13 14 **Abstract**

15 Few studies have investigated the impact of new particle formation (NPF) on cloud condensation
16 nuclei (CCN) in remote Antarctica, and none has elucidated the relationship between NPF and CCN
17 production. To address that knowledge gap, we continuously measured the number size distribution of
18 2.5–300 nm particles and CCN number concentrations at King Sejong Station in the Antarctic Peninsula
19 from January 1 to December 31, 2018. Ninety-seven new particle formation (NPF) events were detected
20 throughout the year. The estimated median spatial scale of NPF around Antarctic peninsula was found to
21 be approximately 155 km, indicating the large-scale of NPF events. Air back-trajectory analysis revealed
22 that 80 cases of NPF events were associated with air masses originating over the ocean, followed by sea
23 ice (12 cases), multiple (3 cases), and land (2 cases) regions. We present and discuss three major NPF
24 categories: (1) marine NPF (2) sea ice NPF, and (3) multiple NPF. Our results showed that the photo-
25 oxidation of oceanic biogenic precursors such as dimethyl sulfide (DMS) could be a key component in
26 marine NPF events, whereas halogen compounds released from ice-covered areas could contribute to sea-
27 ice NPF events. Terrestrial sources (wild life colonies, vegetation, and meltwater ponds) from Antarctica
28 could affect aerosol production in multiple air masses. Out of 97 observed NPF events, 83 cases were
29 characterized by the simultaneous increase in the CCN concentration by 2–270% (median 44%) in the

30 following 1 to 36 hours (median 8 hours) after NPF events. Overall, Antarctic NPF events were found to
31 be a significant source of particles with different physical characteristics and related to biogenic sources
32 in and around the Antarctic Peninsula, which subsequently grew to cloud nuclei.

33

34 **1. Introduction**

35 Antarctic peninsula is warming more rapidly than Earth's global mean rate (Chen et al., 2009;
36 Vaughan et al., 2003), leading to shrinking sea ice coverage and consequent sea-level rise (Pritchard et
37 al., 2009). In the Antarctic region, ambient aerosols play a crucial role in governing radiative transfer,
38 directly by the scattering and absorption of solar radiation and indirectly by acting as cloud condensation
39 nuclei (CCN) (IPCC, 2013). The magnitude of the radiative forcing caused by the interactions between
40 aerosols and CCN remains highly uncertain due to a poor understanding of pristine natural aerosols
41 (Carslaw et al., 2013). To reduce this uncertainty, the physicochemical properties of aerosol particles (e.g.,
42 number concentrations, size distributions, chemical compositions, and hygroscopicity) have been studied
43 at several Antarctic locations including King Sejong Station (Kim et al., 2019), Aboa (Asmi et al., 2010;
44 Virkkula et al., 2006), Dome C (Järvinen et al., 2013), Halley (Lachlan-Cope et al., 2020; O'Dowd et al.,
45 1997), Kohen (Weller et al., 2018), McMurdo (Giordano et al., 2018; Liu et al., 2018), Neumayer (Teinilä
46 et al., 2014; Weller et al., 2015), Princess Elisabeth (Herenz et al., 2019) and Syowa (Hara et al., 2011;
47 Ito, 1993), as well as from shipborne observations (Fossum et al., 2018; Humphries et al., 2015;
48 Humphries et al., 2016). Overall, aerosol particle number concentrations follow a clear annual trend,
49 being much higher in austral summer than in other seasons (Järvinen et al., 2013; Kerminen et al., 2018;
50 Weller et al., 2011). For instance, Kim et al. (2017) found that summertime concentrations in the Antarctic
51 Peninsula were ~20 times higher than in winter. This pattern can be largely explained by new particle
52 formation (NPF) events.

53 Precursor gases for NPF in this region can originate from the ocean, sea ice, meltwater ponds, and
54 terrestrial animal colonies. Oceanic emissions of dimethyl sulfide (DMS) represent the largest natural
55 sulfur source in the Antarctic atmosphere (Simó, 2001), and its photooxidation is a key process

56 contributing to NPF (Giordano et al., 2017; Jang et al., 2019 and 2022). In situ (Saiz-Lopez et al., 2007)
57 and satellite (Schönhardt et al., 2008) measurements have also shown Antarctica to be an iodine emission
58 hotspot, particularly from the sea ice in the Weddell Sea during spring (Atkinson et al., 2012). Dall'Osto
59 et al. (2017) reported that microbiota in sea ice were associated with atmospheric organic nitrogen
60 formation in the Southern Ocean near Antarctica. According to Kyrö et al. (2013), the precursor vapors
61 responsible for NPF and subsequent growth could originate from the cyanobacteria, which are abundant
62 in Antarctic meltwater ponds. In addition, continental Antarctica is a habitat for various types of seabirds
63 and penguins, with guano species acting as a crucial source of ammonia and organic compounds and may
64 contribute to NPF in coastal Antarctic areas (Schmale et al., 2013; Weber et al., 1998; Zhu et al., 2011).

