## Abstract

Few studies have investigated the impact of new particle formation (NPF) on cloud condensation nuclei (CCN) in remote Antarctica, and none has elucidated the relationship between NPF and CCN production. To address that knowledge gap, we continuously measured the number size distribution of 2.5–300 nm particles and CCN number concentrations at King Sejong Station in the Antarctic Peninsula from January 1 to December 31, 2018. Ninety-seven new particle formation (NPF) events were detected throughout the year. Clear annual and seasonal patterns of NPF were observed: high concentration and frequency of nucleation-mode particles in summer (December–February: 53 NPF cases) and undetected nucleation-mode particles in winter (June–August: no NPF cases). The estimated median spatial scale of NPF around Antarctic peninsula was found to be approximately 155 km, indicating the large-scale of NPF events. Air back-trajectory analysis revealed that 80 cases of NPF events were associated with air masses originating over the ocean, followed by sea-ice (12 cases), multiple (3 cases), and land (2 cases) regions. We present and discuss three major NPF categories: (1) marine NPF (2) sea-ice NPF, and (3) multiple NPF. Satellite-estimates for sea surface dimethylsulfoniopropionate (DMSP; a precursor of gaseous dimethyl sulfide) data showed that the production of oceanic biogenic precursors could be a key component in marine NPF events, whereas halogen compounds released from ice-covered areas could

30 contribute to sea-ice NPF events. Terrestrial sources (wild life colonies, vegetation, and meltwater ponds)  
31 from Antarctica could affect aerosol production in multiple air masses. Out of 97 observed NPF events,  
32 83 cases were characterized by the simultaneous increase in the CCN concentration by 2–270% (median  
33 44%) in the following 1 to 36 hours (median 8 hours) after NPF events. Overall, Antarctic NPF events  
34 were found to be a significant source of particles with different physical characteristics and related to  
35 biogenic sources in and around the Antarctic Peninsula, which subsequently grew to cloud condensation  
36 nuclei.

37

## 38 **1. Introduction**

39 Antarctic peninsula is warming more rapidly than Earth’s global mean rate (Chen et al., 2009;  
40 Vaughan et al., 2003), leading to shrinking sea-ice coverage and consequent sea-level rise (Pritchard et  
41 al., 2009). In the Antarctic region, ambient aerosols play a crucial role in governing radiative transfer,  
42 directly by the scattering and absorption of solar radiation and indirectly by acting as cloud condensation  
43 nuclei (CCN) (IPCC, 2013). The magnitude of the radiative forcing caused by the interactions between  
44 aerosols and CCN remains highly uncertain due to a poor understanding of pristine natural aerosols  
45 (Carslaw et al., 2013). To reduce this uncertainty, the physicochemical properties of aerosol particles (e.g.,  
46 number concentrations, size distributions, chemical compositions, and hygroscopicity) have been studied  
47 at several Antarctic stations including King Sejong Station (Kim et al., 2019), Aboa (Asmi et al., 2010;  
48 Virkkula et al., 2006), Dome C (Järvinen et al., 2013), Halley (Lachlan-Cope et al., 2020; O’Dowd et al.,  
49 1997), Kohn (Weller et al., 2018), McMurdo (Giordano et al., 2018; Liu et al., 2018), Neumayer (Teinilä  
50 et al., 2014; Weller et al., 2015), Princess Elisabeth (Herenz et al., 2019) and Syowa (Hara et al., 2011;  
51 Ito, 1993). Furthermore, open ocean and coastal Antarctic expeditions such as SIPEXII (Sea Ice Physics  
52 and Ecosystems eXperiment, 2012; Humphries et al., 2015; Humphries et al., 2016), PEGASO (Plankton-  
53 derived Emissions of trace Gases and Aerosols in the Southern Ocean, 2015; Dall’Osto et al., 2017;  
54 Decesari et al., 2020; Fossum et al., 2018), ACE-SPACE (Antarctic Circumnavigation Expedition – Study  
55 of Preindustrial-like Aerosol Climate Effects, 2017; Schmale et al., 2019; Walton and Thomas, 2018),

56 PCAN (Polar Cell Aerosol Nucleation, 2017; Simmons et al., 2021); PI-ICE (Polar atmosphere-ice-ocean  
57 Interactions: Impact on Climate and Ecology, 2019; Brean et al., 2021; Dall'Osto et al., 2022) studies on  
58 the influences of marine aerosols on climate and ecology. Overall, aerosol particle number concentrations  
59 follow a clear annual trend, being much higher in austral summer than in other seasons (Järvinen et al.,  
60 2013; Kerminen et al., 2018; Weller et al., 2011). For instance, Kim et al. (2017) found that summertime  
61 concentrations in the Antarctic Peninsula were ~20 times higher than in winter. This pattern can be largely  
62 explained by new particle formation (NPF) events.

63 Precursor gases for NPF in this region can originate from the ocean, sea-ice, meltwater ponds,  
64 terrestrial animal colonies, anthropogenic activity and continental ecosystem. Oceanic emissions of  
65 dimethyl sulfide (DMS) represent the largest natural sulfur source in the Antarctic atmosphere (Simó,  
66 2001), and its photooxidation is a key process contributing to NPF (Giordano et al., 2017; Jang et al.,  
67 2019 and 2022). For instance, in situ (Saiz-Lopez et al., 2007) and satellite (Schönhardt et al., 2008)  
68 measurements have shown Antarctica to be an iodine emission hotspot, particularly from the sea-ice in  
69 the Weddell Sea during spring (Atkinson et al., 2012). Indeed, Sipilä et al. (2016) measured iodic acid  
70 ( $\text{HIO}_3$ ) in Antarctica and found that the Antarctic oceanic regions may be strong sources of molecular  
71 iodine, which is then converted to  $\text{HIO}_3$  in gas-phase reactions. Dall'Osto et al. (2017) reported that  
72 microbiota in sea-ice were associated with atmospheric organic nitrogen formation in the Southern Ocean  
73 near Antarctica. According to Kyrö et al. (2013), the precursor vapors responsible for NPF and subsequent  
74 growth could originate from the cyanobacteria, which are abundant in Antarctic meltwater ponds. In  
75 addition, continental Antarctica is a habitat for various types of seabirds and penguins, with guano species  
76 acting as a crucial source of ammonia and organic compounds and may contribute to NPF in coastal  
77 Antarctic areas (Schmale et al., 2013; Weber et al., 1998; Zhu et al., 2011). At continental South Pole NPF  
78 event are commonly associated with the local anthropogenic pollution during calm weather conditions  
79 (Park et al., 2004). In addition, the biomass burning aerosol from South American continental outflow has  
80 been observed at Troll Research Station (Fiebig et al., 2009). During the daytime, higher radiation  
81 enhances photo-active emissions from land ecosystems (mosses, grasses, and lichens) of the Antarctic

82 Peninsula and can lead to NPF and aerosol growth (Decesari et al., 2020; Quéléver et al., 2022; Schmale  
83 et al., 2013). However, land sources are rather unlikely due to a small footprint of emerging land and the  
84 associated short overpass over the sparse vegetation.

85 In recent years, long-term records of aerosol size distribution have become an important aspect of  
86 investigations into the sources and dynamical processes of NPF. The majority of Antarctic field studies  
87 have focused on the annual and spatial patterns of the number size distribution of particles  $> 10$  nm (Belosi  
88 et al., 2012; Järvinen et al., 2013; Kim et al., 2019; Kyrö et al., 2013; Lachlan-Cope et al., 2020). Although  
89 NPF events are typically characterized by a rapid increase in the number concentration of cluster from 1–  
90 3 nm (Kulmala et al., 2004), datasets for these types of aerosol size distribution remain rare. To date,  
91 number size distribution of particles  $> 3$  nm has been reported by Asmi et al. (2010) at Aboa during from  
92 December 29, 2006 to January 29, 2007; by Pant et al. (2011) at Maitri from January 1 to February 28,  
93 2015; by Weller et al. (2015) at Neumayer from January 20 to March 26, 2012; by Jokinen et al. (2018)  
94 at Aboa from November 2014 to February 2015; by Weller et al. (2018) at Kohnen during January 2015  
95 and 2016; by Quéléver et al. (2022) at Marambio during the austral summer between January 15 and  
96 February 25, 2018; and by Brean et al. (2021) during the PI-ICE cruise from January 25 to February 4,  
97 2019. However, all of these measurements were made during the Antarctic summer due to restricted  
98 access and, therefore, limited information on seasonal cycles.

99 Newly formed particles can grow into larger sizes that act as CCN, becoming relevant for cloud  
100 formation (O’Dowd, 2002; Williamson et al., 2019). In a highly pristine atmosphere such as Antarctica,  
101 where CCN concentration is extremely low (Kim et al., 2017), NPF may be a significant phenomenon  
102 controlling the CCN budget (Kyrö et al., 2013). For instance, Herenz et al. (2019) showed that an elevated  
103  $\text{CN}_{2.5}$  (total number concentration of particles  $> 2.5$  nm) during NPF events was accompanied by an  
104 increase in CCN concentrations at Princess Elisabeth during austral summer (December to February,  
105 2013–2016). Ship-based observations during the ACE-SPACE found that the fraction of particle serving  
106 as CCN was higher near the coast of Antarctica compared to open ocean, resulting from multiple  
107 processing cycles of dissipating and condensing clouds and/or the higher availability condensable gases

108 [originating from marine microbial activity \(Schmale et al., 2019\)](#). In addition, seasonal variability in  
109  $CN_{2.5-10}$  (number concentration of particles within the 2.5 nm and 10 nm range and attributed to NPF)  
110 and CCN concentrations at King Sejong Station from March 2009 to December 2016 were investigated  
111 by Kim et al. (2019), who concluded that CCN concentrations during NPF events increased by ~11%  
112 compared to the background concentration. However, to date, only one study (Kim et al., 2019) has  
113 reported the contribution of NPF to CCN in the Antarctic Peninsula, and that study did not consider  
114 aerosol number size distribution.

