4). 12 NPF events~~
423 ~~were observed in air masses originating over the sea ice domain, while the remaining 5 events were~~
424 ~~associated with multi-regional origin (3 cases) and land origin (2 cases). Multi-regional origin indicated~~
425 ~~air masses simultaneously influenced by all three domains. Our results indicated that NPF events were~~
426 ~~more common in air masses originating over the ocean and sea ice compared to those originating from~~
427 ~~the land. Precursors released by both ocean and sea ice could play an important role in the formation of~~
428 ~~new particles in the Antarctic atmosphere.~~

431 3.2. Case studies

432 This section presents a detailed overview of the ocean, sea ice, and multi-regional NPF events.

433 3.2.1. Marine NPF event

434 A striking series of NPF events took place over seven days (Figure 6), starting at approximately
435 00:00 on December 9, 2018. Events starting at midnight can likely indicate their formation few hours
436 earlier during afternoon sunlight, because the events are observed with an already grown nucleation mode.
437 Time series of meteorological parameters, air mass origins, oceanic biological activity (estimated by
438 chlorophyll and DMSP exposures), particle size distribution (measured by nano-SMPS and standard-
439 SMPS), and CCN concentrations are shown in Figure 6. During this time, the prevailing northerly winds
440 (median 307 °) were stable at 7.7 m s⁻¹. Air temperature varied from -1.5 to 2.1 °C (median 0.5 °C) and
441 RH varied from 75–97% (median 89 %). There were no data for solar radiation during these events. Air
442 masses predominantly traveled over the Antarctic Ocean (46.9, 0.7, and 0.4 h over ocean, land, and sea
443 ice, respectively) and could be categorized as originating from the Antarctic Ocean. Specifically, the air
444 mass originated mainly from Bellingshausen Sea (Figure 5a). During this event, the median total DMSP
445 and chlorophyll exposures in the surface sea were 18 nmol L⁻¹ and 0.26 mg m⁻³, respectively.

446 Between 00:00 and 20:00 on December 9, N_{NUC} increased from 196 to 688 cm^{-3} . At the same time,
447 CCN concentrations at 0.4 % supersaturation gradually increased from 138 (00:00 on December 0) to 326
448 cm^{-3} (12:00 on December 11), an increase of 135%. In addition, elevated N_{NUC} occurred at 00:00 on
449 December 13, ranging from 118–522 cm^{-3} . CCN number concentration at 0.4% supersaturation began to
450 increase at this time (95 cm^{-3}) and reached its maximum at 18:00 (503 cm^{-3}), with a concentration increase
451 of 431%.

452

453 3.2.2. Sea-ice NPF event

454 The NPF event with subsequent particle growth were detected from around 19:00 on January 13,
455 2018, to around 08:00 on January 14, 2018 (Figure 7). Air temperature and RH during the event were
456 0.1 °C and 85%, respectively, while solar radiation decreased from 131.7 to 0.2 W m^{-2} . Winds were mild
457 and stable (1.9–5.7 m sec^{-1}), with a prevailing northwesterly (262–350°) direction and air masses
458 predominantly coming from sea-ice. The average retention times of the 2 d back trajectories traveling
459 over ocean, sea-ice, and land were 20.0, 20.9, and 7.1 h, respectively, indicating sea-ice-influenced air
460 masses (Figure 5b). During the NPF event, both total DMSP and chlorophyll exposure values are stable,
461 with median exposures of 13.3 nmol L^{-1} and 0.2 mg m^{-3} , respectively.

462 During the event, $\text{CN}_{2.5}$ and CN_{10} increased to 5669 and 5097 cm^{-3} , respectively. Furthermore, the
463 median N_{NUC} , N_{AIT} , and N_{ACC} values were 508, 376, and 66 cm^{-3} , respectively. Elevated CCN
464 concentrations at 0.2 and 0.4 % supersaturations were not observed, whereas CCN concentrations at 0.6,
465 0.8, and 1.0 % supersaturations slightly increased during the event. For instance, CCN concentration at
466 0.8 % supersaturation was 517 cm^{-3} at 20:00 on January 13, then increased to 688 cm^{-3} , until 23:00 on
467 January 13. The CCN concentration at 0.6, 0.8, and 1.0% supersaturations increased by 11%, 33%, and
468 58%, respectively. Two NPF events with subsequent particle growth were detected from around 18:00 on
469 January 2, 2018, to around 00:00 on January 3, 2018 (Figure 7). Air temperature and RH during the event
470 were 0.2 °C and 81%, respectively, while solar radiation decreased from 211 to 0.0 W m^{-2} . Winds were
471 mild and stable (2.0–4.5 m sec^{-1}), with a prevailing northwesterly (220–330°) direction and air masses

472 predominantly coming from sea ice. The average retention times of the 2-d back trajectories traveling
473 over ocean, sea ice, and land were 13.1, 30.3, and 4.6 h, respectively, indicating sea ice influenced air
474 masses (Figure 5b). Both total DMSP and chlorophyll exposure values suddenly increased from 15:00 to
475 17:00 before the NPF event, while during it, they dropped drastically before somewhat stabilizing, with
476 median exposures of 11.8 nmol L^{-1} and 0.2 mg m^{-3} , respectively.

477 During the event, $\text{CN}_{2.5}$ and CN_{10} increased to 3982 and 1534 cm^{-3} , respectively. In addition, the
478 median N_{NUC} , N_{AIT} , and N_{ACC} values were 1148, 286, and 165 cm^{-3} , respectively. Furthermore, elevated
479 CCN concentrations were observed during NPF and growth events. Before the NPF event, CCN
480 concentration at 0.4 % supersaturation was 273.2 cm^{-3} at 17:00 on February 2, then slowly increased to
481 380 cm^{-3} , until 02:00 on February 3. During the NPF event, the CCN concentration increased by 39%.

483 3.2.3. Multiple NPF event

484 An intensive NPF event occurred from November 16 to November 17, 2018 (Figure 8). Air
485 temperature during the event ranged from -2.5 to $-0.1 \text{ }^{\circ}\text{C}$ (median $-1.3 \text{ }^{\circ}\text{C}$). RH ranged from 70–95%
486 (median 79%), slightly lower than that for the marine and sea-ice NPF events described above. During
487 the NPF event observed from 20:00 on November 16 to 02:00 on November 17, solar radiation decreased
488 from 30 to 0 W m^{-2} . This suggested that the NPF event occurred upwind of the measurement site,
489 especially due to observed grown mode. Wind speed ranged from 4.3–9.5 m s^{-1} with a constant direction
490 from the southwest (median 239 °). Air mass back trajectories showed multiple origins before reaching
491 the station, passing over ocean (25.7 h, 53% of residence time), sea-ice (12.4 h, 26% of residence time),
492 and land (10.0 h, 21% of residence time) (Figure 5c). During the event, the median total DMSP and
493 chlorophyll exposures in the sea surface were 6.0 nmol L^{-1} and 0.2 mg m^{-3} , respectively.

494 At the start of the event (17:00 on November 16), N_{NUC} , N_{AIT} , and N_{ACC} were 687, 83, and 13 cm^{-3} ,
495 respectively. The particle number concentration of the nucleation mode sharply increased to 1610 cm^{-3} at
496 the NPF time, and its peak concentration occurred 7 h after the start of the event (00:00 on November 17),
497 indicating spatial extent of the formation region. The peak concentration of Aitken mode particles

508 successively appeared 14 h after the start of the event (07:00 on November 17) and 22 h respectively for
509 accumulation mode particles (15:00 on November 17). The values in the Aitken and accumulation mode
500 ranges were 448 and 92 cm⁻³, respectively. We also observed a gradual increase in CCN concentration for
501 23 h. CCN concentration at 0.4 % supersaturation increased from 78 (17:00 on November 16) to 272 cm⁻³
502 (15:00 on November 17). This NPF event may have been a source of CCN, which enhanced CCN
503 concentrations by 248%.