65 In recent years, long-term records of aerosol size distribution have become an important aspect of
66 investigations into the sources and dynamical processes of NPF. The majority of Antarctic field studies
67 have focused on the annual and spatial patterns of the number size distribution of particles > 10 nm (Belosi
68 et al., 2012; Järvinen et al., 2013; Kim et al., 2019; Kyrö et al., 2013; Lachlan-Cope et al., 2020). Although
69 NPF events are typically characterized by a rapid increase in the number concentration of cluster from 1–
70 3 nm (Kulmala et al., 2004), datasets for these types of aerosol size distribution remain rare. To date,
71 number size distribution of particles > 3 nm has been reported by Asmi et al. (2010) at Aboa during from
72 December 29, 2006 to January 29, 2007; by Pant et al. (2011) at Maitri from January 1 to February 28,
73 2015; by Weller et al. (2015) at Neumayer from January 20 to March 26, 2012; by Jokinen et al. (2018)
74 at Aboa from November 2014 to February 2015; and by Weller et al. (2018) at Kohnen during January
75 2015 and 2016. However, all of these measurements were made during the Antarctic summer due to
76 restricted access and, therefore, limited information on seasonal cycles.

77 Newly formed particles can grow into larger sizes that act as CCN, becoming relevant for cloud
78 formation (O'Dowd, 2002; Williamson et al., 2019). In a highly pristine atmosphere such as Antarctica,
79 where CCN concentration is extremely low (Kim et al., 2017), NPF may be a significant phenomenon
80 controlling the CCN budget (Kyrö et al., 2013). For instance, Herenz et al. (2019) showed that an elevated
81 $CN_{2.5}$ (total number concentration of particles > 2.5 nm) during NPF events was accompanied by an

82 increase in CCN concentrations at Princess Elisabeth during austral summer (December to February,
83 2013–2016). In addition, seasonal variability in $CN_{2.5-10}$ (number concentration of particles within the 2.5
84 nm and 10 nm range and attributed to NPF) and CCN concentrations at King Sejong Station from March
85 2009 to December 2016 were investigated by Kim et al. (2019), who concluded that CCN concentrations
86 during NPF events increased by ~11% compared to the background concentration. However, to date, only
87 one study (Kim et al., 2019) has reported the contribution of NPF to CCN in the Antarctic Peninsula, and
88 that study did not consider aerosol number size distribution.

89 In this study, we continuously recorded the number size distribution of 2.5–300 nm particles and
90 CCN number concentrations at King Sejong Station in the Antarctic Peninsula from January 1, 2018, to
91 December 31, 2018. Our primary goals were to (1) characterize the seasonal variation and occurrence of
92 NPF events from the perspective of aerosol physical properties (total number concentration, number size
93 distribution, formation and growth rates, and condensation sink); (2) improve our understanding of the
94 major sources (including open ocean, sea ice, and land) and processes influencing NPF and particle
95 growth; and (3) estimate the contribution of atmospheric NPF to CCN activity in this pristine environment.
96 To our knowledge, this is the first study to present direct evidence of CCN production associated with
97 NPF and growth events in the Antarctic Peninsula, using simultaneous measurements of particle number
98 size distributions (down to 3 nm) and CCN properties for a full year.

99

100 **2. Experimental methods**

101 **2.1. Sampling site and instrumentation**

102 Continuous measurements of the physical properties of aerosol particles were conducted from
103 January 2018 to December 2018 at King Sejong Station in the Antarctic Peninsula (62.22° S, 58.78° W).
104 Full details of the sampling site and measurement setup are given in Kim et al. (2017). In brief, a
105 cylindrical stainless inlet (0.1 m diameter and 5.2 m length; total flow rate of the sampled air was 150 L
106 min^{-1}) was placed on the observatory roof following Global Atmosphere Watch aerosol measurement
107 guidelines and recommendations. Two condensation particle counters (TSI model 3776 CPC and TSI

108 model 3772 CPC) were used to measure the total number concentration of particles every 1 second, with
109 aerosol sample flow rates of 1.5 and 1.0 L min⁻¹, respectively. A nano-scanning mobility particle sizer
110 (nano-SMPS) consisting of a nano-differential mobility analyzer (nano-DMA) (TSI model 3085, USA)
111 and an ultrafine condensation particle counter (TSI model 3776, USA) was used to measure the number
112 size distribution of particles from 2.5–64 nm every 3 minutes. The aerosol flow rate was 1.5 L min⁻¹ and
113 the sheath flow rate was 15 L min⁻¹ inside the nano-DMA.