115 In this study, we continuously recorded the number size distribution of 2.5–300 nm particles and  
116 CCN number concentrations at King Sejong Station in the Antarctic Peninsula from January 1, 2018, to  
117 December 31, 2018. Our primary goals were to (1) characterize the seasonal variation and occurrence of  
118 NPF events from the perspective of aerosol physical properties (total number concentration, number size  
119 distribution, formation and growth rates, and condensation sink); (2) improve our understanding of the  
120 major sources (including open ocean, sea-ice, and land) and processes influencing NPF and particle  
121 growth; and (3) estimate the contribution of atmospheric NPF to CCN activity in this pristine environment.  
122 To our knowledge, this is the first study to present direct evidence of CCN production associated with  
123 NPF and growth events in the Antarctic Peninsula, using simultaneous measurements of particle number  
124 size distributions (down to 3 nm) and CCN properties for a full year.

125

## 126 **2. Experimental methods**

### 127 **2.1. Sampling site and instrumentation**

128 Continuous measurements of the physical properties of aerosol particles were conducted from  
129 January 2018 to December 2018 at King Sejong Station in the Antarctic Peninsula (62.22° S, 58.78° W).  
130 Full details of the sampling site and measurement setup are given in Kim et al. (2017). In brief, a  
131 cylindrical stainless inlet (0.1 m diameter and 5.2 m length; total flow rate of the sampled air was 150 L  
132  $\text{min}^{-1}$ ) was placed on the observatory roof following Global Atmosphere Watch aerosol measurement  
133 guidelines and recommendations. [Two condensation particle counters \(TSI model 3776 CPC and TSI](#)

134 model 3772 CPC) were used to measure the total number concentration of particles larger than 2.5  
135 (corresponding data  $CN_{2.5}$ ) and 10 nm (corresponding data  $CN_{10}$ ) every 1 s, respectively. The aerosol  
136 sample flow rates of TSI model 3776 CPC and TSI model 3772 CPC were 1.5 and 1.0 L min<sup>-1</sup>, respectively.  
137 A nano-scanning mobility particle sizer (nano-SMPS) consisting of a nano-differential mobility analyzer  
138 (nano-DMA) (TSI model 3085, USA) and an ultrafine condensation particle counter (TSI model 3776,  
139 USA) was used to measure the number size distribution of particles from 2.5–64 nm every 3 minutes. The  
140 aerosol flow rate was 1.5 L min<sup>-1</sup> and the sheath flow rate was 15 L min<sup>-1</sup> inside the nano-DMA.

141 The particle number size distribution (from 10–300 nm every 3 min) was measured with a standard-  
142 SMPS consisting of a long DMA (TSI model 3081, USA) and a CPC (TSI model 3772, USA). The aerosol  
143 flow rate was 1.0 L min<sup>-1</sup>, and the sheath flow rate was 10 L min<sup>-1</sup> inside the long DMA. To obtain the  
144 number size distribution of particles from 2.5–300 nm, the nano-SMPS and standard-SMPS were merged.  
145 For particle diameters 2.5–20 nm, nano-SMPS data were chosen because this was optimized to operate  
146 with a smaller particle diameter. In the nano-DMA, the aerosol residence time can be reduced by  
147 shortening the inlet transport passage (5.0 cm) and increasing the inlet flow (up to 16.5 L min<sup>-1</sup>) (< 10 nm)  
148 (Chen et al., 1998). Hence, the number size distribution data from both nano-SMPS and standard-SMPS  
149 were merged at a diameter of 20 nm. Furthermore, three-point median filter and five point moving average  
150 were performed on merging the number size distribution data to remove nano-SMPS noise, as suggested  
151 by Kulmala et al. (2012).

152 The black carbon (BC) concentration was measured using an aethalometer (AE22, Magee Scientific  
153 Co., USA) every 5 min to examine long-range polluted aerosol transport from other continents and to  
154 assess the influence of local pollution from the station. The flow rate through a sharp-cut 2.5 µm cyclone  
155 (BGI, Inc., USA) was set to 5 L min<sup>-1</sup>. The CCN counter (CCNC: CCN-100, Droplet Measurement  
156 Technologies, USA) measured CCN number concentrations at five different supersaturation levels of 0.2%  
157 0.4%, 0.6%, 0.8%, and 1% every 30 minute. The total flow rate in the CCN counter was 0.5 L min<sup>-1</sup>. The  
158 sample and sheath flow rates of the CCN counter were 0.05 and 0.45 L min<sup>-1</sup>, respectively. In addition,  
159 basic meteorological parameters (temperature, pressure, relative humidity (RH), wind speed, wind

160 direction, and solar radiation intensity) were measured using an automatic weather station (Vaisala  
161 HMP45).

162

## 163 **2.2. Data evaluation**

164 As the observatory is located ~400 m southwest of the main station buildings and several kilometers  
165 away from other research stations, measurement data were impacted by local emissions from station  
166 activities (e.g., power generators and incineration) or anthropogenic pollutions near the observatory (e.g.,  
167 plumes from other research station about several kilometers, vessels providing research station supply,  
168 and commercial cruise vessels). To obtain an unperturbed aerosol population of pristine Antarctic  
169 environment, contaminated measurements were removed manually based on wind direction, wind speed,  
170 BC concentration, and total particle number concentration. The following data elimination procedure was  
171 applied: (1) the measurements taken within wind sector of  $355^\circ$  and  $55^\circ$  were discarded as directly  
172 impacted by local pollution sources; (2) relative wind speed below  $2.0 \text{ m s}^{-1}$ , as stagnant conditions would  
173 have facilitated contaminated particle propagation to the measurement location; (3) equivalent BC mass  
174 concentrations exceeding  $50 \text{ ng m}^{-3}$ , because elevated BC concentration unambiguously pointed at  
175 polluted particles; and (4) a sharp increase in the total number concentration over the entire particle  
176 diameter range in a short time scale of less than an hour, as such abrupt peaks and spikes are related to  
177 potential contamination or instrumental malfunctions. For instance, CPC and SMPS data were removed  
178 for time periods when particle number concentrations suddenly increased to more than twice the  
179 background values.

180 Based on a four-year (2016-2019) BC dataset, six types of Antarctic Peninsula air-pollution levels  
181 were identified (Grigas et al., 2017): (1) pristine air with BC concentrations  $< 15 \text{ ng m}^{-3}$ , (2) clean air with  
182 BC levels  $15\text{--}50 \text{ ng m}^{-3}$ , (3) slightly polluted air with BC levels  $50\text{--}100 \text{ ng m}^{-3}$ , (4) moderately polluted  
183 air with BC levels  $100\text{--}300 \text{ ng m}^{-3}$ , (5) polluted air with BC levels  $300\text{--}1000 \text{ ng m}^{-3}$ , and (6) extremely  
184 polluted air with BC concentrations  $> 1000 \text{ ng m}^{-3}$  (Figure 1). Previously, BC data were used as indicators  
185 for local contamination in Antarctica when BC concentration level exceeded  $50 \text{ ng m}^{-3}$  (Herenz et al.,

186 2019) or  $100 \text{ ng m}^{-3}$  (Jang et al., 2018; Kim et al., 2017; Kim et al., 2019; Weller et al., 2011; Weller et  
187 al., 2015). Hara et al. (2019) measured BC concentration at Syowa station Antarctica from February 2005  
188 until December 2016. They found that the daily median BC concentrations were below the detection limit  
189 ( $0.2 \text{ ng m}^{-3}$ ) to  $63.8 \text{ ng m}^{-3}$  at Syowa Station (median,  $1.8 \text{ ng m}^{-3}$ ; mean,  $2.7 \text{ ng m}^{-3}$  during the measurement  
190 period). During the ACE-SPACE expedition, BC concentration reach its background levels of  $19.2 \text{ ng m}^{-3}$   
191 (Schmale et al., 2019). Arctic shipborne-observations measured BC concentration throughout the Arctic  
192 Ocean and Pacific Ocean during the summer of 2017, all pointing to pristine clean marine air masses with  
193 BC values of approximately  $20 \pm 10 \text{ ng m}^{-3}$ . (Park et al., 2020).

194 Of the total time period assessed, pristine air conditions represented 30% (mean value of BC:  $6.00$   
195  $\pm 6.35 \text{ ng m}^{-3}$ ), clean for 44% (mean value of BC:  $29.85 \pm 9.81 \text{ ng m}^{-3}$ ), lightly polluted 19% (mean value  
196 of BC:  $68.78 \pm 13.57 \text{ ng m}^{-3}$ ), moderately polluted 6% (mean value of BC:  $150.43 \pm 47.12 \text{ ng m}^{-3}$ ),  
197 polluted 1% (mean value of BC:  $498.74 \pm 173.87 \text{ ng m}^{-3}$ ), and extremely polluted less than 1% (mean  
198 value of BC:  $1537.41 \pm 595.47 \text{ ng m}^{-3}$ ). Together, pristine and clean air conditions accounted for ~72%  
199 of the time with the remaining 28% ( $\text{BC} > 50 \text{ ng m}^{-3}$ ) removed prior to data analysis.