504

505 3.3. Influence of air mass origin on the NPF event

506 3.3.1. Parameters related to NPF

507 Our results show that NPF and its growth events had largely different features depending on air
508 mass origin (Figure S6). Although only 3 cases of multi-regional NPF eventsevents occurred during the
509 pristine and clean periods (not included in Figure 9), the most intense NPF event was observed with multi-
510 regional source region. Here, we compared N_{NUC}, FR GR, and CS, for the ocean and sea-ice air masses
511 (Figure 9 a-d). The FR, GR, and CS values agreed well with those reported in previous studies at other
512 Antarctic sites (Järvinen et al., 2013; Kim et al., 2019; Kyrö et al., 2013; Weller et al., 2015), but
513 significantly lower than the values reported by the Quéléver et al. (2022), who showed the average FR
514 and GR were 0.686 cm⁻³ s⁻¹ and 4.2 nm h⁻¹, respectively. The median N_{NUC} and FR values for the ocean
515 air mass (N_{NUC}: 220 cm⁻³ and FR: 1.2 × 10⁻² cm⁻³ s⁻¹) were 1.6 and 3.0 times lower than those of sea-ice
516 air mass (N_{NUC}: 343 cm⁻³ and FR: 3.6 × 10⁻² cm⁻³ s⁻¹), respectively. This implies that marine NPF events
517 are frequent, but weak in terms of N_{NUC} and FR values. Unlike N_{NUC} and FR, there were no marked
518 differences between the median values of GR and CS by air mass category. The median particle GR
519 values for ocean, sea-ice, and multiple air masses were 0.8, 0.7, and 0.9 nm h⁻¹, respectively. In
520 comparison, Jokinen et al. (2018) reported that GR values ranged from 0.3 to 1.3 nm h⁻¹ at Aboa, and
521 Brean et al. (2021) showed GR of 0.4 to 0.6 nm h⁻¹ measured during the PI-ICE cruise. To examine the
522 effects of oceanic biological activity on NPF properties, we examined solar radiation intensity,

523 chlorophyll exposure and DMSP exposure for the three air mass (or source region) categories (Figure 9
524 e-g). There was no difference in the former, while the latter two were highest in air masses originating
525 from the ocean. The median chlorophyll exposure in ocean-influenced air masses (0.2 mg m^{-3}) was
526 roughly twice that of the sea-ice-influenced air mass (0.1 mg m^{-3}). Total DMSP exposure for the ocean-
527 influenced air mass was ~ 2.7 times that of the sea-ice air mass.

528

529 **3.3.2. Potential sources facilitating new particle formation**

530 Chlorophyll exposure and DMSP exposure were highest during marine NPF events, suggesting a
531 large chance to carry biologically-derived organic compounds from the open ocean areas to the
532 observation site. DMSP, a metabolite of oceanic phytoplankton, is partly converted into gaseous DMS
533 through enzymatic cleavage (Simó, 2001), which is the largest natural sulfur source in the atmosphere
534 (Barnes et al., 2006). Hence, the photooxidation products of biogenic DMS in the Antarctic atmosphere
535 (e.g., Sulfuric acid and Methane sulfonic acid)~~(i.e., secondary DMS-derived aerosols)~~ could be a major
536 contributor to NPF and its growth when the air mass originates from the ocean. Jang et al. (2019) reported
537 that NPF events were more frequent in air masses originating from the Bellingshausen Sea than the
538 Weddell Sea during the biologically productive austral summer, and it is likely that the taxonomic
539 composition of phytoplankton can be related to the formation of new particles in the Antarctic Ocean.
540 Biogenic DMS was found to be a precursor of NPF in coastal Antarctica (Yu and Luo, 2010).

541 Although sea-ice algae bloom underneath the sea-ice cannot be captured by satellite-estimates of
542 biological activity, the air mass exposure to chlorophyll and DMSP for sea-ice NPF events were 1.8 and
543 2.7 times lower than those of marine NPF events. This could be explained by volatile iodine compounds
544 released from ice-covered areas in Antarctica (Jokinen et al; 2018; Saiz-Lopez et al., 2007; Sipilä et al.,
545 2016); however, iodine compounds were not measured during our study period. Previously, iodine
546 compounds were found in large concentrations in and above the sea-ice of the Weddell Sea in Antarctica
547 during spring and summer (Atkinson et al., 2012). Roscoe et al. (2015) also confirmed that iodine
548 compounds may contribute to the secondary production of a significant number of particles measured at

549 Halley and Neumayer on the Antarctic coast.

550 In our study, sea-ice NPF events occurred frequently in January (middle of austral summer) and
551 September (early austral spring) (Figure 4). We compared the JR, GR, and CS values for the sea-ice NPF
552 cases observed between January and September (Figure S7) because of their notable differences in ice
553 coverage. In Antarctica, the minimum ice coverage is observed in February and the maximum in
554 September (Parkinson and Cavalieri, 2012). Our results showed that JR, GR, and CS values were much
555 higher in January than in September, indicating different NPF processes. The January events occurred
556 under low ice-coverage conditions, similar to previous studies from polar areas such as Svalbard
557 (Dall'Osto et al., 2017) and Greenland (Dall'Osto et al., 2018). Both studies showed that NPF events are
558 related to biogenic precursors released by open water and melting sea-ice regions, particularly during the
559 summer. In contrast, the September events occurred under high ice-coverage conditions. The monthly
560 median values of solar radiation showed that solar radiation intensity was very low from May to August
561 and then started to increase from September (Table 1). During the September events, median solar
562 radiation intensity was found to be 63 W m^{-2} . It is therefore possible that elevated sea-ice concentrations
563 under sufficient solar radiation around Antarctica lead to an increase in the concentration of halogen
564 species, resulting in the production of newly formed particles. Solar photooxidation of frozen iodine-
565 containing solution has been shown to accelerate gas-phase iodine concentrations (Kim et al., 2016).

566 The most intensive NPF event was observed in multiple air masses, although the oceanic biological
567 activity was lower than that in the oceanic air mass. This indicated that terrestrial sources from continental
568 Antarctica, in addition to both DMS (mainly from the ocean) and iodine (mainly from sea-ice), may have
569 contributed to NPF. First, previous studies have reported that precursors emitted from seabird colonies
570 are linked to NPF (Schmale et al., 2013; Weber et al., 1998). The Chottaebawi area in the southwestern
571 part of King George Island (around 2 km away from our observation site) is an important penguin colony
572 in the Antarctic region (Lee et al., 2009), while the cape area near King Sejong Station is abundantly
573 populated by flying seabirds such as skua. Given the proximity and abundance of seabird colonies at King
574 Sejong Station, seabird colony emissions are the likely sources of NPF. In fact, 2 NPF events (4 February

575 2018 for marine air mass origin and 18 February 2018 for multiple air mass origin) were observed when
576 winds were seen to originate from the south sector where strong emission from the penguin colonies
577 (southeast sector of 106–140°). Figure S8 showed the contour plots of the size distributions and wind
578 roses during those days. Although we did not directly measure the precursor gases such as ammonia and
579 amine that can trigger the NPF, we can speculate that the fauna on the land or at the shore such as penguin
580 and seabird colonies could not be excluded as the potential source of NPF events locally although highly
581 productive and ice melting Weddell sea is coinciding with southeast direction too. Previous studies
582 reported that precursor gases for NPF (e.g., ammonia) can originate from the decomposition of excreta
583 from seabirds and penguins (Lachlan-Cope et al., 2020; Legrand et al., 1998; Liu et al., 2018; Schmale et
584 al., 2013). More recently, Quéléver et al. (2022) proposed that nitrogen-containing species could be land-
585 sourced (e.g., from a high penguin population during the summertime) or marine-sourced (e.g., from the
586 biological activity of plankton in the ocean and melting sea ice). The ammonia from seabird-colony guano
587 is a key factor contributing to bursts of newly formed particles, which are observed in the summertime
588 Arctic (Croft et al., 2016). Second, biogenic emissions from vegetation in the Antarctic Peninsula, mainly
589 composed of relatively small and sparse patches of lichens and mosses (Miranda et al., 2020), could be
590 associated with NPF and growth. Kim et al. (2006) studied plant communities on the Barton Peninsula
591 around King Sejong Station in the maritime Antarctic and concluded that ~47% of the investigated area
592 was covered by vegetation although generally sparse. Finally, biogenic precursors from meltwater ponds
593 in continental Antarctica have also been suggested (Kyrö et al., 2013) as a possible source of aerosol
594 production (Weller et al., 2018). Overall, our data suggest that complex interconnected ecosystems across
595 ocean, sea ice, and land can lead to an enhancement in Antarctic NPF.