114 The particle number size distribution (from 10–300 nm every 3 min) was measured with a standard-
115 SMPS consisting of a long DMA (TSI model 3081, USA) and a CPC (TSI model 3772, USA). The aerosol
116 flow rate was 1.0 L min⁻¹, and the sheath flow rate was 10 L min⁻¹ inside the long DMA. To obtain the
117 number size distribution of particles from 2.5–300 nm, the nano-SMPS and standard-SMPS were merged.
118 For particle diameters 2.5–20 nm, nano-SMPS data were chosen because this was optimized to operate
119 with a smaller particle diameter. In the nano-DMA, the aerosol residence time can be reduced by
120 shortening the inlet transport passage (5.0 cm) and increasing the inlet flow (up to 16.5 L min⁻¹) (< 10 nm)
121 (Chen et al., 1998). Hence, the number size distribution data from both nano-SMPS and standard-SMPS
122 were merged at a diameter of 20 nm. Furthermore, three-point median filter and five point moving average
123 were performed on merging the number size distribution data to remove nano-SMPS noise, as suggested
124 by Kulmala et al. (2012).

125 The black carbon (BC) concentration was measured using an aethalometer (AE22, Magee Scientific
126 Co., USA) every 5 min to examine long-range polluted aerosol transport from other continents and to
127 assess the influence of local pollution from the station. The flow rate through a sharp-cut 2.5 µm cyclone
128 (BGI, Inc., USA) was set to 5 L min⁻¹. The CCN counter (CCNC: CCN-100, Droplet Measurement
129 Technologies, USA) measured CCN number concentrations at five different supersaturations (0.2%, 0.4%,
130 0.6%, 0.8%, and 1.0%) every 30 minute. The total flow rate in the CCN counter was 0.5 L min⁻¹. The
131 sample and sheath flow rates of the CCN counter were 0.05 and 0.45 L min⁻¹, respectively. In addition,
132 basic meteorological parameters (temperature, pressure, relative humidity (RH), wind speed, wind
133 direction, and solar radiation intensity) were measured using an automatic weather station (Vaisala

134 HMP45).

135

136 **2.2. Data evaluation**

137 As the observatory is located ~400 m southwest of the main station buildings, measurement data
138 were impacted by local emissions from station activities (e.g., power generators and incineration). To
139 obtain an unperturbed aerosol population of pristine Antarctic environment, contaminated measurements
140 were removed manually based on wind direction, wind speed, BC concentration, and total particle number
141 concentration. The following data elimination procedure was applied: (1) the measurements taken within
142 wind sector of 355° and 55° were discarded as directly impacted by local pollution sources; (2) relative
143 wind speed below 2.0 m s^{-1} , as stagnant conditions would have facilitated contaminated particle
144 propagation to the measurement location; (3) equivalent BC mass concentrations exceeding 50 ng m^{-3} ,
145 because elevated BC concentration unambiguously pointed at polluted particles; and (4) a sharp increase
146 in the total number concentration over the entire particle diameter range in a short time scale of less than
147 an hour, as such abrupt peaks and spikes are related to potential contamination or instrumental
148 malfunctions. For instance, CPC and SMPS data were removed for time periods when particle number
149 concentrations suddenly increased to more than twice the background values.

150 Based on a four-year (2016-2019) BC dataset, six types of Antarctic Peninsula air-pollution levels
151 were identified (Grigas et al., 2017): (1) pristine air with BC concentrations $< 15 \text{ ng m}^{-3}$, (2) clean air with
152 BC levels $15\text{--}50 \text{ ng m}^{-3}$, (3) slightly polluted air with BC levels $50\text{--}100 \text{ ng m}^{-3}$, (4) moderately polluted
153 air with BC levels $100\text{--}300 \text{ ng m}^{-3}$, (5) polluted air with BC levels $300\text{--}1000 \text{ ng m}^{-3}$, and (6) extremely
154 polluted air with BC concentrations $> 1000 \text{ ng m}^{-3}$ (Figure 1). Previously, BC data were used as indicators
155 for local contamination in Antarctica when BC concentration level exceeded 50 ng m^{-3} (Herenz et al.,
156 2019) or 100 ng m^{-3} (Jang et al., 2018; Kim et al., 2017; Kim et al., 2019; Weller et al., 2011; Weller et
157 al., 2015). Several studies have also reported that BC concentrations not exceeding 15 ng m^{-3} were used
158 to reliably exclude anthropogenically impacted air masses over the Northeast Atlantic (Grigas et al., 2017;
159 O'Dowd et al., 2015; Ovadnevaite et al., 2014).