200

### 201 **2.3. Definition of NPF and growth events**

202 NPF events were visually identified by the particle number size distribution based on the protocol  
203 described by Dal Maso et al. (2005) and Kulmala et al. (2012). Here, these were defined when a distinct  
204 new mode of particles (initially  $< 25 \text{ nm}$ ), appearing in the particle number size distribution at nucleation-  
205 mode size (3–25 nm), prevailed for more than an hour. Using these criteria, the particle size distribution  
206 data showed that in some cases, there was only a short burst of nucleation-mode particles without clearly  
207 discernible particle growth, whereas in other cases, particle formation with subsequent particle growth  
208 lasted for several hours, representing a regional-scale phenomenon (Ström et al., 2009). This enabled us  
209 to determine the particle growth rate (GR), which is not possible during short bursts of nucleation-mode  
210 particles.

211 The particle growth and formation rates along with the condensation sink were calculated from the

212 measured particle number size distribution. The GR was determined using the maximum concentration  
213 and mode-fitting methods (Dal Maso et al., 2005; Yli-Juuti et al., 2009). GR was calculated by a linear fit  
214 through the geometric mean diameter of the nucleation-mode particles as a function of time during NPF.  
215 The formation rate (FR) of nucleation-mode particles ( $J_{3-25}$ ) was calculated by taking into account the  
216 time evolution of the particle number concentration in this size range and particle losses due to the  
217 coagulation sink and condensational growth out of the size range (Kulmala et al., 2012). The surface area  
218 of particles available for the condensation of gaseous molecules can be characterized by a condensation  
219 sink (CS), which determines how rapidly vapor molecules condense onto pre-existing particles (Collins  
220 et al., 2017; Dal Maso et al., 2002).

221

#### 222 **2.4. Backward trajectory analysis and potential source regions**

223 Air mass back trajectories were obtained using the Hybrid Single-Particle Lagrangian Integrated  
224 Trajectory (HYSPLIT) model to investigate their relationships with the physical characteristics of aerosol  
225 particles (Draxler and Hess, 1998). The 2 days air mass back trajectories (48 hours) were determined at  
226 hourly intervals and combined with satellite-derived geographical information to estimate the transport  
227 history of the air masses arriving at the observation site (Jang et al., 2022 and Park et al., 2021). The  
228 potential origins of the aerosols were divided into three categories based on the retention time of the 2  
229 days back trajectories over three major domains: ocean (including the Weddell and Bellingshausen Seas),  
230 sea-ice, and land (including the Antarctic Peninsula). Daily geographical information on ocean, sea-ice,  
231 and land area was obtained from the Sea Ice Index (25 km resolution) provided by the National Snow and  
232 Ice Data Center (NSIDC). The sea-ice zone was defined as the area with a sea-ice coverage >15% (Stroeve  
233 et al., 2016). Air masses that passed over the Weddell and Bellingshausen Sea-regions were categorized  
234 as originating from the ocean (i.e. > 50% retention over the ocean region). The air masses that frequently  
235 advected over the sea-ice region were categorized as originated over the sea-ice (i.e. > 50% retention over  
236 the sea-ice domain). Air masses that traveled through the Antarctic Peninsula were categorized as  
237 originating from the land (i.e. > 50% retention over the land). Finally, the air masses which passed over

238 the ocean, sea-ice, and land regions simultaneously were categorized as originating from the multiple  
239 regions (i.e., 20–40 % retention over each ocean, sea-ice, and land domain).

240 To evaluate the influence of oceanic biological characteristics on NPF properties, the phytoplankton  
241 biomass of the ocean domains was estimated by calculating their chlorophyll concentration from the  
242 Moderate Resolution Imaging Spectroradiometer on the Aqua (MODIS-Aqua) satellite at 4 km resolution  
243 during the entire study period. Phytoplankton produces dimethylsulfoniopropionate (DMSP, a precursor  
244 of gaseous DMS) and other organic vapors all of which are potential precursors to new particle formation.  
245 Thus, the spatiotemporal distribution of sea-surface DMSP could be an indicator of contemporary DMS  
246 emissions. The total DMSP concentration on the sea-surface was estimated using the algorithm developed  
247 by Galí et al. (2015). The algorithm for the total DMSP concentration was based on the satellite-derived  
248 chlorophyll concentration and photosynthetic radiation exposure. To calculate the air mass exposures to  
249 ocean chlorophyll and DMSP (Jang et al., 2019), hourly back trajectory position was combined with  
250 satellite-derived chlorophyll concentration and total DMSP concentration, providing a good measure for  
251 quantitatively investigating the biological exposure history of sampled air over the several days before its  
252 arrival at the observation site (Park et al., 2018 and 2021).

253

## 254 **3. Results and discussion**

### 255 **3.1. General features and annual cycle**

256 We investigated the overall seasonality of particle number size distributions focusing on NPF events.  
257 In addition, local meteorological parameters (e.g., temperature, RH, wind speed, wind direction, pressure,  
258 and solar radiation) and air mass back trajectories were used to support the interpretation of the seasonal  
259 trends of the particle number size distribution and the dynamics of NPF events observed at the station.

#### 260 **3.1.1. Particle number concentrations and size distributions**

261 Figure 2 shows a time series of the one-hour average total particle number concentration and size-  
262 segregated particle number concentrations over the entire measurement period conforming to pristine (BC  
263  $< 15 \text{ ng m}^{-3}$ ) and clean (BC:  $15\text{--}50 \text{ ng m}^{-3}$ ) conditions. [In addition, monthly medians for total number](#)

264 concentration of particles, size-segregated particles number concentration, CCN number concentration at  
265 supersaturation of 0.4%, and meteorological parameters are included in Table 1. The  $CN_{2.5}$  and  $CN_{10}$   
266 ranged from 60 to 3982  $cm^{-3}$  and 30 to 3304  $cm^{-3}$ , respectively. The annual median number concentrations  
267 of particles for the nucleation mode ( $N_{NUC}$ ; 2.5–25 nm in diameter), Aitken mode ( $N_{AIT}$ ; 25–100 nm in  
268 diameter), and accumulation mode ( $N_{ACC}$ ; 100–300 nm in diameter) were 46.8  $cm^{-3}$ , 53.5  $cm^{-3}$ , and 21.7  
269  $cm^{-3}$ , respectively. The highest median  $N_{NUC}$ ,  $N_{AIT}$ , and  $N_{ACC}$  values were recorded in December (193.5  
270  $cm^{-3}$ ), December (227.6  $cm^{-3}$ ), and January (83.8  $cm^{-3}$ ), respectively (Table 1). The lowest  $N_{NUC}$ ,  $N_{AIT}$ ,  
271 and  $N_{ACC}$  values were recorded during austral winter in June – 12.2  $cm^{-3}$ , 12.5  $cm^{-3}$  and 9.2  $cm^{-3}$ ,  
272 respectively. Overall, clear annual and seasonal patterns of particle number concentrations in all size  
273 classes were observed: high concentrations in summer (December–February) and low concentrations in  
274 winter (June–August), similar to those observed at Marambio Station in the Antarctic Peninsula (Asmi et  
275 al, 2018), at coastal Neumayer Station (Weller et al., 2011), at Concordia Station Dome C (Järvinen et al.,  
276 2013), and at Troll Station (Fiebig et al., 2014). Furthermore, the hourly average  $CN_{10}$  value was  
277 positively correlated with the hourly average  $N_{NUC}$  ( $R = 0.88$ ; not shown), implying that the summer  
278 maximum of total particle number concentrations was largely influenced by newly formed particles in the  
279 Antarctic atmosphere.

### 280 3.1.2. Influence of meteorological parameters on NPF events

281 The meteorological parameters after data filtering ( $BC < 50$   $ng\ m^{-3}$  indicating pristine and clean  
282 conditions) were characterized by a solar radiation range of 0–919  $W\ m^{-2}$  (median 10.7  $W\ m^{-2}$ ), a  
283 temperature range of -20–6  $^{\circ}C$  (median -1.2  $^{\circ}C$ ), an RH range of 52–98 % (median 88 %), a pressure  
284 range of 950–1022 hPa (median 988 hPa), a wind speed range of 0.3–21  $m\ sec^{-1}$  (median 7.4  $m\ sec^{-1}$ ),  
285 and wind direction range of 3–357 $^{\circ}$  (median 296 $^{\circ}$ ) (Figure S1). To understand impacts on the particle  
286 number size distributions, we determined the relationships between the size-segregated particle number  
287 concentrations and meteorological parameters (Figure S2).  $CN_{10}$ ,  $N_{NUC}$ ,  $N_{AIT}$ , and  $N_{ACC}$  were positively  
288 correlated with both solar radiation intensity and temperature. In particular,  $N_{NUC}$  had the highest  
289 correlation with solar radiation intensity ( $R = 0.39$ ) of any meteorological condition, suggesting that solar