596 **3.3.3. NPF as a source of CCN**

597 For a given SS of 0.4%, the median CCN number concentrations were rather similar 184, 144, and
598 178 cm⁻³ for ocean, sea ice, and multiple air masses, respectively (Figure 9h). The values are in line with
599 previous studies published from the Antarctic regions. Humphries et al. (2023) reported CCN
600 concentrations nearby East Antarctic observations from Macquarie Island and Kennaook / Cape Grim as

601 well as recent ship voyages of the RSV *Aurora Australis* and the RV *Investigator* in the region. The median
602 CCN value at a SS of 0.5% was in the ranges of 88–145 cm⁻³ at Macquarie Island, 57–158 cm⁻³ at
603 Kennaook / Cape Grim, and 40–230 cm⁻³ during the voyages (No voyage data exist for the winter months),
604 respectively. The PCAN project exhibited that a median particle number concentration larger than 3 nm
605 of 354 cm⁻³ was observed from the voyage and median CCN at 0.55 % supersaturation were 167 cm⁻³,
606 implying approximately half the particles measured as CN₃ could be activated as CCN (Simmons et al.,
607 2021). Recently, several ship-based measurements over the Southern Ocean found significantly increased
608 MSA concentrations in air masses originating close to the Antarctic coastline, alongside enhancements in
609 CCN concentration (Humphries et al., 2021). Of the 83 NPF events, CCN concentrations increased by 2–
610 268% (median 44%) following 1 to 36 hours (median 8 hours) after NPF events. The median increase in
611 CCN concentrations was 44 %, 34 %, and 107 % for ocean, sea ice, and multiple air masses, respectively.
612 NPF can be an important source of CCN in Antarctica, and the highest CCN enhancement was observed
613 when air masses passed through multiple regions, followed by ocean and sea-ice regions. Moreover, we
614 newly calculated CCN increase rate, which defined as the change rates of representative CCN
615 concentrations (CCN₁(t₁) and CCN₂(t₂)) with the highest CCN concentrations at certain times (t₁ and t₂),
616 when elevated CCN concentration was observed during the NPF. The CCN rate varied from 1.4 to 76.7
617 cm⁻³ hr⁻¹, with a median value of 10.2 cm⁻³ hr⁻¹. Our results provide the first direct evidence of CCN
618 production resulting from an NPF event in the Antarctic atmosphere, based on simultaneous
619 measurements of particle number size distribution (e.g., diameter ranges of 2.5–300 nm) and CCN number
620 concentrations in real time throughout the year.

621 We also compared CCN activity and critical diameter for the three selected periods (Figure 9i and
622 j). The median values of CCN activity, i.e. the ratio of the number concentration of particles that activated
623 to become CCN at a given supersaturation to the total number concentration or particles larger than 10
624 nm (CN₁₀), were similar (about 5%) in three different air masses. The critical diameter (D_c), the diameter
625 at which the integration of aerosol size distribution from the largest particle diameter to the lowest one
626 matches the measured CCN concentration, was determined using the measured aerosol size distribution,

627 CN₁₀, and CCN concentrations (Furutani et al., 2018). The median D_c value at 0.4% supersaturation was
628 estimated to be 41 nm, 32 nm, and 37 nm for ocean, sea ice, and multiple air masses, respectively. These
629 results agreed well with those reported in previous studies that determined D_c at the Finnish Antarctic
630 Research Station, Aboa (Kyrö et al., 2013), a clean subarctic background site (Komppula et al., 2005),
631 and over remote Southern Ocean around Antarctica (Fossum et al., 2018; Fossum et al., 2020). For
632 instance, Kyrö et al. (2013) found the smallest D_c at 48 nm. The median D_c , as suggested by Komppula
633 et al. (2005), varied from 50–128 nm (average 80 nm). The D_c value for maritime polar and marine
634 modified continental Antarctic air masses were 71 and 59 nm, respectively (Fossum et al., 2020).

635 A time series of daily mean CCN concentrations at five different supersaturation ratio of 0.2, 0.4,
636 0.6, 0.8, and 1 was illustrated in Figure S10. To understand the contribution of growing particles on the
637 CCN concentrations during NPF event, we determined the increase in CCN concentration during growth
638 periods (i.e., growth to smaller than 40 nm particles and growth to larger than 40 nm particles) compared
639 to baseline values (black) under different supersaturation conditions (Figure 10), according to the method
640 suggested by Chang et al. (2022). When particle growth was smaller than to 40 nm (growth \leq 40 nm), the
641 mean CCN concentrations increased by 59–178 cm⁻³ for a SS of 0.2 %–1.0 %, representing a 172.3–
642 216.7 % increase compared to the values during baseline conditions. When particle growth was larger
643 than to 40 nm (growth $>$ 40 nm), the mean CCN concentrations increased by 57–227 cm⁻³ for a SS of
644 0.2 %–1.0 %, representing a 169.9–249.1 % increase compared to baseline values. Our results indicate
645 that particles formed from NPF events can lead to the significantly enhanced CCN concentration in
646 Antarctic Peninsula, and this effect is more pronounced if we consider particle growth larger than 40 nm,
647 consistent with ship-based observations (Chang et al., 2022) and aircraft-based observation (Willis et al.,
648 2016) in the Canadian Arctic during summer.

649

650 **4. Conclusions**

651 We measured the number size distribution of 2.5–300 nm particles and CCN number concentrations
652 at King Sejong Station in the Antarctic Peninsula continuously from January 1 to December 31, 2018.

653 The annual median values of N_{NUC} , N_{AIT} , and N_{ACC} were 46.8 cm^{-3} , 53.5 cm^{-3} , and 21.7 cm^{-3} , respectively.
654 Overall, clear annual and seasonal patterns of particle number concentrations in all size classes were
655 observed (high concentrations in summer and low concentrations in winter). Furthermore, the monthly
656 CN_{10} value was positively correlated with the monthly N_{NUC} , implying that summer maximum particle
657 concentrations could be largely influenced by newly formed particles in the Antarctic atmosphere. Among
658 meteorological parameters, the elevated N_{NUC} values (i.e., indicators of NPF events) were more likely to
659 be accompanied by high solar radiation, high temperature, and low RH, regardless of wind speed.

660 NPF events were identified based on size distribution data measured using two SMPSs. During the
661 pristine and clean periods, 97 events (26% of observation days) with elevated N_{NUC} were observed. NPF
662 events occurred more frequently in summer than in any other season. Based on air mass back-trajectory
663 analysis, we distinguished three different types of NPF events: marine (80 cases), sea ice (12 cases), and
664 multiple (3 cases). Marine NPF events were frequent and weak (N_{NUC} , 220 cm^{-3} ; $\text{FR} = 1.2 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$;
665 $\text{GR} = 0.8 \text{ nm hr}^{-1}$) and occurred when the air mass exposure to oceanic phytoplankton was high
666 (chlorophyll, 0.2 mg m^{-3} ; DMSP, 18 nmol L^{-1}). The photooxidation of biogenic DMS in the Antarctic
667 atmosphere could be a major contributor to marine NPF events. In contrast, sea-ice NPF events (N_{NUC} ,
668 343 cm^{-3} ; FR , $3.6 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$; GR , 0.7 nm h^{-1}) were observed when the air mass exposure to oceanic
669 phytoplankton was relatively low (chlorophyll, 0.1 mg m^{-3} ; DMSP, 7 nmol L^{-1}), which may be due to
670 volatile iodine compounds released from ice-covered areas. Strong NPF events (N_{NUC} , 516 cm^{-3} ; FR , 3.2
671 $\times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$; GR , 0.9 nm hr^{-1}) were associated with multiple air masses, indicating complex
672 interconnected ecosystems leading to an enhancement in Antarctic NPF.

673 To investigate the connection between newly formed particles and CCN production, we compared
674 CCN properties for the three air mass categories. The median CCN number concentrations at a given SS
675 of 0.4% were 184, 144, and 178 cm^{-3} for ocean, sea ice, and multiple air masses, respectively. Of the 83
676 events, an increase in CCN concentrations after the NPF events was detected, ranging from 2–268 %
677 (median 44 %). The median increase in CCN concentrations was 44 %, 34 %, and 107 % for ocean, sea
678 ice, and multiple air masses, respectively. NPF events led to increased CCN concentrations at King Sejong

679 Station. The median value of D_c at a supersaturation of 0.4% was estimated to be 41 nm, 32 nm, and 37
680 nm for ocean, sea ice, and multiple air masses, respectively. This study is the first to report CCN
681 production resulting from Antarctic NPF events in the Antarctic Peninsula. However, further detailed
682 measurements of the chemical properties of aerosol particles and precursor gases (e.g., ammonia) during
683 NPF events are required to better understand the contribution of these compounds to the formation and
684 growth of aerosol particles and to explore their impacts on CCN formation in the remote Antarctic
685 environment.~~However, further detailed measurements of the chemical properties of aerosol particles and~~
686 ~~precursors during NPF events are required to better understand the contribution of these compounds to~~
687 ~~the formation and growth of aerosol particles and to explore their impacts on CCN formation in the remote~~
688 ~~Antarctic environment.~~

^aN_{NUC}, N_{AIT}, and N_{ACC} represent the particle number concentrations in the nucleation mode (2.5–25 nm), Aitken mode (25–100 nm), and accumulation mode (100–300 nm).