160 Of the total time period assessed, pristine air conditions represented 30% (mean value of BC: 6.00
161 ± 6.35 ng m⁻³), clean for 44% (mean value of BC: 29.85 ± 9.81 ng m⁻³), lightly polluted 19% (mean value
162 of BC: 68.78 ± 13.57 ng m⁻³), moderately polluted 6% (mean value of BC: 150.43 ± 47.12 ng m⁻³),
163 polluted 1% (mean value of BC: 498.74 ± 173.87 ng m⁻³), and extremely polluted less than 1% (mean
164 value of BC: 1537.41 ± 595.47 ng m⁻³). Together, pristine and clean air conditions accounted for ~72%
165 of the time with the remaining 28% (BC > 50 ng m⁻³) removed prior to data analysis. For comparison,
166 mean BC measured at the Mace Head Research Station on the Irish coast from 2009–2014 (Grigas et al.,
167 2017) ranged from 8 ng m⁻³ (pristine) to 1700 ng m⁻³ (extreme), where clean and pristine air conditions
168 accounted for 63% of the total time.

169

170 **2.3. Definition of NPF and growth events**

171 NPF events were visually identified by the particle number size distribution based on the protocol
172 described by Dal Maso et al. (2005) and Kulmala et al. (2012). Here, these were defined when a distinct
173 new mode of particles (initially < 25 nm), appearing in the particle number size distribution at nucleation-
174 mode size (3–25 nm), prevailed for more than an hour. Using these criteria, the particle size distribution
175 data showed that in some cases, there was only a short burst of nucleation-mode particles without clearly
176 discernible particle growth, whereas in other cases, particle formation with subsequent particle growth
177 lasted for several hours, representing a regional-scale phenomenon (Ström et al., 2009). This enabled us
178 to determine the particle growth rate (GR), which is not possible during short bursts of nucleation-mode
179 particles.

180 The particle growth and formation rates along with the condensation sink were calculated from the
181 measured particle number size distribution. The GR was determined using the maximum concentration
182 and mode-fitting methods (Dal Maso et al., 2005; Yli-Juuti et al., 2009). GR was calculated by a linear fit
183 through the geometric mean diameter of the nucleation-mode particles as a function of time during NPF.
184 The formation rate (FR) of nucleation-mode particles (J_{3-25}) was calculated by taking into account the
185 time evolution of the particle number concentration in this size range and particle losses due to the

186 coagulation sink and condensational growth out of the size range (Kulmala et al., 2012). The surface area
187 of particles available for the condensation of gaseous molecules can be characterized by a condensation
188 sink (CS), which determines how rapidly vapor molecules condense onto pre-existing particles (Collins
189 et al., 2017; Dal Maso et al., 2002).

190

191 **2.4. Backward trajectory analysis and potential source regions**

192 Air mass back trajectories were obtained using the Hybrid Single-Particle Lagrangian Integrated
193 Trajectory (HYSPLIT) model to investigate their relationships with the physical characteristics of aerosol
194 particles (Draxler and Hess, 1998). The 2 days air mass back trajectories (48 hours) were determined at
195 hourly intervals and combined with satellite-derived geographical information to estimate the transport
196 history of the air masses arriving at the observation site (Jang et al., 2022 and Park et al., 2021). The
197 potential origins of the aerosols were divided into three categories based on the retention time of the 2
198 days back trajectories over three major domains: ocean (including the Weddell and Bellingshausen Seas),
199 sea ice, and land (including the Antarctic Peninsula). Daily geographical information on ocean, sea ice,
200 and land area was obtained from the Sea Ice Index (25 km resolution) provided by the National Snow and
201 Ice Data Center (NSIDC). The sea ice zone was defined as the area with a sea ice coverage >15% (Stroeve
202 et al., 2016). Air masses that passed over the Weddell and Bellingshausen Sea regions were categorized
203 as originating from the ocean (i.e. > 50% retention over the ocean region). The air masses that frequently
204 advected over the sea-ice region were categorized as originated over the sea ice (i.e. > 50% retention over
205 the sea-ice domain). Air masses that traveled through the Antarctic Peninsula were categorized as
206 originating from the land (i.e. > 50% retention over the land). Finally, the air masses which passed over
207 the ocean, sea ice, and land regions simultaneously were categorized as originating from the multiple
208 regions (i.e., 20–40 % retention over each ocean, sea ice, and land domain).

209 To evaluate the influence of oceanic biological characteristics on NPF properties, the phytoplankton
210 biomass of the ocean domains was estimated by calculating their chlorophyll concentration from the
211 Moderate Resolution Imaging Spectroradiometer on the Aqua (MODIS-Aqua) satellite at 4 km resolution

212 during the entire study period. Phytoplankton produces dimethylsulfoniopropionate (DMSP, a precursor
213 of gaseous DMS) and other organic vapors all of which are potential precursors to new particle formation.
214 Thus, the spatiotemporal distribution of sea-surface DMSP could be an indicator of contemporary DMS
215 emissions. The total DMSP concentration on the sea-surface was estimated using the algorithm developed
216 by Galí et al. (2015). The algorithm for the total DMSP concentration was based on the satellite-derived
217 chlorophyll concentration and photosynthetic radiation exposure. To calculate the air mass exposures to
218 ocean chlorophyll and DMSP (Jang et al., 2019), hourly back trajectory position was combined with
219 satellite-derived chlorophyll concentration and total DMSP concentration, providing a good measure for
220 quantitatively investigating the biological exposure history of sampled air over the several days before its
221 arrival at the observation site (Park et al., 2018 and 2021).