290 radiation is one of the most important factors influencing NPF events, as it can drive photochemical  
291 reactions leading to the production and further reaction of precursor gases. In contrast, there was a weak  
292 anticorrelation between RH and  $N_{\text{NUC}}$ , supporting the view that NPF occurs preferentially at low RH  
293 (Dada et al., 2017; Hamed et al., 2011; Jeong et al., 2010; Laaksonen et al., 2008). Field observations  
294 have reported that during NPF events, RH was negatively related to the number concentration of freshly  
295 formed particles (Jeong et al., 2004; Lachlan-Cope et al., 2020; Weber et al., 1997) because of the  
296 enhanced coagulation from scavenging effect of sub-3 nm nanoparticles at high RH and the diminished  
297 solar radiation at high RH. Previously, some NPF events were associated with high wind speeds at various  
298 Antarctic stations, such as Neumayer (Weller et al., 2015) and Aboa (Asmi et al., 2010; Virkkula et al.,  
299 2007). These studies found an enhanced particle number concentration  $< 10$  nm during stormy weather  
300 and suggested ion production by frictional processes in fast-moving snow and ice crystals, followed by  
301 subsequent ion-mediated nucleation during strong winds. However, in our study, wind speed was not  
302 correlated with  $N_{\text{NUC}}$  ( $R = -0.18$ ),  $N_{\text{AIT}}$  ( $R = -0.04$ ), or  $N_{\text{ACC}}$  ( $R = -0.05$ ), as recently suggested by Liu et  
303 al. (2018). Our results indicated that wind speed did not affect NPF events. [A possible explanation for the  
304 wind speed independence is that an increase in wind speed contributes to the increase of cluster size ion  
305 number concentrations by friction processes \(Virkkula et al., 2007\), but it was also accompanied by  
306 cloudy conditions.](#) In summary, the elevated  $N_{\text{NUC}}$  values (i.e., indicator of NPF events) at King Sejong  
307 Station were more likely to be accompanied by high solar radiation, high temperature, and low RH,  
308 regardless of wind speed. [Recent studies concluded that Antarctic NPF occurred under combined high  
309 solar radiation, high temperature and low RH conditions, similar to previous study measured at the  
310 Marambio Antarctic research station \(Quéléver et al., 2022\). Quéléver et al. \(2022\) found all NPF events  
311 were observed during the daytime with high solar radiation \(clear-sky conditions\), mostly with above-  
312 freezing temperature and with low RH.](#)

### 313 **3.1.3. Characteristics of NPF events**

314 NPF events in this study were identified based on the size distribution data measured using the  
315 standard-SMPS (Figure 2e) and nano-SMPS (Figure 2f). During the pristine and clean periods

316 (comprising of 355 observation days and 169166 [size distribution spectra](#) for the standard-SMPS, and of  
317 349 observation days and 165259 [size distribution spectra](#) for nano-SMPS), NPF events were frequently  
318 observed at King Sejong Station, as shown by the size distribution data (Figure 2f). 97 events (26% of  
319 observation days) with elevated  $N_{\text{NUC}}$  were observed when taking place in pristine ( $\text{BC} < 15 \text{ ng m}^{-3}$ ) and  
320 clean ( $\text{BC}: 15\text{--}50 \text{ ng m}^{-3}$ ) conditions. Median value of BC concentrations during NPF events was  $21.0 \text{ ng m}^{-3}$ ,  
321 similar to that of whole measurement periods after data filtering (median BC value:  $18.8 \text{ ng m}^{-3}$ )  
322 (section 2.2). This indicated that NPF events are independent of occasional increases of BC during clean  
323 periods. [The NPF events were classified into: \(1\) burst event and \(2\) nucleation with growth event](#)  
324 [according to the classification by Dal Maso et al. \(2005\) as seen in Figure S3. The burst events and](#)  
325 [nucleation with growth events were observed on 1 January 2018 and 16 December 2018, respectively.](#)  
326 NPF events were more frequently observed in summer (~55%) than in any other season (Figure 4), with  
327 the highest frequency in January (22%) and December (22%) followed by spring (September–November,  
328 34%) and autumn (March–May, 11%). Similar results were reported by Järvinen et al. (2013) based on  
329 observations from Dome C and Kim et al. (2019) based on observations from King Sejong Station.  
330 Although Järvinen et al. (2013) reported winter events that occurred in the absence of sunlight, we did  
331 not detect NPF events during austral winter from May through to August.

332 In order to investigate the seasonal characteristics of NPF event, we compared mean size  
333 distributions of aerosol particles for summer, spring (transition period of the melting ocean), and autumn  
334 (transition period of refreezing of the ocean) (Figure S4). Trimodal distributions were presented in all  
335 seasons excepting winter when nucleation mode or particle formation was not observed. For instance, a  
336 trimodal distribution was seen at 7 nm, 30 nm, 122 nm during summer months. The number concentration  
337 of nucleation and Aitken modes were higher than the accumulation modes, indicating that NPF event  
338 regulates the aerosol processes in Antarctic peninsula. The largest mode at 126 nm or 103 nm may be due  
339 to a combination of primary (produced by bubble-bursting process) and secondary (produced by gas-to-  
340 particle conversion process) aerosol components. Results are broadly in line with previous results  
341 published from the Arctic and Antarctic regions. A ship-borne field campaign over Arctic Ocean found a

342 trimodal distribution at 18 nm, 53 nm and 150 nm for open-ocean marine Arctic NPF event (Park et al.,  
343 2020). Lachlan-Cop et al. (2020) presented k-mean cluster analysis of particle size distribution measured  
344 at Halley, Antarctica, showing a nucleation peak at 15 nm for “nucleation” ultrafine category and a  
345 nucleation peak at 27 nm for “bursting” ultrafine category.

346 Air mass back trajectories were calculated at hourly intervals to investigate possible source regions  
347 for the observed NPF events. Figure 2g shows the residence times of air masses over the three domains.  
348 Based on 2-days air mass transport history analysis, air masses allocated to ocean, sea-ice and land  
349 account for 83, 12 and 5%, respectively, during the study period. 97 cases were identified as NPF events,  
350 80 of which were observed when the air mass originated over the ocean domain (Figure 4). 12 NPF events  
351 were observed in air masses originating over the sea-ice domain, while the remaining 5 events were  
352 associated with multi-regional origin (3 cases) and land origin (2 cases). Multi-regional origin indicated  
353 air masses simultaneously influenced by all three domains. Median BC concentration for ocean, sea-ice,  
354 and multiple air masses found to be 23.8 ng m<sup>-3</sup>, 12.7 ng m<sup>-3</sup>, 9.8 ng m<sup>-3</sup>, respectively, (Figure S5),  
355 indicating pristine clean air masses with minimum influence from anthropogenic pollutions during each  
356 NPF event case. Our results indicated that NPF events were more common in air masses originating over  
357 the ocean and sea-ice compared to those originating from the land. Precursors released by both ocean and  
358 sea-ice could play an important role in the formation of new particles in the Antarctic atmosphere.

### 359 **3.1.4. Spatial extension of regional nucleation event**

360 Many previous studies have reported that key steps of the nucleation process (e.g., cluster  
361 stabilization) occur in the size range ~2 nm, in line with recent direct observations of atmospheric  
362 molecular clusters (Kerminen et al., 2018; Kulmala et al., 2013). However, during NPF events, we did  
363 not observe particle formation starting directly from the lower end of the particle size spectrum (2.5 nm),  
364 showing that the formation of freshly nucleated particles could not have actually taken place at the site.  
365 Indeed, the initial diameter of particles that arrived to the measurement site during the NPF ranged from  
366 4 nm to 16 nm (Figure 3a). Median values of NPF event duration (Figure 3b) and growth rate (Figure 3c)  
367 were 4.0 hour and 0.83 nm hr<sup>-1</sup>, respectively. We assumed that they were transported from elsewhere or

368 produced aloft, and detected the appearance of an already grown mode. Consistent with these studies,  
369 NPF events can be a regional-scale phenomenon extending over spatial scales of tens to hundreds of  
370 kilometers in several regions, such as the remote marine boundary layer (Zheng et al., 2021), Canadian  
371 high Arctic (Eureka, Nunavut, on Ellesmere Island in the Canadian Arctic Archipelago) (Tremblay et al.,  
372 2019), and Arctic ship-based observations.

373 Assuming the region is characterized by homogenous meteorological conditions, we estimated the  
374 spatial scale of NPF by multiplying the time during which a distinct nucleation mode can be observed at  
375 the sampling site by the locally measured wind speed (Birmili et al., 2003; Crippa and Pryor, 2013). As  
376 shown in Figure 3d, the spatial extend of NPF event associated with substantial particle growth can be  
377 16–816 km (median value: 155 km), indicating the large-scale NPF events. Weller et al. (2015) measured  
378 size distributions at the coastal Antarctic station Neumayer during two summer campaigns (from 20  
379 January to 26 March 2012 and 1 February to 30 April 2014). They found that the spatial extend of NPF  
380 event was estimated to be around  $170 \pm 85$  km, taking into account the prevailing wind velocity (around  
381  $8 \pm 4$  m s<sup>-1</sup>) and the confined NPF duration (around 6h).

382

### 383 **3.2. Case studies**

384 This section presents a detailed overview of the ocean, sea ice, and multi-regional NPF events.

#### 385 **3.2.1. Marine NPF event**

386 A striking series of NPF events took place over seven days (Figure 6), starting at approximately  
387 00:00 on December 9, 2018. Events starting at midnight can likely indicate their formation few hours  
388 earlier during afternoon sunlight, because the events are observed with an already grown nucleation mode.  
389 Time series of meteorological parameters, air mass origins, oceanic biological activity (estimated by  
390 chlorophyll and DMSP exposures), particle size distribution (measured by nano-SMPS and standard-  
391 SMPS), and CCN concentrations are shown in Figure 6. During this time, the prevailing northerly winds  
392 (median 307 °) were stable at 7.7 m s<sup>-1</sup>. Air temperature varied from -1.5 to 2.1 °C (median 0.5 °C) and  
393 RH varied from 75–97% (median 89 %). There were no data for solar radiation during these events. Air

394 masses predominantly traveled over the Antarctic Ocean (46.9, 0.7, and 0.4 h over ocean, land, and sea  
395 ice, respectively) and could be categorized as originating from the Antarctic Ocean. Specifically, the air  
396 mass originated mainly from Bellingshausen Sea (Figure 5a). During this event, the median total DMSP  
397 and chlorophyll exposures in the surface sea were  $18 \text{ nmol L}^{-1}$  and  $0.26 \text{ mg m}^{-3}$ , respectively.