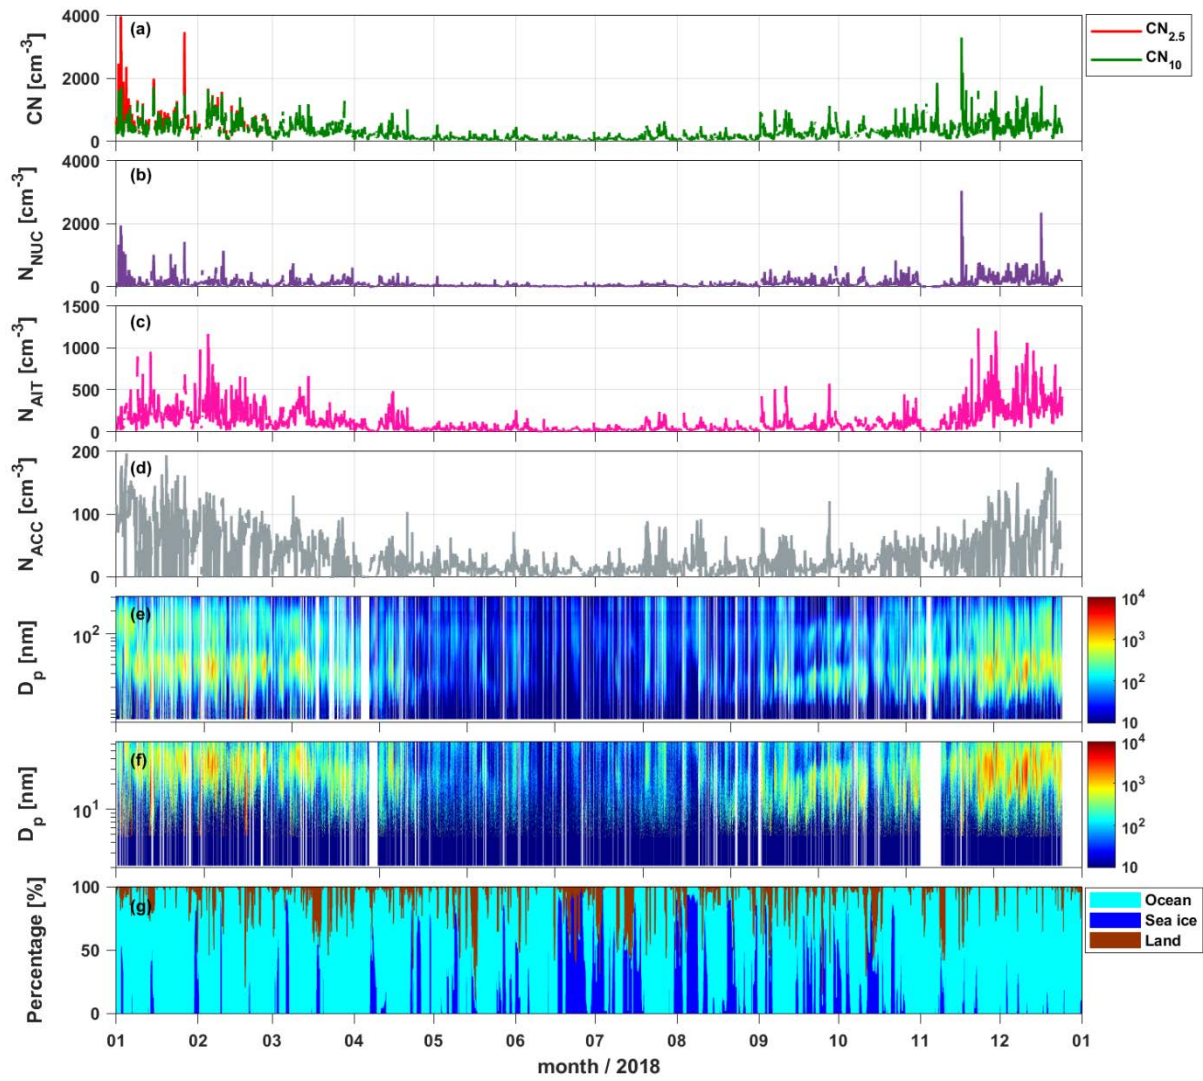

Figure 1. Frequency of occurrence of BC mass concentration for six types of Antarctic Peninsula air-pollution levels classified from four-year BC data.

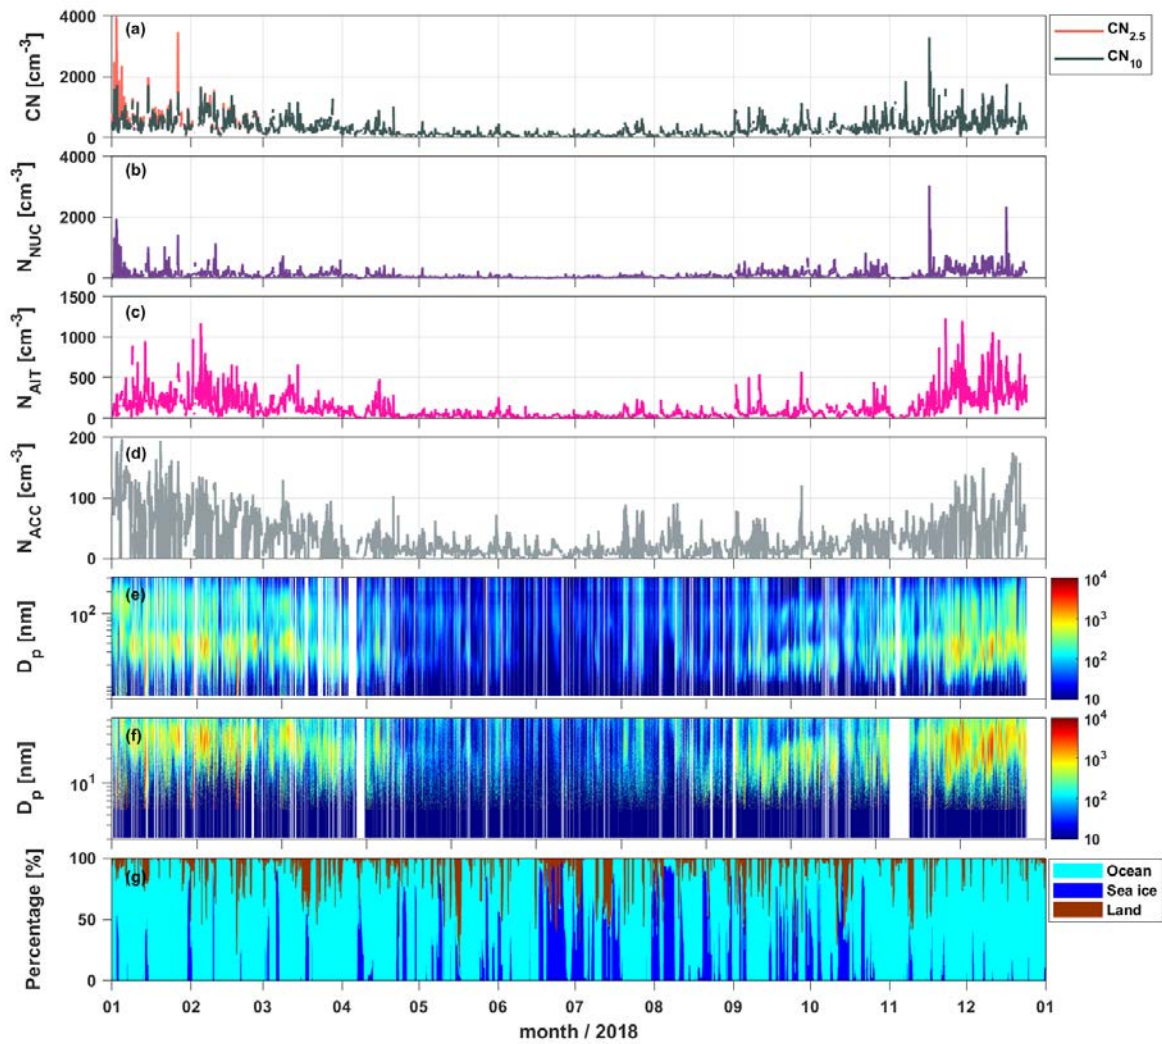

Figure 2. Time series of 1 h averages for (a) $\text{CN}_{2.5}$ and CN_{10} , (b) nucleation mode (N_{NUC} ; 2.5–25 nm), (c) Aitken mode (N_{AIT} ; 25–100 nm), and (d) accumulation mode (N_{ACC} ; 100–300 nm); contour plots of the size distributions measured using (e) standard and (f) nano-SMPS; and (g) residence time of air masses passing over ocean, sea ice, and land. [CN 2.5 data are only available from January to March due to the instrumental malfunctions.](#)

Figure 3. Frequency of (a) initial diameter of particles, (b) duration time, (c) growth rate, and (d) extension for the NPF event. Two NPF cases were excluded when the wind speed was higher than 10 ms^{-1} .