222

223 **3. Results and discussion**

224 **3.1. General features and annual cycle**

225 We investigated the overall seasonality of particle number size distributions focusing on NPF events.
226 In addition, local meteorological parameters (e.g., temperature, RH, wind speed, wind direction, pressure,
227 and solar radiation) and air mass back trajectories were used to support the interpretation of the seasonal
228 trends of the particle number size distribution and the dynamics of NPF events observed at the station.

229 **3.1.1. Particle number concentrations and size distributions**

230 Figure 2 and Table 1 shows a time series of the one-hour average total particle number concentration
231 and size-segregated particle number concentrations over the entire measurement period conforming to
232 pristine ($BC < 15 \text{ ng m}^{-3}$) and clean ($BC: 15\text{--}50 \text{ ng m}^{-3}$) conditions. The total particle number
233 concentrations including ultrafine particles ($CN_{2.5}$; TSI 3776 CPC) and particles larger than 10 nm (CN_{10} ;
234 TSI 3772 TSI) ranged from 60 to 4982 cm^{-3} and 30 to 3304 cm^{-3} , respectively. The annual median number
235 concentrations of particles for the nucleation mode (N_{NUC} ; 3–25 nm in diameter), Aitken mode (N_{AIT} ; 25–
236 100 nm in diameter), and accumulation mode (N_{ACC} ; 100–300 nm in diameter) were 52.4 cm^{-3} , 65.9 cm^{-3} ,
237 21.7 cm^{-3} , respectively. The highest median N_{NUC} , N_{AIT} , and N_{ACC} values were recorded in

238 December (193.5 cm^{-3}), December (227.6 cm^{-3}), and January (83.8 cm^{-3}), respectively (Table 1). The
239 lowest N_{NUC} , N_{AIT} , and N_{ACC} values were recorded during austral winter in June – 12.2 cm^{-3} , 12.5 cm^{-3}
240 and 9.2 cm^{-3} , respectively. Overall, clear annual and seasonal patterns of particle number concentrations
241 in all size classes were observed: high concentrations in summer (December–February) and low
242 concentrations in winter (June–August), similar to those observed at Marambio Station in the Antarctic
243 Peninsula (Asmi et al, 2018), at coastal Neumayer Station (Weller et al., 2011), at Concordia Station
244 Dome C (Järvinen et al., 2013), and at Troll Station (Fiebig et al., 2014). Furthermore, the monthly median
245 CN_{10} value was positively correlated with the monthly median N_{NUC} ($R = 0.78$; not shown), implying that
246 the summer maximum of total particle number concentrations was largely influenced by newly formed
247 particles in the Antarctic atmosphere.

248 The meteorological parameters after data filtering ($\text{BC} < 50 \text{ ng m}^{-3}$ indicating pristine and clean
249 conditions) were characterized by a solar radiation range of $0\text{--}919 \text{ W m}^{-2}$ (median 10.7 W m^{-2}), a
250 temperature range of $-20\text{--}6 \text{ }^{\circ}\text{C}$ (median $-1.2 \text{ }^{\circ}\text{C}$), an RH range of $52\text{--}98 \%$ (median 88%), a pressure
251 range of $950\text{--}1022 \text{ hPa}$ (median 988 hPa), a wind speed range of $0.3\text{--}21 \text{ m sec}^{-1}$ (median 7.4 m sec^{-1}),
252 and wind direction range of $3\text{--}357^{\circ}$ (median 296°) (Figure S1). To understand impacts on the particle
253 number size distributions, we determined the relationships between the size-segregated particle number
254 concentrations and meteorological parameters (Figure S2). CN_{10} , N_{NUC} , N_{AIT} , and N_{ACC} were positively
255 correlated with both solar radiation intensity and temperature. In particular, N_{NUC} had the highest
256 correlation with solar radiation intensity ($R = 0.39$) of any meteorological condition, suggesting that solar
257 radiation is one of the most important factors influencing NPF events, as it can drive photochemical
258 reactions leading to the production and further reaction of precursor gases. In contrast, there was a weak
259 anticorrelation between RH and N_{NUC} , supporting the view that NPF occurs preferentially at low RH
260 (Dada et al., 2017; Hamed et al., 2011; Jeong et al., 2010; Laaksonen et al., 2008). Field observations
261 have reported that during NPF events, RH was negatively related to the number concentration of freshly
262 formed particles (Jeong et al., 2004; Lachlan-Cope et al., 2020; Weber et al., 1997) because of the
263 enhanced coagulation from scavenging effect of sub-3 nm nanoparticles at high RH and the diminished