398 Between 00:00 and 20:00 on December 9,  $N_{\text{NUC}}$  increased from 196 to  $688 \text{ cm}^{-3}$ . At the same time,  
399 CCN concentrations at 0.4 % supersaturation gradually increased from 138 (00:00 on December 0) to  $326$   
400  $\text{cm}^{-3}$  (12:00 on December 11), an increase of 135%. In addition, elevated  $N_{\text{NUC}}$  occurred at 00:00 on  
401 December 13, ranging from 118–522  $\text{cm}^{-3}$ . CCN number concentration at 0.4% supersaturation began to  
402 increase at this time ( $95 \text{ cm}^{-3}$ ) and reached its maximum at 18:00 ( $503 \text{ cm}^{-3}$ ), with a concentration increase  
403 of 431%.

404

### 405 **3.2.2. Sea-ice NPF event**

406 The NPF event with subsequent particle growth were detected from around 19:00 on January 13,  
407 2018, to around 08:00 on January 14, 2018 (Figure 7). Air temperature and RH during the event were  
408  $0.1 \text{ }^{\circ}\text{C}$  and 85%, respectively, while solar radiation decreased from  $131.7$  to  $0.2 \text{ W m}^{-2}$ . Winds were mild  
409 and stable ( $1.9\text{--}5.7 \text{ m sec}^{-1}$ ), with a prevailing northwesterly ( $262\text{--}350^{\circ}$ ) direction and air masses  
410 predominantly coming from sea-ice. The average retention times of the 2 d back trajectories traveling  
411 over ocean, sea-ice, and land were 20.0, 20.9, and 7.1 h, respectively, indicating sea-ice-influenced air  
412 masses (Figure 5b). During the NPF event, both total DMSP and chlorophyll exposure values are stable,  
413 with median exposures of  $13.3 \text{ nmol L}^{-1}$  and  $0.2 \text{ mg m}^{-3}$ , respectively.

414 During the event,  $\text{CN}_{2.5}$  and  $\text{CN}_{10}$  increased to 5669 and 5097  $\text{cm}^{-3}$ , respectively. Furthermore, the  
415 median  $N_{\text{NUC}}$ ,  $N_{\text{AIT}}$ , and  $N_{\text{ACC}}$  values were 508, 376, and 66  $\text{cm}^{-3}$ , respectively. Elevated CCN  
416 concentrations at 0.2 and 0.4 % supersaturations were not observed, whereas CCN concentrations at 0.6,  
417 0.8, and 1.0 % supersaturations slightly increased during the event. For instance, CCN concentration at  
418 0.8 % supersaturation was  $517 \text{ cm}^{-3}$  at 20:00 on January 13, then increased to  $688 \text{ cm}^{-3}$ , until 23:00 on  
419 January 13. The CCN concentration at 0.6, 0.8, and 1.0% supersaturations increased by 11%, 33%, and

420 58%, respectively.

421

### 422 3.2.3. Multiple NPF event

423 An intensive NPF event occurred from November 16 to November 17, 2018 (Figure 8). Air  
424 temperature during the event ranged from -2.5 to -0.1 °C (median -1.3 °C). RH ranged from 70–95%  
425 (median 79%), slightly lower than that for the marine and sea-ice NPF events described above. During  
426 the NPF event observed from 20:00 on November 16 to 02:00 on November 17, solar radiation decreased  
427 from 30 to 0 W m<sup>-2</sup>. This suggested that the NPF event occurred upwind of the measurement site,  
428 especially due to observed grown mode. Wind speed ranged from 4.3–9.5 m s<sup>-1</sup> with a constant direction  
429 from the southwest (median 239 °). Air mass back trajectories showed multiple origins before reaching  
430 the station, passing over ocean (25.7 h, 53% of residence time), sea-ice (12.4 h, 26% of residence time),  
431 and land (10.0 h, 21% of residence time) (Figure 5c). During the event, the median total DMSP and  
432 chlorophyll exposures in the sea surface were 6.0 nmol L<sup>-1</sup> and 0.2 mg m<sup>-3</sup>, respectively.

433 At the start of the event (17:00 on November 16), N<sub>NUC</sub>, N<sub>AIT</sub>, and N<sub>ACC</sub> were 687, 83, and 13 cm<sup>-3</sup>,  
434 respectively. The particle number concentration of the nucleation mode sharply increased to 1610 cm<sup>-3</sup> at  
435 the NPF time, and its peak concentration occurred 7 h after the start of the event (00:00 on November 17),  
436 indicating spatial extent of the formation region. The peak concentration of Aitken mode particles  
437 successively appeared 14 h after the start of the event (07:00 on November 17) and 22 h respectively for  
438 accumulation mode particles (15:00 on November 17). The values in the Aitken and accumulation mode  
439 ranges were 448 and 92 cm<sup>-3</sup>, respectively. We also observed a gradual increase in CCN concentration for  
440 23 h. CCN concentration at 0.4 % supersaturation increased from 78 (17:00 on November 16) to 272 cm<sup>-3</sup>  
441 (15:00 on November 17). This NPF event may have been a source of CCN, which enhanced CCN  
442 concentrations by 248%.

443

### 444 3.3. Influence of air mass origin on the NPF event

### 445 3.3.1. Parameters related to NPF

446 Our results show that NPF and its growth events had largely different features depending on air  
447 mass origin (Figure S6). Although only 3 cases of multi-regional NPF events occurred during the pristine  
448 and clean periods (not included in Figure 9), the most intense NPF event was observed with multi-regional  
449 source region. Here, we compared  $N_{\text{NUC}}$ , FR GR, and CS, for the ocean and sea-ice air masses (Figure 9  
450 a-d). The FR, GR, and CS values agreed well with those reported in previous studies at other Antarctic  
451 sites (Järvinen et al., 2013; Kim et al., 2019; Kyrö et al., 2013; Weller et al., 2015), but significantly lower  
452 than the values reported by the Quéléver et al. (2022), who showed the average FR and GR were  $0.686$   
453  $\text{cm}^{-3} \text{s}^{-1}$  and  $4.2 \text{ nm h}^{-1}$ , respectively. The median  $N_{\text{NUC}}$  and FR values for the ocean air mass ( $N_{\text{NUC}}$ :  $220$   
454  $\text{cm}^{-3}$  and FR:  $1.2 \times 10^{-2} \text{ cm}^{-3} \text{s}^{-1}$ ) were 1.6 and 3.0 times lower than those of sea-ice air mass ( $N_{\text{NUC}}$ :  $343$   
455  $\text{cm}^{-3}$  and FR:  $3.6 \times 10^{-2} \text{ cm}^{-3} \text{s}^{-1}$ ), respectively. This implies that marine NPF events are frequent, but  
456 weak in terms of  $N_{\text{NUC}}$  and FR values. Unlike  $N_{\text{NUC}}$  and FR, there were no marked differences between  
457 the median values of GR and CS by air mass category. The median particle GR values for ocean, sea-ice,  
458 and multiple air masses were 0.8, 0.7, and  $0.9 \text{ nm h}^{-1}$ , respectively. In comparison, Jokinen et al. (2018)  
459 reported that GR values ranged from 0.3 to  $1.3 \text{ nm h}^{-1}$  at Aboa, and Brean et al. (2021) showed GR of 0.4  
460 to  $0.6 \text{ nm h}^{-1}$  measured during the PI-ICE cruise. To examine the effects of oceanic biological activity on  
461 NPF properties, we examined solar radiation intensity, chlorophyll exposure and DMSP exposure for the  
462 three air mass (or source region) categories (Figure 9 e-g). There was no difference in the former, while  
463 the latter two were highest in air masses originating from the ocean. The median chlorophyll exposure in  
464 ocean-influenced air masses ( $0.2 \text{ mg m}^{-3}$ ) was roughly twice that of the sea-ice-influenced air mass ( $0.1$   
465  $\text{mg m}^{-3}$ ). Total DMSP exposure for the ocean-influenced air mass was  $\sim 2.7$  times that of the sea-ice air  
466 mass.

### 467 468 3.3.2. Potential sources facilitating new particle formation

469 Chlorophyll exposure and DMSP exposure were highest during marine NPF events, suggesting a  
470 large chance to carry biologically-derived organic compounds from the open ocean areas to the

471 observation site. DMSP, a metabolite of oceanic phytoplankton, is partly converted into gaseous DMS  
472 through enzymatic cleavage (Simó, 2001), which is the largest natural sulfur source in the atmosphere  
473 (Barnes et al., 2006). Hence, the photooxidation products of biogenic DMS in the Antarctic atmosphere  
474 (e.g., Sulfuric acid and Methane sulfonic acid) could be a major contributor to NPF and its growth when  
475 the air mass originates from the ocean. Jang et al. (2019) reported that NPF events were more frequent in  
476 air masses originating from the Bellingshausen Sea than the Weddell Sea during the biologically  
477 productive austral summer, and it is likely that the taxonomic composition of phytoplankton can be related  
478 to the formation of new particles in the Antarctic Ocean. Biogenic DMS was found to be a precursor of  
479 NPF in coastal Antarctica (Yu and Luo, 2010).