Figure 4. Seasonal variations in the number of NPF days by air mass origin.

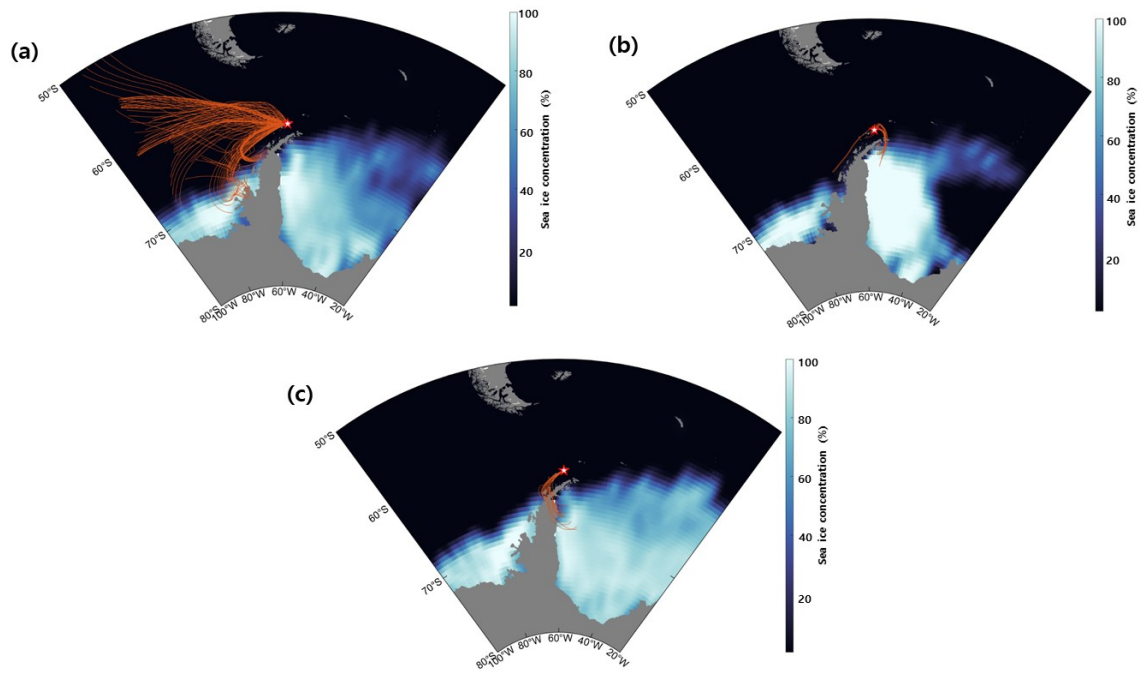

Figure 5. Air mass back trajectories for arrival at 50 m for the three case study NPF events: (a) marine, (b) sea ice, and (c) multiple.

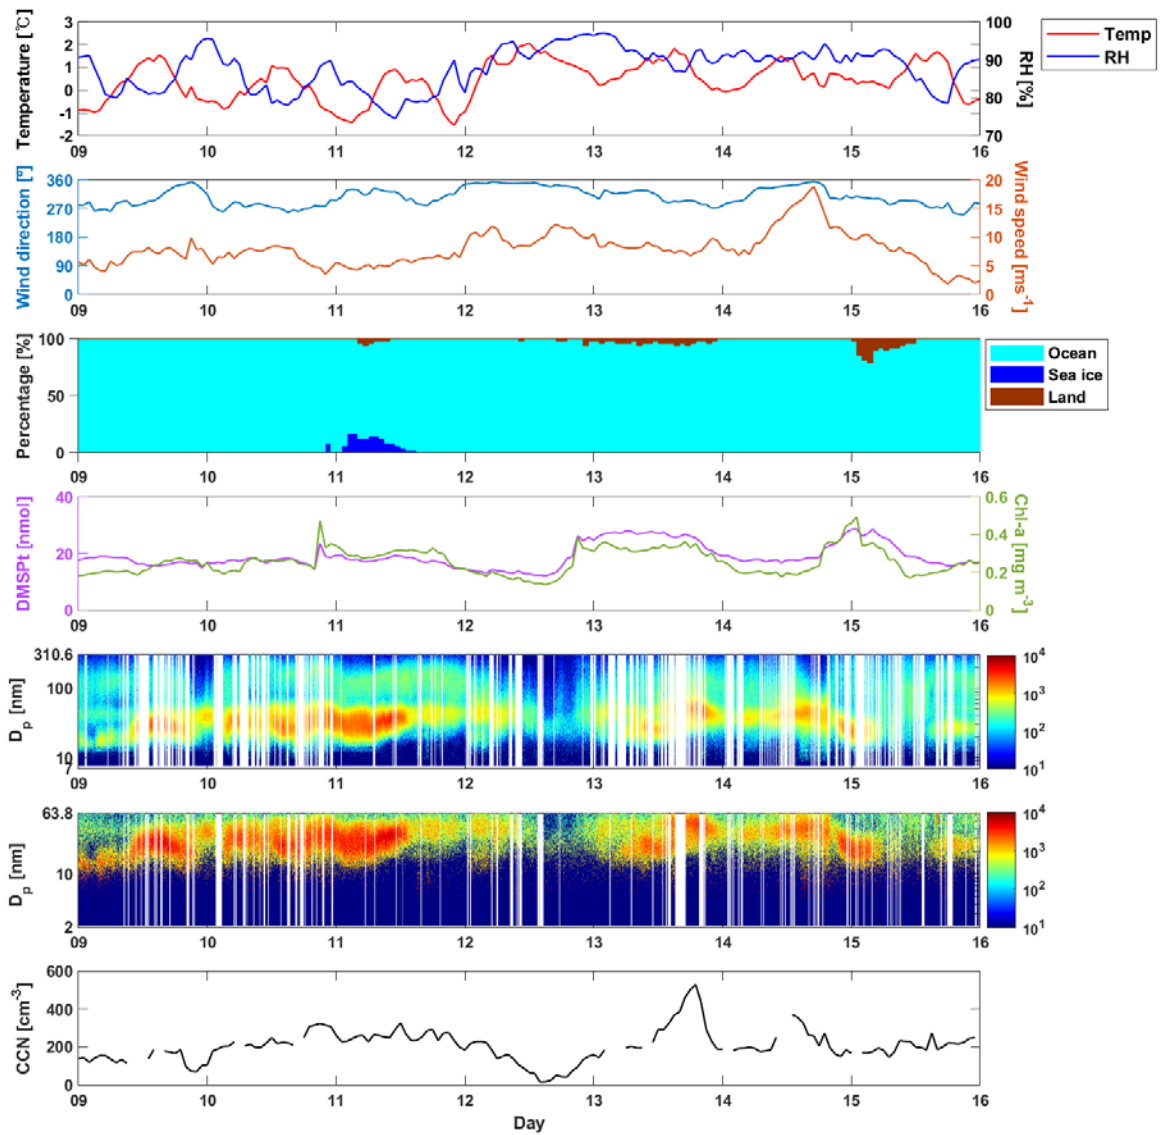

Figure 6. Marine NPF event observed from December 9–15, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard SMPS and nano-SMPS, and CCN number concentration.