264 solar radiation at high RH. Previously, some NPF events were associated with high wind speeds at various
265 Antarctic stations, such as Neumayer (Weller et al., 2015) and Aboa (Asmi et al., 2010; Virkkula et al.,
266 2007). These studies found an enhanced particle number concentration < 10 nm during stormy weather
267 and suggested ion production by frictional processes in fast-moving snow and ice crystals, followed by
268 subsequent ion-mediated nucleation during strong winds. However, in our study, wind speed was not
269 correlated with N_{NUC} ($R = -0.18$), N_{AIT} ($R = -0.04$), or N_{ACC} ($R = -0.05$), as recently suggested by Liu et
270 al. (2018). Our results indicated that wind speed did not affect NPF events. A possible explanation for
271 this wind speed independence is that an increase in wind speed contributes to the enhanced emissions of
272 volatile organic compounds from the surface, but it was also accompanied by cloudy conditions. In
273 summary, the elevated N_{NUC} values (i.e., indicator of NPF events) at King Sejong Station were more
274 likely to be accompanied by high solar radiation, high temperature, and low RH, regardless of wind speed.

275 3.1.2. Spatial extension of regional nucleation event

276 NPF events were frequently observed at King Sejong Station, as shown by the size distribution data
277 (Figure 2f). Many previous studies have reported that key steps of the nucleation process (e.g., cluster
278 stabilization) occur in the size range ~ 2 nm, in line with recent direct observations of atmospheric
279 molecular clusters (Kerminen et al., 2018; Kulmala et al., 2013). However, during NPF events, we did
280 not observe particle formation starting directly from the lower end of the particle size spectrum (2.5 nm),
281 showing that the formation of freshly nucleated particles could not have actually taken place at the site.
282 Indeed, the initial diameter of particles that arrived to the measurement site during the NPF ranged from
283 4 nm to 16 nm (Figure 3a). Median values of NPF event duration (Figure 3b) and growth rate (Figure 3c)
284 were 4.0 hour and 0.83 nm hr^{-1} , respectively. We assumed that they were transported from elsewhere or
285 produced aloft, and detected the appearance of an already grown mode. Consistent with these studies,
286 NPF events can be a regional-scale phenomenon extending over spatial scales of tens to hundreds of
287 kilometers in several regions, such as the remote marine boundary layer (Zheng et al., 2021), Canadian
288 high Arctic (Eureka, Nunavut, on Ellesmere Island in the Canadian Arctic Archipelago) (Tremblay et al.,
289 2019), and Arctic ship-based observations.

290 Assuming the region is characterized by homogenous meteorological conditions, we estimated the
291 spatial scale of NPF by multiplying the time during which a distinct nucleation mode can be observed at
292 the sampling site by the locally measured wind speed (Birmili et al., 2003; Crippa and Pryor, 2013). As
293 shown in Figure 3d, the spatial extend of NPF event associated with substantial particle growth can be
294 16–815 km (median value: 155 km), indicating the large-scale NPF events. Weller et al. (2015) measured
295 size distributions at the coastal Antarctic station Neumayer during two summer campaigns (from 20
296 January to 26 March 2012 and 1 February to 30 April 2014). They found that the spatial extend of NPF
297 event was estimated to be around 170 ± 85 km, taking into account the prevailing wind velocity (around
298 8 ± 4 m s⁻¹) and the confined NPF duration (around 6h).

299

300 3.1.3. Characteristics of NPF events

301 NPF events in this study were identified based on the size distribution data measured using the
302 standard-SMPS (Figure 2e) and nano-SMPS (Figure 2f). During the pristine and clean periods
303 (comprising of 355 observation days and 169166 size spectra for the standard-SMPS, and of 349
304 observation days and 165259 size spectra for nano-SMPS), 97 events (26% of observation days) with
305 elevated N_{NUC} were observed when taking place in pristine ($\text{BC} < 15$ ng m⁻³) and clean (BC : 15–50 ng m⁻³)
306 conditions. Median value of BC concentrations during NPF events was 21.0 ng m⁻³, similar to that of
307 whole measurement periods after data filtering (median BC value: 18.8 ng m⁻³) (section 2.2). This
308 indicated that NPF events are independent of occasional increases of BC during clean periods. NPF events
309 were more frequently observed in summer (~55%) than in any other season (Figure 4), with the highest
310 frequency in January (22%) and December (22%) followed by spring (September–November, 34%) and
311 autumn (March–May, 11%). Similar results were reported by Järvinen et al. (2013) based on observations
312 from Dome C and Kim et al. (2019) based on observations from King Sejong Station. Although Järvinen
313 et al. (2013) reported winter events that occurred in the absence of sunlight, we did not detect NPF events
314 during austral winter from May through to August.