480 Although sea-ice algae bloom underneath the sea-ice cannot be captured by satellite-estimates of  
481 biological activity, the air mass exposure to chlorophyll and DMSP for sea-ice NPF events were 1.8 and  
482 2.7 times lower than those of marine NPF events. This could be explained by volatile iodine compounds  
483 released from ice-covered areas in Antarctica (Jokinen et al.; 2018; Saiz-Lopez et al., 2007; Sipilä et al.,  
484 2016); however, iodine compounds were not measured during our study period. Previously, iodine  
485 compounds were found in large concentrations in and above the sea-ice of the Weddell Sea in Antarctica  
486 during spring and summer (Atkinson et al., 2012). Roscoe et al. (2015) also confirmed that iodine  
487 compounds may contribute to the secondary production of a significant number of particles measured at  
488 Halley and Neumayer on the Antarctic coast.

489 In our study, sea-ice NPF events occurred frequently in January (middle of austral summer) and  
490 September (early austral spring) (Figure 4). We compared the JR, GR, and CS values for the sea-ice NPF  
491 cases observed between January and September (Figure S7) because of their notable differences in ice  
492 coverage. In Antarctica, the minimum ice coverage is observed in February and the maximum in  
493 September (Parkinson and Cavalieri, 2012). Our results showed that JR, GR, and CS values were much  
494 higher in January than in September, indicating different NPF processes. The January events occurred  
495 under low ice-coverage conditions, similar to previous studies from polar areas such as Svalbard  
496 (Dall'Osto et al., 2017) and Greenland (Dall'Osto et al., 2018). Both studies showed that NPF events are

497 related to biogenic precursors released by open water and melting sea-ice regions, particularly during the  
498 summer. In contrast, the September events occurred under high ice-coverage conditions. The monthly  
499 median values of solar radiation showed that solar radiation intensity was very low from May to August  
500 and then started to increase from September (Table 1). During the September events, median solar  
501 radiation intensity was found to be  $63 \text{ W m}^{-2}$ . It is therefore possible that elevated sea-ice concentrations  
502 under sufficient solar radiation around Antarctica lead to an increase in the concentration of halogen  
503 species, resulting in the production of newly formed particles. Solar photooxidation of frozen iodine-  
504 containing solution has been shown to accelerate gas-phase iodine concentrations (Kim et al., 2016).

505 The most intensive NPF event was observed in multiple air masses, although the oceanic biological  
506 activity was lower than that in the oceanic air mass. This indicated that terrestrial sources from continental  
507 Antarctica, in addition to both DMS (mainly from the ocean) and iodine (mainly from sea-ice), may have  
508 contributed to NPF. First, previous studies have reported that precursors emitted from seabird colonies  
509 are linked to NPF (Schmale et al., 2013; Weber et al., 1998). The Chottaebawi area in the southwestern  
510 part of King George Island (around 2 km away from our observation site) is an important penguin colony  
511 in the Antarctic region (Lee et al., 2009), while the cape area near King Sejong Station is abundantly  
512 populated by flying seabirds such as skua. Given the proximity and abundance of seabird colonies at King  
513 Sejong Station, seabird colony emissions are the likely sources of NPF. In fact, 2 NPF events (4 February  
514 2018 for marine air mass origin and 18 February 2018 for multiple air mass origin) were observed when  
515 winds were seen to originate from the south sector where strong emission from the penguin colonies  
516 (southeast sector of  $106\text{--}140^\circ$ ). Figure S8 showed the contour plots of the size distributions and wind  
517 roses during those days. Although we did not directly measure the precursor gases such as ammonia and  
518 amine that can trigger the NPF, we can speculate that the fauna on the land or at the shore such as penguin  
519 and seabird colonies could not be excluded as the potential source of NPF events locally although highly  
520 productive and ice melting Weddell sea is coinciding with southeast direction too. Previous studies  
521 reported that precursor gases for NPF (e.g., ammonia) can originate from the decomposition of excreta  
522 from seabirds and penguins (Lachlan-Cope et al., 2020; Legrand et al., 1998; Liu et al., 2018; Schmale et

523 al., 2013). More recently, Quéléver et al. (2022) proposed that nitrogen-containing species could be land-  
524 sourced (e.g., from a high penguin population during the summertime) or marine-sourced (e.g., from the  
525 biological activity of plankton in the ocean and melting sea ice). The ammonia from seabird-colony guano  
526 is a key factor contributing to bursts of newly formed particles, which are observed in the summertime  
527 Arctic (Croft et al., 2016). Second, biogenic emissions from vegetation in the Antarctic Peninsula, mainly  
528 composed of relatively small and sparse patches of lichens and mosses (Miranda et al., 2020), could be  
529 associated with NPF and growth. Kim et al. (2006) studied plant communities on the Barton Peninsula  
530 around King Sejong Station in the maritime Antarctic and concluded that ~47% of the investigated area  
531 was covered by vegetation although generally sparse. Finally, biogenic precursors from meltwater ponds  
532 in continental Antarctica have also been suggested (Kyrö et al., 2013) as a possible source of aerosol  
533 production (Weller et al., 2018). Overall, our data suggest that complex interconnected ecosystems across  
534 ocean, sea ice, and land can lead to an enhancement in Antarctic NPF.

### 535 **3.3.3. NPF as a source of CCN**

536 For a given SS of 0.4%, the median CCN number concentrations were rather similar 184, 144, and  
537 178 cm<sup>-3</sup> for ocean, sea ice, and multiple air masses, respectively (Figure 9h). The values are in line with  
538 previous studies published from the Antarctic regions. Humphries et al. (2023) reported CCN  
539 concentrations nearby East Antarctic observations from Macquarie Island and Kennaook / Cape Grim as  
540 well as recent ship voyages of the RSV *Aurora Australis* and the RV *Investigator* in the region. The median  
541 CCN value at a SS of 0.5% was in the ranges of 88–145 cm<sup>-3</sup> at Macquarie Island, 57–158 cm<sup>-3</sup> at  
542 Kennaook / Cape Grim, and 40–230 cm<sup>-3</sup> during the voyages (No voyage data exist for the winter months),  
543 respectively. The PCAN project exhibited that a median particle number concentration larger than 3 nm  
544 of 354 cm<sup>-3</sup> was observed from the voyage and median CCN at 0.55 % supersaturation were 167 cm<sup>-3</sup>,  
545 implying approximately half the particles measured as CN<sub>3</sub> could be activated as CCN (Simmons et al.,  
546 2021). Recently, several ship-based measurements over the Southern Ocean found significantly increased  
547 MSA concentrations in air masses originating close to the Antarctic coastline, alongside enhancements in  
548 CCN concentration (Humphries et al., 2021). Of the 83 NPF events, CCN concentrations increased by 2–

268% (median 44%) following 1 to 36 hours (median 8 hours) after NPF events. The median increase in CCN concentrations was 44 %, 34 %, and 107 % for ocean, sea ice, and multiple air masses, respectively. NPF can be an important source of CCN in Antarctica, and the highest CCN enhancement was observed when air masses passed through multiple regions, followed by ocean and sea-ice regions. Moreover, we newly calculated CCN increase rate, which defined as the change rates of representative CCN concentrations ( $CCN_1(t_1)$  and  $CCN_2(t_2)$ ) with the highest CCN concentrations at certain times ( $t_1$  and  $t_2$ ), when elevated CCN concentration was observed during the NPF. The CCN rate varied from 1.4 to 76.7  $cm^{-3} hr^{-1}$ , with a median value of 10.2  $cm^{-3} hr^{-1}$ . Our results provide the first direct evidence of CCN production resulting from an NPF event in the Antarctic atmosphere, based on simultaneous measurements of particle number size distribution (e.g., diameter ranges of 2.5–300 nm) and CCN number concentrations in real time throughout the year.

We also compared CCN activity and critical diameter for the three selected periods (Figure 9i and j). The median values of CCN activity, i.e. the ratio of the number concentration of particles that activated to become CCN at a given supersaturation to the total number concentration or particles larger than 10 nm ( $CN_{10}$ ), were similar (about 5%) in three different air masses. The critical diameter ( $D_c$ ), the diameter at which the integration of aerosol size distribution from the largest particle diameter to the lowest one matches the measured CCN concentration, was determined using the measured aerosol size distribution,  $CN_{10}$ , and CCN concentrations (Furutani et al., 2018). The median  $D_c$  value at 0.4% supersaturation was estimated to be 41 nm, 32 nm, and 37 nm for ocean, sea ice, and multiple air masses, respectively. These results agreed well with those reported in previous studies that determined  $D_c$  at the Finnish Antarctic Research Station, Aboa (Kyrö et al., 2013), a clean subarctic background site (Komppula et al., 2005), and over remote Southern Ocean around Antarctica (Fossum et al., 2018; Fossum et al., 2020). For instance, Kyrö et al. (2013) found the smallest  $D_c$  at 48 nm. The median  $D_c$ , as suggested by Komppula et al. (2005), varied from 50–128 nm (average 80 nm). The  $D_c$  value for maritime polar and marine modified continental Antarctic air masses were 71 and 59 nm, respectively (Fossum et al., 2020).