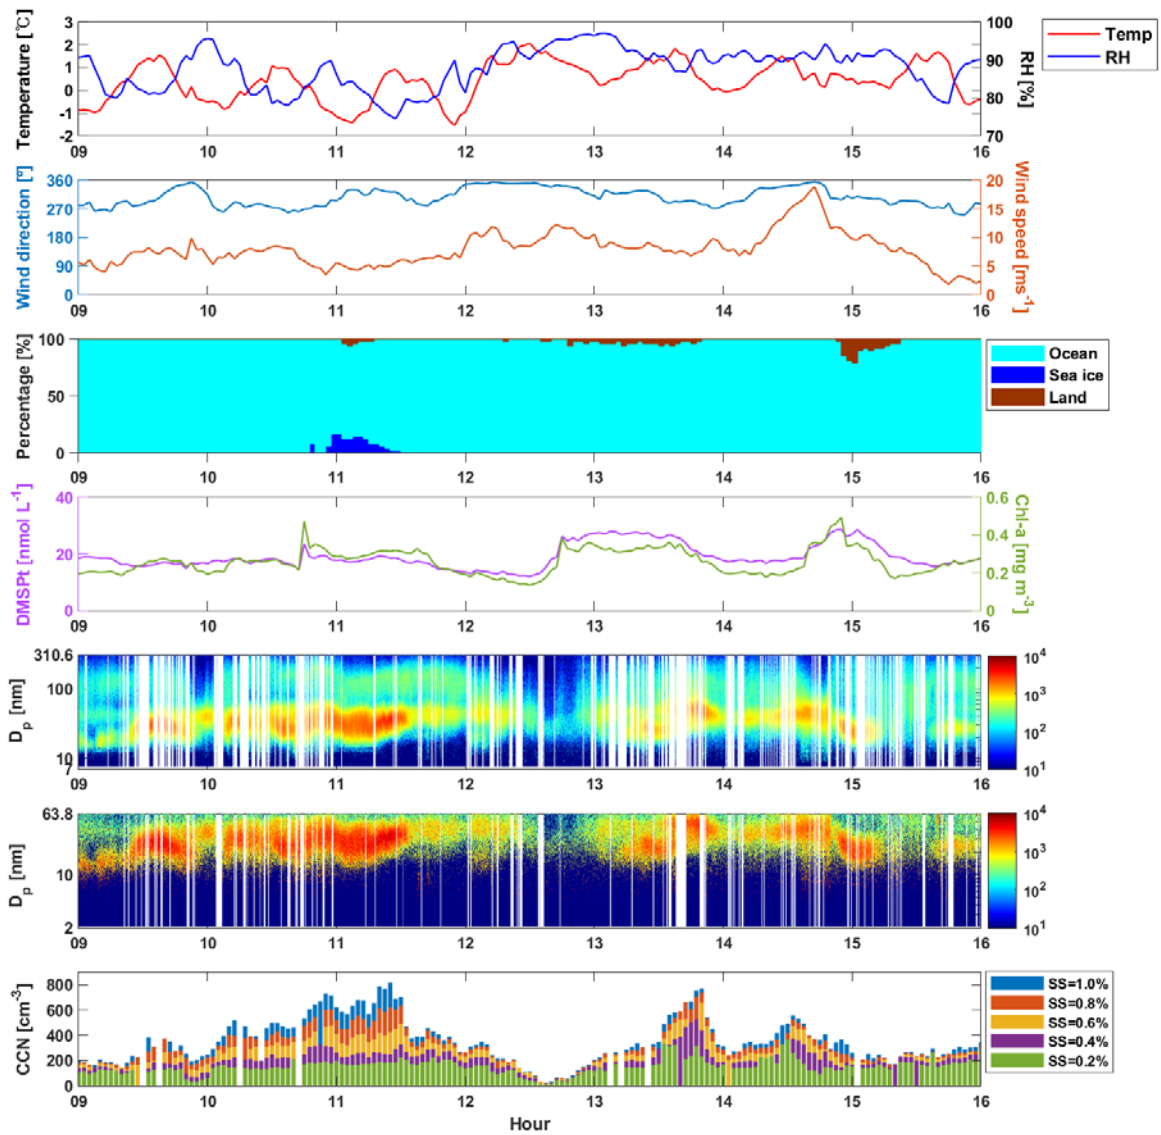

Figure 6. Marine NPF event observed from December 9–15, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration. The x-axis represents local time.

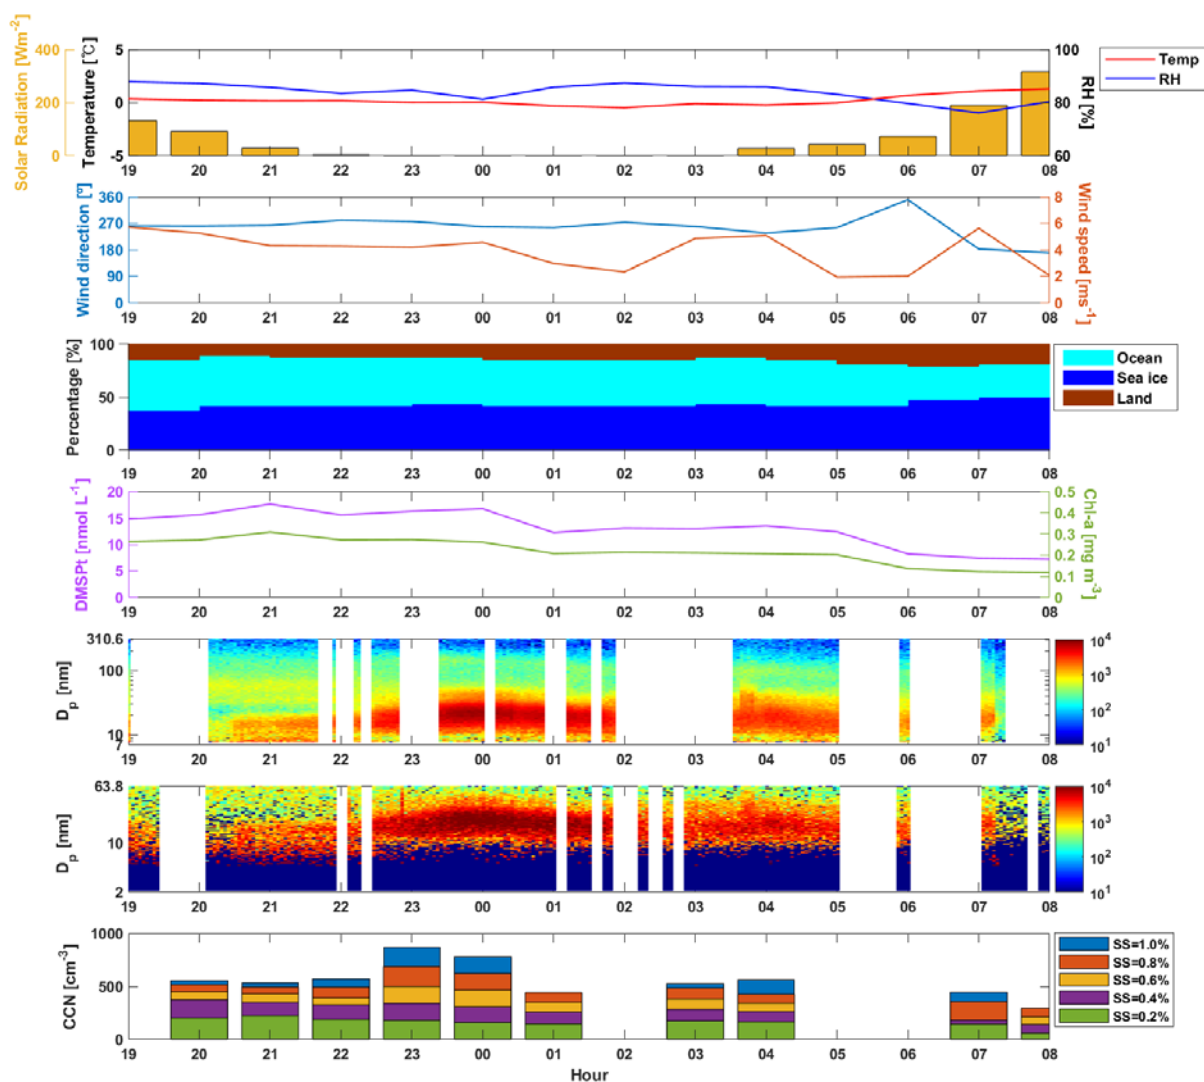

Figure 7. Sea ice NPF event observed from January 13–14, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration. The x-axis represents local time.