315 Air mass back trajectories were calculated at hourly intervals to investigate possible source regions

316 for the observed NPF events. Figure 2g shows the residence times of air masses over the three domains.
317 Based on 2-days air mass transport history analysis, air masses allocated to ocean, sea-ice and land
318 account for 76, 19 and 2%, respectively, during the study period. 97 cases were identified as NPF events,
319 80 of which were observed when the air mass originated over the ocean domain (Figure 4). 12 NPF events
320 were observed in air masses originating over the sea-ice domain, while the remaining 5 events were
321 associated with multi-regional origin (3 cases) and land origin (2 cases). Multi-regional origin indicated
322 air masses simultaneously influenced by all three domains. Our results indicated that NPF events were
323 more common in air masses originating over the ocean and sea ice compared to those originating from
324 the land. Precursors released by both ocean and sea ice could play an important role in the formation of
325 new particles in the Antarctic atmosphere.

326

327 **3.2. Case studies**

328 This section presents a detailed overview of the marine, sea ice, and multi-regional NPF events.

329 **3.2.1. Marine NPF event**

330 A striking series of NPF events took place over seven days (Figure 6), starting at approximately
331 00:00 on December 9, 2018. Events starting at midnight can likely indicate their formation few hours
332 earlier during afternoon sunlight, because the events are observed with an already grown nucleation mode.
333 Time series of meteorological parameters, air mass origins, oceanic biological activity (estimated by
334 chlorophyll and DMSP exposures), particle size distribution (measured by nano-SMPS and standard-
335 SMPS), and CCN concentrations are shown in Figure 6. During this time, the prevailing northerly winds
336 (median 307°) were stable at 7.7 m s^{-1} . Air temperature varied from -1.5 to 2.1°C (median 0.5°C) and
337 RH varied from 75–97% (median 89 %). There were no data for solar radiation during these events. Air
338 masses predominantly traveled over the Antarctic Ocean (46.9, 0.7, and 0.4 h over ocean, land, and sea
339 ice, respectively) and could be categorized as originating from the Antarctic Ocean. Specifically, the air
340 mass originated mainly from Bellingshausen Sea (Figure 5a). During this event, the median total DMSP
341 and chlorophyll exposures in the surface sea were 18 nmol L^{-1} and 0.25 mg m^{-3} , respectively.

342 Between 00:00 and 20:00 on December 9, N_{NUC} increased from 196 to 688 cm^{-3} . At the same time,
343 CCN concentrations at 0.4 % supersaturation gradually increased from 138 (00:00 on December 0) to 326
344 cm^{-3} (12:00 on December 11), an increase of 135%. In addition, elevated N_{NUC} occurred at 00:00 on
345 December 13, ranging from 118–522 cm^{-3} . CCN number concentration at 0.4% supersaturation began to
346 increase at this time (95 cm^{-3}) and reached its maximum at 18:00 (503 cm^{-3}), with a concentration increase
347 of 430%.

348

349 **3.2.2. Sea-ice NPF event**

350 Two NPF events with subsequent particle growth were detected from around 18:00 on January 2,
351 2018, to around 00:00 on January 3, 2018 (Figure 7). Air temperature and RH during the event were -
352 0.2 °C and 81%, respectively, while solar radiation decreased from 211 to 0.0 W m^{-2} . Winds were mild
353 and stable (2.0–4.5 m sec^{-1}), with a prevailing northwesterly (220–330°) direction and air masses
354 predominantly coming from sea ice. The average retention times of the 2 d back trajectories traveling
355 over ocean, sea ice, and land were 13.1, 30.3, and 4.6 h, respectively, indicating sea-ice-influenced air
356 masses (Figure 5b). Both total DMSP and chlorophyll exposure values suddenly increased from 15:00 to
357 17:00 before the NPF event, while during it, they dropped drastically before somewhat stabilizing, with
358 median exposures of 11.8 nmol L^{-1} and 0.2 mg m^{-3} , respectively.

359 During the event, $\text{CN}_{2.5}$ and CN_{10} increased to 3982 and 1534 cm^{-3} , respectively. In addition, the
360 median N_{NUC} , N_{AIT} , and N_{ACC} values were 1148, 286, and 165 cm^{-3} , respectively. Furthermore, elevated
361 CCN concentrations were observed during NPF and growth events. Before the NPF event, CCN
362 concentration at 0.4 % supersaturation was 273.2 cm^{-3} at 17:00 on February 2, then slowly increased to
363 380 cm^{-3} , until 02:00 on February 3. During the NPF event, the CCN concentration increased by 39%.