[A time series of daily mean CCN concentrations at five different supersaturation ratio of 0.2, 0.4,](#)

0.6, 0.8, and 1 was illustrated in Figure S10. To understand the contribution of growing particles on the CCN concentrations during NPF event, we determined the increase in CCN concentration during growth periods (i.e., growth to smaller than 40 nm particles and growth to larger than 40 nm particles) compared to baseline values (black) under different supersaturation conditions (Figure 10), according to the method suggested by Chang et al. (2022). When particle growth was smaller than to 40 nm (growth  $\leq$  40 nm), the mean CCN concentrations increased by 59–178  $\text{cm}^{-3}$  for a SS of 0.2 %–1.0 %, representing a 172.3–216.7 % increase compared to the values during baseline conditions. When particle growth was larger than to 40 nm (growth  $>$  40 nm), the mean CCN concentrations increased by 57–227  $\text{cm}^{-3}$  for a SS of 0.2 %–1.0 %, representing a 169.9–249.1 % increase compared to baseline values. Our results indicate that particles formed from NPF events can lead to the significantly enhanced CCN concentration in Antarctic Peninsula, and this effect is more pronounced if we consider particle growth larger than 40 nm, consistent with ship-based observations (Chang et al., 2022) and aircraft-based observation (Willis et al., 2016) in the Canadian Arctic during summer.

588

#### 589 **4. Conclusions**

590 We measured the number size distribution of 2.5–300 nm particles and CCN number concentrations  
591 at King Sejong Station in the Antarctic Peninsula continuously from January 1 to December 31, 2018.  
592 The annual median values of  $N_{\text{NUC}}$ ,  $N_{\text{AIT}}$ , and  $N_{\text{ACC}}$  were 46.8  $\text{cm}^{-3}$ , 53.5  $\text{cm}^{-3}$ , and 21.7  $\text{cm}^{-3}$ , respectively.  
593 Overall, clear annual and seasonal patterns of particle number concentrations in all size classes were  
594 observed (high concentrations in summer and low concentrations in winter). Furthermore, the monthly  
595  $\text{CN}_{10}$  value was positively correlated with the monthly  $N_{\text{NUC}}$ , implying that summer maximum particle  
596 concentrations could be largely influenced by newly formed particles in the Antarctic atmosphere. Among  
597 meteorological parameters, the elevated  $N_{\text{NUC}}$  values (i.e., indicators of NPF events) were more likely to  
598 be accompanied by high solar radiation, high temperature, and low RH, regardless of wind speed.

599 NPF events were identified based on size distribution data measured using two SMPSs. During the  
600 pristine and clean periods, 97 events (26% of observation days) with elevated  $N_{\text{NUC}}$  were observed. NPF

601 events occurred more frequently in summer than in any other season. Based on air mass back-trajectory  
602 analysis, we distinguished three different types of NPF events: marine (80 cases), sea ice (12 cases), and  
603 multiple (3 cases). Marine NPF events were frequent and weak ( $N_{\text{NUC}}$ ,  $220 \text{ cm}^{-3}$ ;  $\text{FR} = 1.2 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$ ;  
604  $\text{GR} = 0.8 \text{ nm hr}^{-1}$ ) and occurred when the air mass exposure to oceanic phytoplankton was high  
605 (chlorophyll,  $0.2 \text{ mg m}^{-3}$ ; DMSP,  $18 \text{ nmol L}^{-1}$ ). The photooxidation of biogenic DMS in the Antarctic  
606 atmosphere could be a major contributor to marine NPF events. In contrast, sea-ice NPF events ( $N_{\text{NUC}}$ ,  
607  $343 \text{ cm}^{-3}$ ;  $\text{FR}$ ,  $3.6 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$ ;  $\text{GR}$ ,  $0.7 \text{ nm h}^{-1}$ ) were observed when the air mass exposure to oceanic  
608 phytoplankton was relatively low (chlorophyll,  $0.1 \text{ mg m}^{-3}$ ; DMSP,  $7 \text{ nmol L}^{-1}$ ), which may be due to  
609 volatile iodine compounds released from ice-covered areas. Strong NPF events ( $N_{\text{NUC}}$ ,  $516 \text{ cm}^{-3}$ ;  $\text{FR}$ ,  $3.2$   
610  $\times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$ ;  $\text{GR}$ ,  $0.9 \text{ nm hr}^{-1}$ ) were associated with multiple air masses, indicating complex  
611 interconnected ecosystems leading to an enhancement in Antarctic NPF.

612 To investigate the connection between newly formed particles and CCN production, we compared  
613 CCN properties for the three air mass categories. The median CCN number concentrations at a given SS  
614 of 0.4% were 184, 144, and  $178 \text{ cm}^{-3}$  for ocean, sea ice, and multiple air masses, respectively. Of the 83  
615 events, an increase in CCN concentrations after the NPF events was detected, ranging from 2–268 %  
616 (median 44 %). The median increase in CCN concentrations was 44 %, 34 %, and 107 % for ocean, sea  
617 ice, and multiple air masses, respectively. NPF events led to increased CCN concentrations at King Sejong  
618 Station. The median value of  $D_c$  at a supersaturation of 0.4% was estimated to be 41 nm, 32 nm, and 37  
619 nm for ocean, sea ice, and multiple air masses, respectively. This study is the first to report CCN  
620 production resulting from Antarctic NPF events in the Antarctic Peninsula. [However, further detailed](#)

<sup>a</sup> $N_{NUC}$ ,  $N_{AIT}$ , and  $N_{ACC}$  represent the particle number concentrations in the nucleation mode (2.5–25 nm), Aitken mode (25–100 nm), and accumulation mode (100–300 nm).

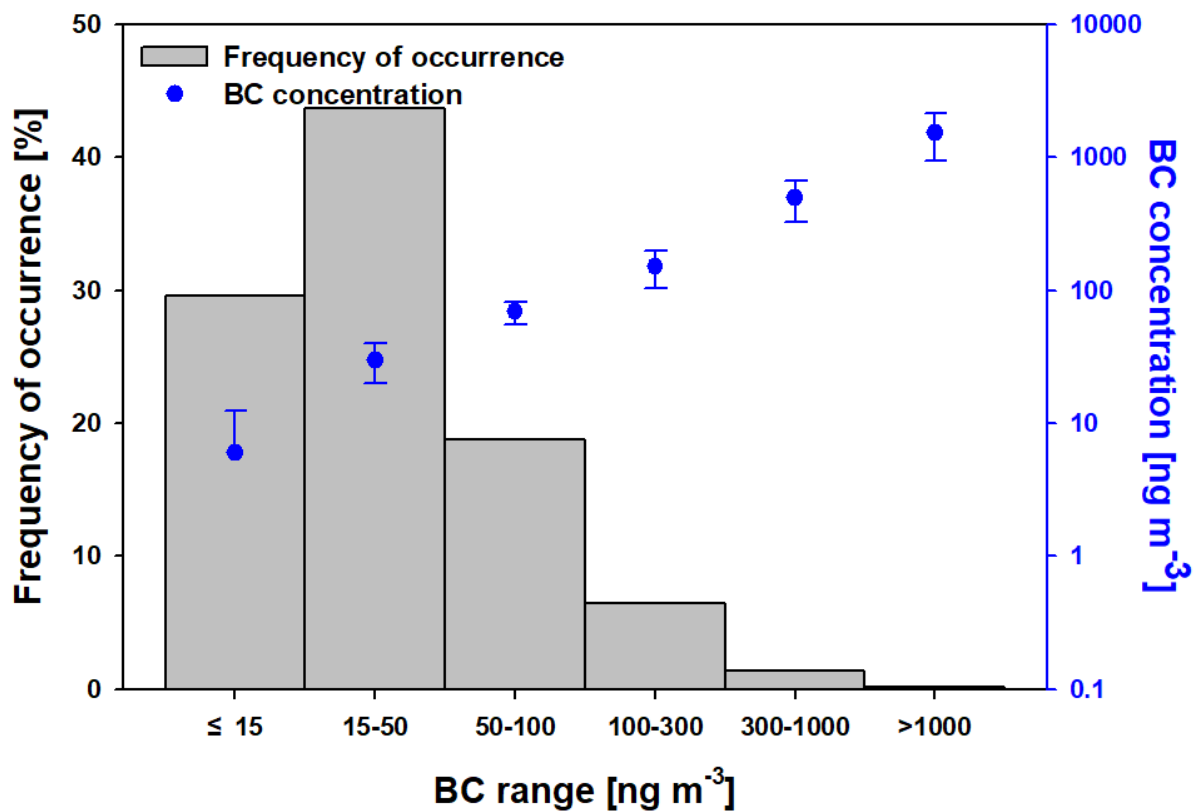

Figure 1. Frequency of occurrence of BC mass concentration for six types of Antarctic Peninsula air-pollution levels classified from four-year BC data.

Figure 2. Time series of 1 h averages for (a)  $CN_{2.5}$  and  $CN_{10}$ , (b) nucleation mode ( $N_{NUC}$ ; 2.5–25 nm), (c) Aitken mode ( $N_{AIT}$ ; 25–100 nm), and (d) accumulation mode ( $N_{ACC}$ ; 100–300 nm); contour plots of the size distributions measured using (e) standard and (f) nano-SMPS; and (g) residence time of air masses passing over ocean, sea ice, and land.  $CN_{2.5}$  data are only available from January to March due to the instrumental malfunctions.

Figure 3. Frequency of (a) initial diameter of particles, (b) duration time, (c) growth rate, and (d) extension for the NPF event. Two NPF cases were excluded when the wind speed was higher than  $10 \text{ ms}^{-1}$ .

Figure 4. Seasonal variations in the number of NPF days by air mass origin.

Figure 5. Air mass back trajectories for arrival at 50 m for the three case study NPF events: (a) marine, (b) sea ice, and (c) multiple.