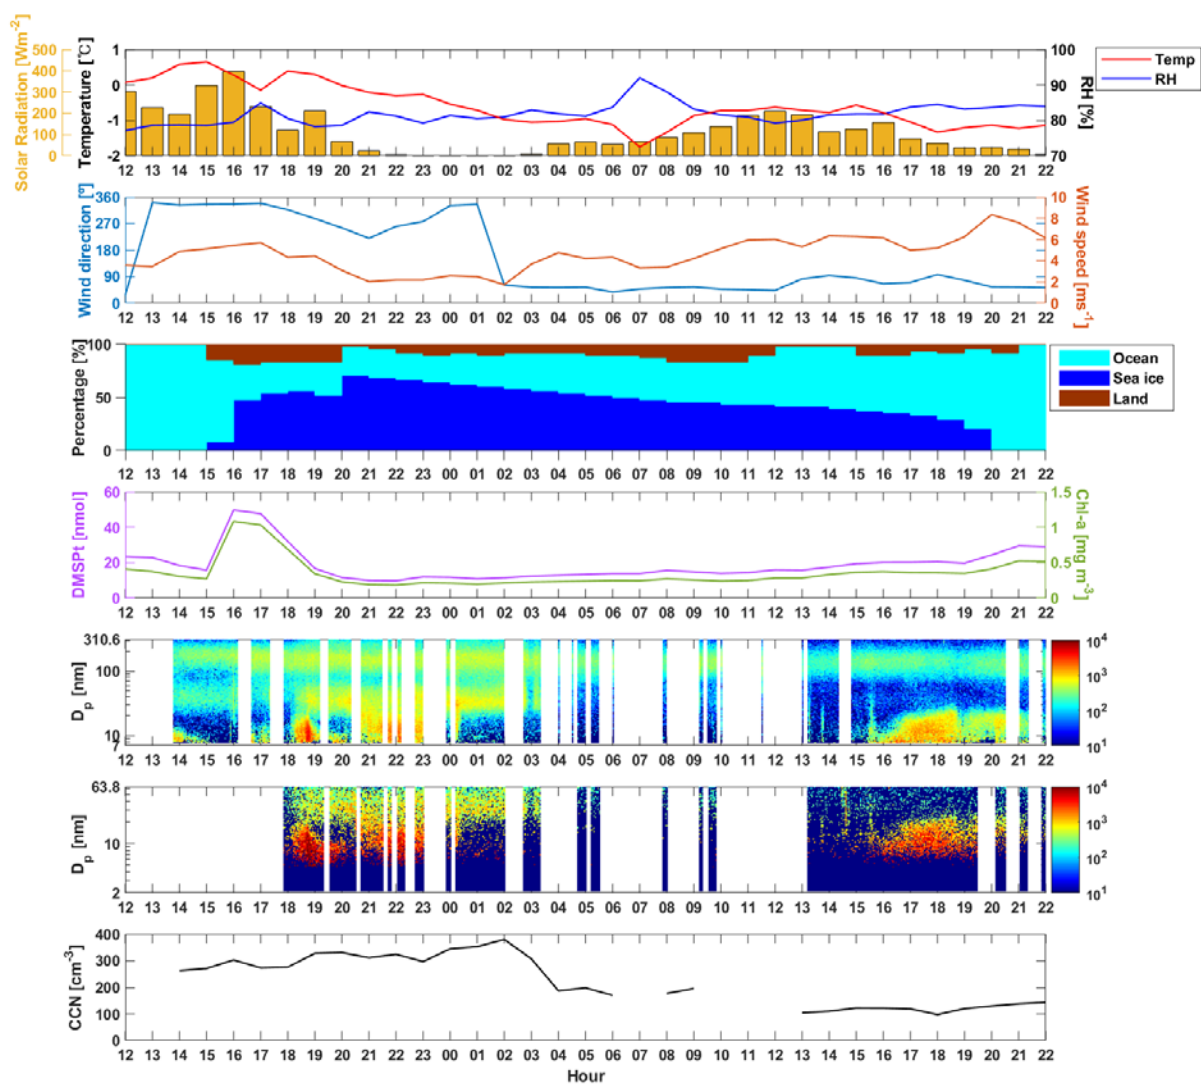

Figure 7. Sea ice NPF event observed from January 2–3, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard SMPS and nano-SMPS, and CCN number concentration.

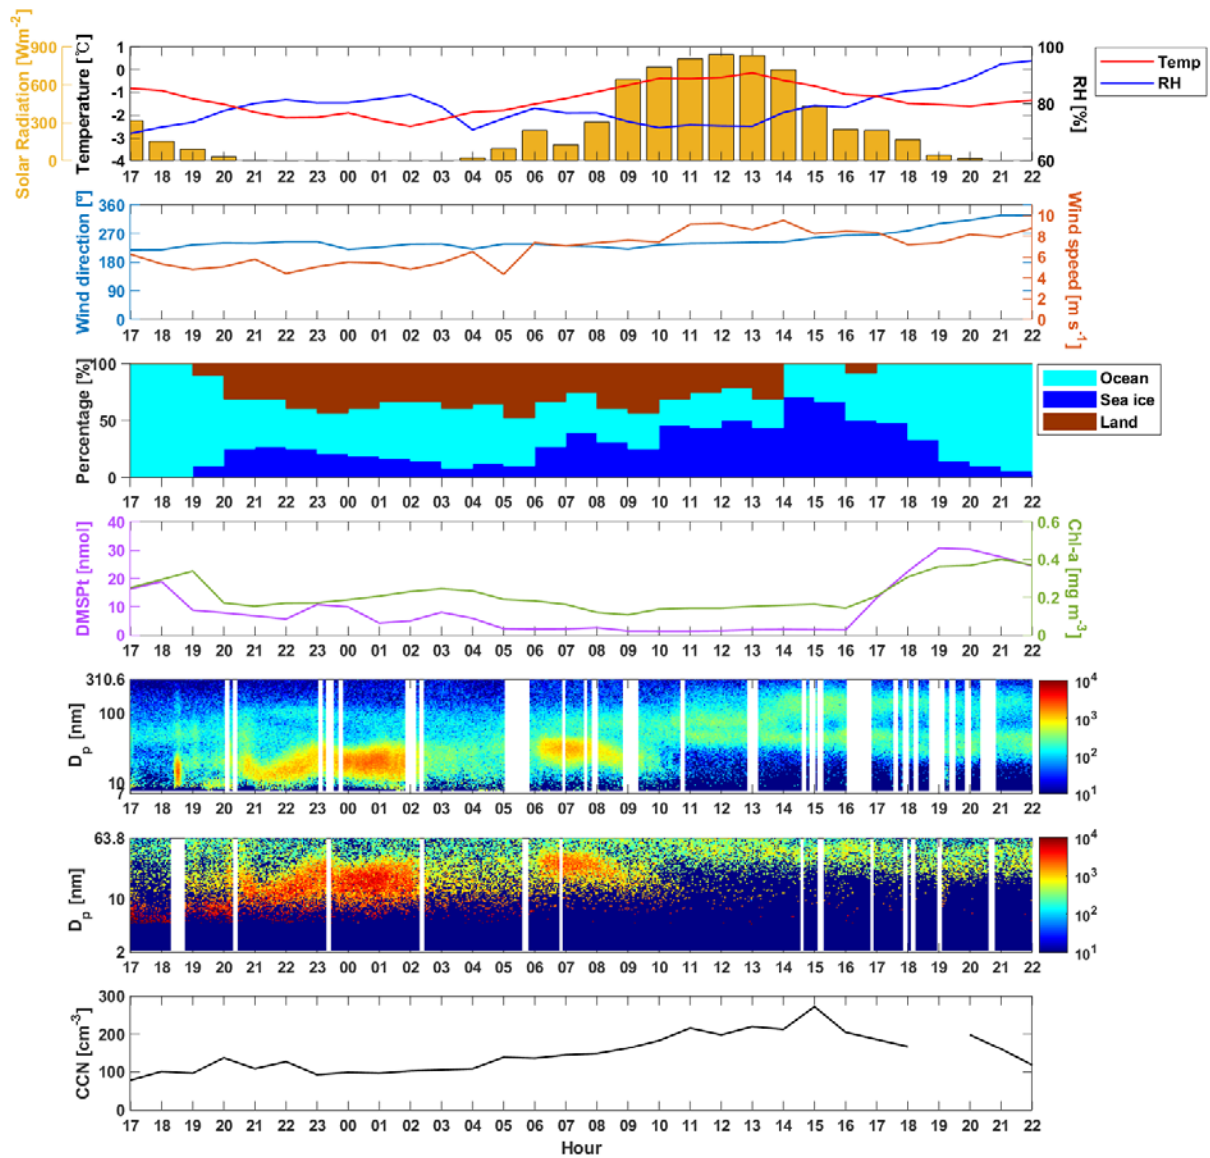

Figure 8. Multiple NPF event observed from November 16–17, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard SMPS and nano-SMPS, and CCN number concentration.