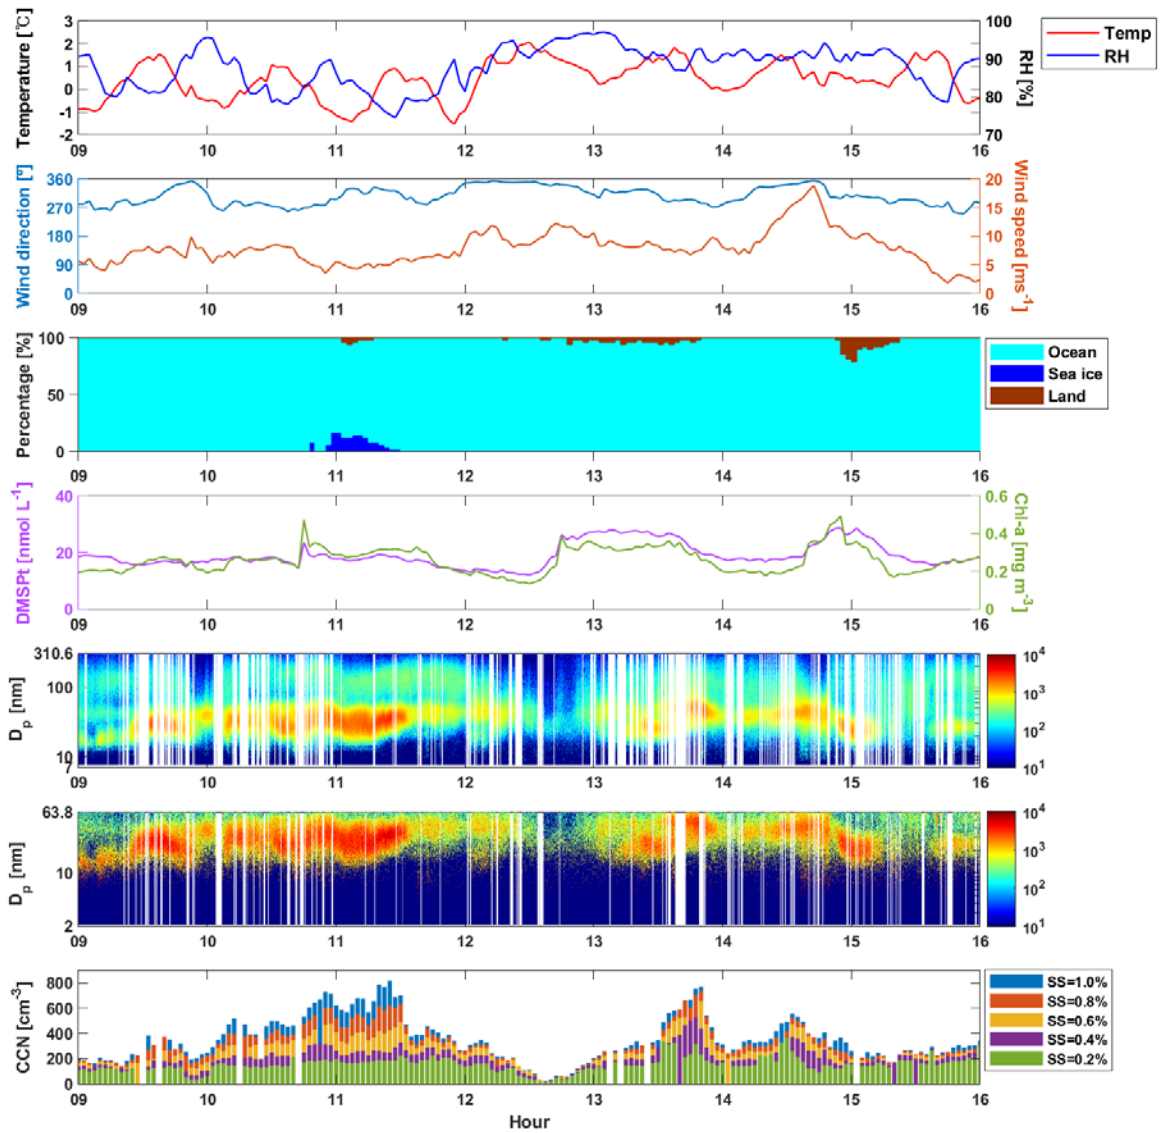

Figure 6. Marine NPF event observed from December 9–15, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration. The x-axis represents local time.

Figure 7. Sea ice NPF event observed from January 13–14, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration. The x-axis represents local time.

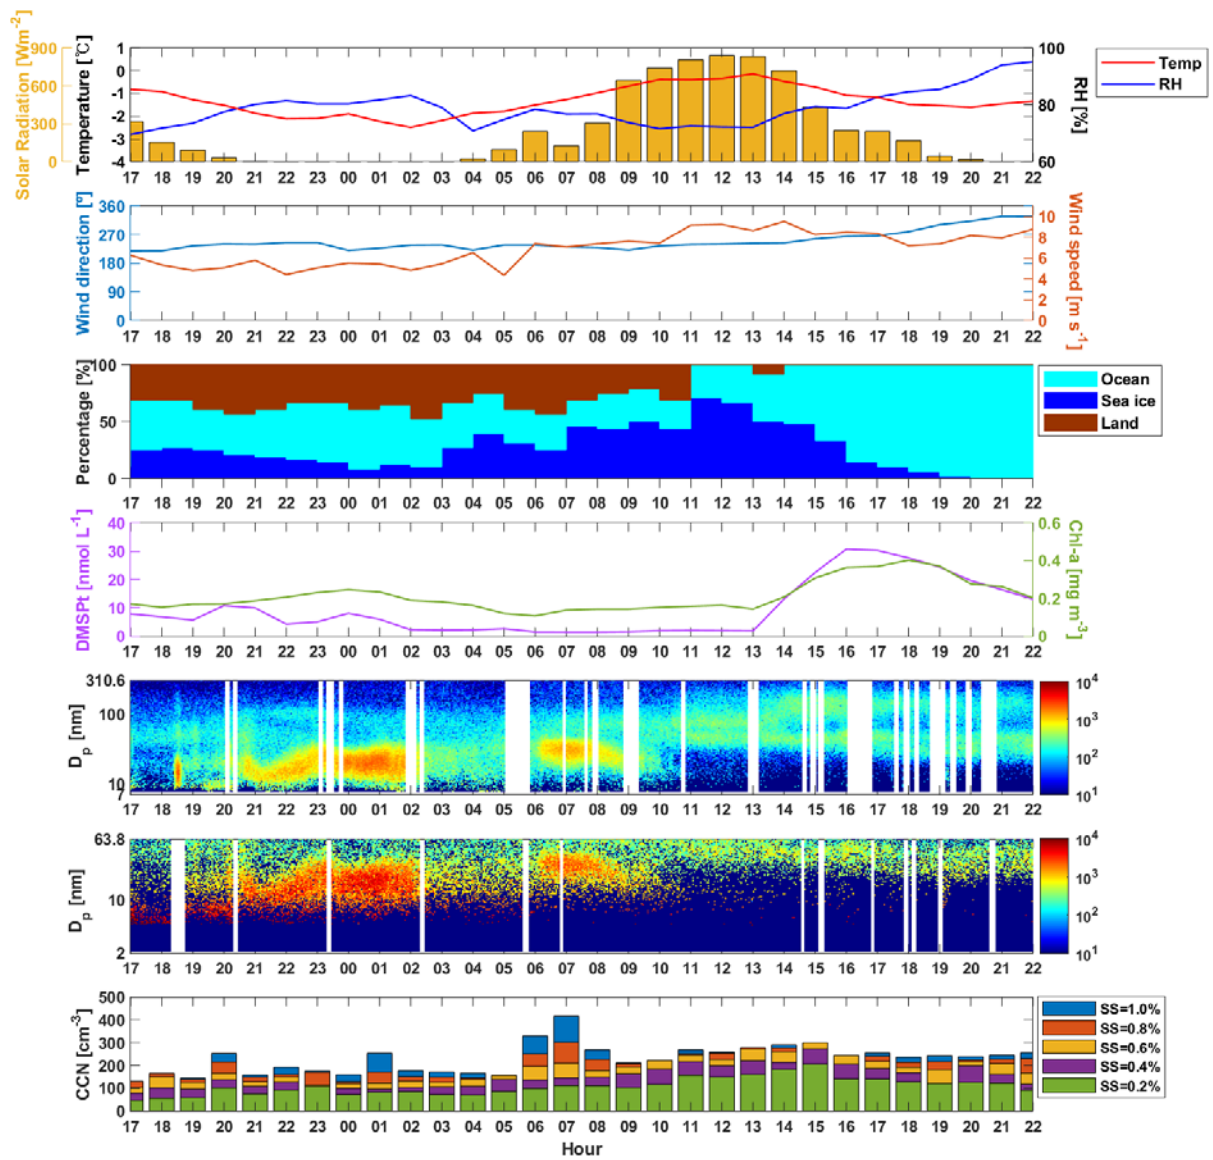

Figure 8. Multiple NPF event observed from November 16–17, 2018. From top to bottom, the plots are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas; number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration. The x-axis represents local time.

Figure 9. Box plots for (a) number concentration of nucleation-mode particles ( $N_{\text{NUC}}$ ), (b) formation rate (FR), (c) growth rate (GR), (d) condensation sink (CS), (e) solar radiation, (f) chlorophyll exposure, (g) DMSP exposure, (h) CCN number concentration, (i) CCN activity, and (j) critical diameter ( $D_c$ ) for ocean, sea ice, and multiple air masses. Upper/lower box limits and solid lines indicate the 75th/25th percentiles and median, respectively.

Figure 10. The increase in CCN concentration during growth to larger than 40 nm particles (green) and smaller than 40 nm (blue) times compared with background times at five different supersaturations.