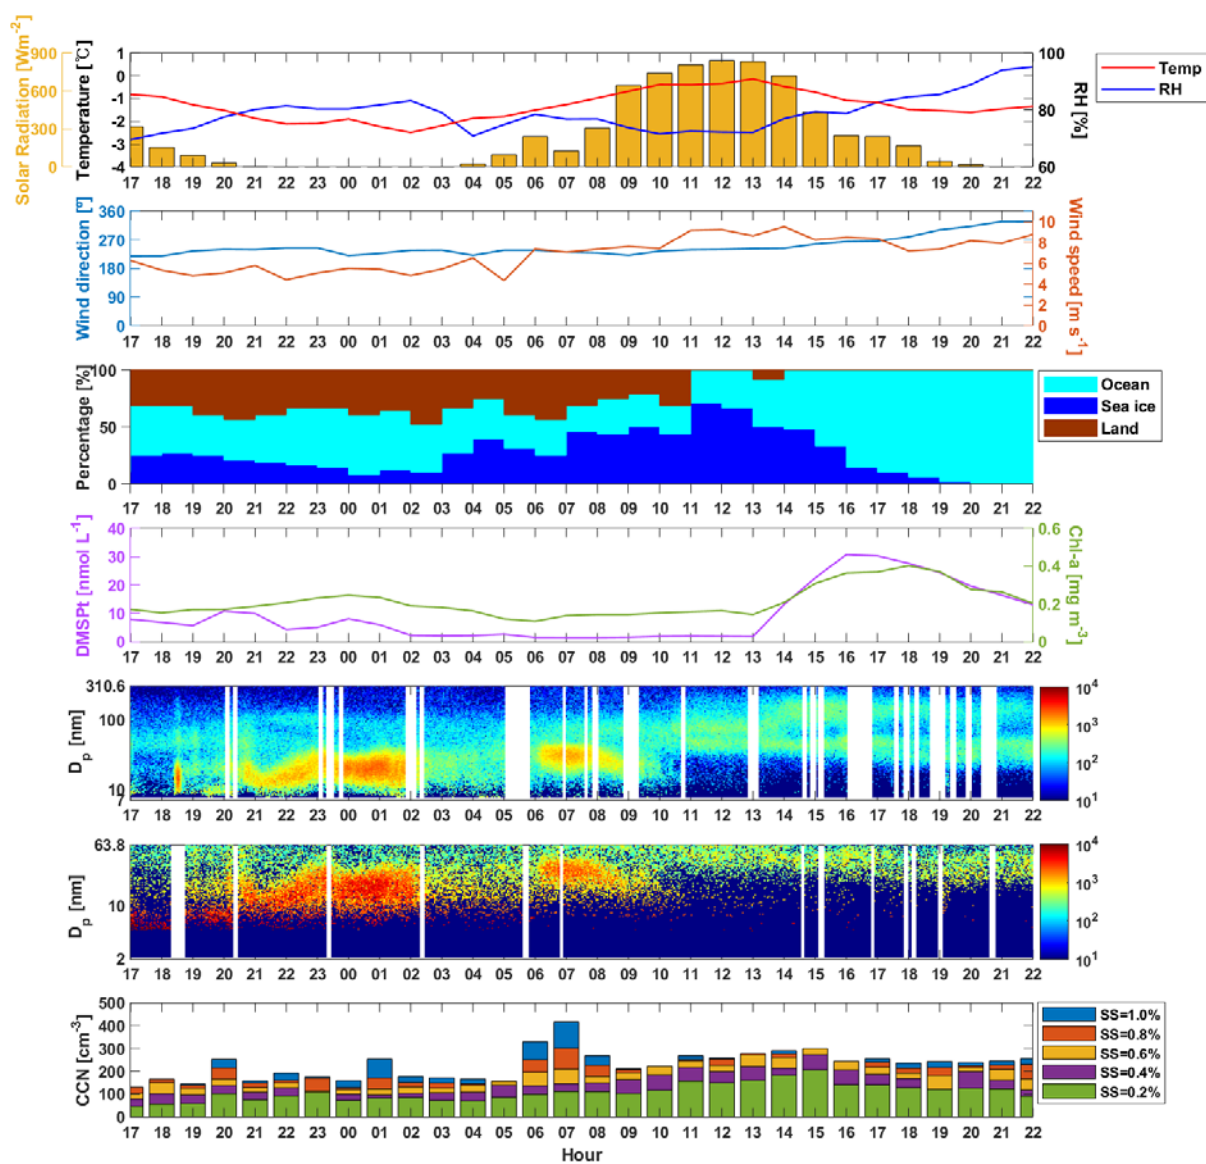

Figure 8. Multiple NPF event observed from November 16–17, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration. The x-axis represents local time.

Figure 9. Box plots for (a) number concentration of nucleation-mode particles (N_{NUC}), (b) formation rate (FR), (c) growth rate (GR), (d) condensation sink (CS), (e) solar radiation, (f) chlorophyll exposure, (g) DMSP exposure, (h) CCN number concentration, (i) CCN activity, and (j) critical diameter (D_c) for ocean, sea ice, and multiple air masses. Upper/lower box limits and solid lines indicate the 75th/25th percentiles and median, respectively.

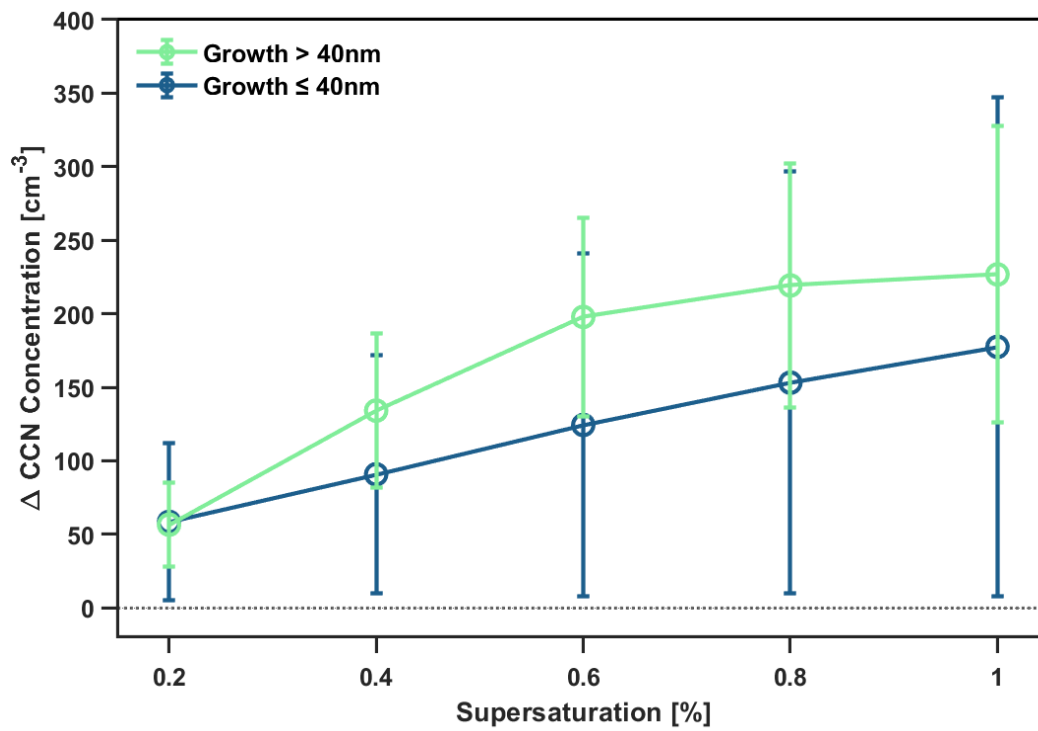

Figure 10. The increase in CCN concentration during growth to larger than 40 nm particles (green) and smaller than 40 nm (blue) times compared with background times at five different supersaturations.