364

365 **3.2.3. Multiple NPF event**

366 An intensive NPF event occurred from November 16 to November 17, 2018 (Figure 8). Air
367 temperature during the event ranged from -2.5 to -0.1 °C (median -1.3 °C). RH ranged from 70–95%

368 (median 79%), slightly lower than that for the marine and sea-ice NPF events described above. During
369 the NPF event observed from 20:00 on November 16 to 02:00 on November 17, solar radiation decreased
370 from 30 to 0 W m⁻². This suggested that the NPF event occurred upwind of the measurement site,
371 especially due to observed grown mode. Wind speed ranged from 4.3–9.5 m s⁻¹ with a constant direction
372 from the southwest (median 239 °). Air mass back trajectories showed multiple origins before reaching
373 the station, passing over ocean (25.7 h, 53% of residence time), sea ice (12.4 h, 26% of residence time),
374 and land (10.0 h, 21% of residence time) (Figure 5c). During the event, the median total DMSP and
375 chlorophyll exposures in the sea surface were 6.0 nmol L⁻¹ and 0.2 mg m⁻³, respectively.

376 At the start of the event (17:00 on November 16), N_{NUC}, N_{AIT}, and N_{ACC} were 687, 83, and 13 cm⁻³,
377 respectively. The particle number concentration of the nucleation mode sharply increased to 1609 cm⁻³ at
378 the NPF time, and its peak concentration occurred 7 h after the start of the event (00:00 on November 17),
379 indicating spatial extent of the formation region. The peak concentration of Aitken mode particles
380 successively appeared 14 h after the start of the event (07:00 on November 17) and 30 h respectively for
381 accumulation mode particles (23:00 on November 17). The values in the Aitken and accumulation-mode
382 ranges were 91 and 447 cm⁻³, respectively. We also observed a gradual increase in CCN concentration for
383 23 h. CCN concentration at 0.4 % supersaturation increased from 78 (17:00 on November 16) to 272 cm⁻³
384 (23:00 on November 17). This NPF event may have been a source of CCN, which enhanced CCN
385 concentrations by 248%.

386

387 **3.3. Influence of air mass origin on the NPF event**

388 **3.3.1. Parameters related to NPF**

389 Our results show that NPF and its growth events had largely different features depending on air
390 mass origin (Figure S3). Although only 3 cases of multi-regional NPF events occurred during the pristine
391 and clean periods (not included in Figure 9), the most intense NPF event was observed with multi-regional
392 source region. Here, we compared N_{NUC}, FR GR, and CS, for the ocean and sea ice air masses (Figure 9

393 a-d). The FR, GR, and CS values agreed well with those reported in previous studies at other Antarctic
394 sites (Järv et al., 2013; Kim et al., 2019; Kyrö et al., 2013; Weller et al., 2015). The median N_{NUC} and FR
395 values for the ocean air mass (N_{NUC} : 220 cm^{-3} and FR: $1.2 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$) were 1.5 and 2.6 times lower
396 than those of sea ice air mass (N_{NUC} : 343 cm^{-3} and FR: $3.6 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$), respectively. This implies
397 that marine NPF events are frequent, but weak in terms of N_{NUC} and FR values. Unlike N_{NUC} and FR,
398 there were no marked differences between the median values of GR and CS by air mass category. The
399 median particle GR values for ocean, sea ice, and multiple air masses were 0.8, 0.7, and 0.9 nm h^{-1} ,
400 respectively.

401 To examine the effects of oceanic biological activity on NPF properties, we examined solar radiation
402 intensity, chlorophyll exposure, and DMSP exposure for the three air mass (or source region) categories
403 (Figure 9 e-g). There was no difference in the former, while the latter two were highest in air masses
404 originating from the ocean. The median chlorophyll exposure in ocean-influenced air masses (0.2 mg m^{-3})
405 was roughly twice that of the sea-ice-influenced air mass (0.1 mg m^{-3}). Total DMSP exposure for the
406 ocean-influenced air mass was ~ 2.8 times that of the sea-ice air mass.

407

408 3.3.2. Potential sources facilitating new particle formation

409 Chlorophyll exposure and DMSP exposure were highest during marine NPF events, suggesting a
410 large chance to carry biologically-derived organic compounds from the open ocean areas to the
411 observation site. DMSP, a metabolite of oceanic phytoplankton, is partly converted into gaseous DMS
412 through enzymatic cleavage (Simó, 2001), which is the largest natural sulfur source in the atmosphere
413 (Barnes et al., 2006). Hence, the photooxidation of biogenic DMS in the Antarctic atmosphere (i.e.,
414 secondary DMS-derived aerosols) could be a major contributor to NPF and its growth when the air mass
415 originates from the ocean. Jang et al. (2019) reported that NPF events were more frequent in air masses
416 originating from the Bellingshausen Sea than the Weddell Sea during the biologically productive austral
417 summer, and it is likely that the taxonomic composition of phytoplankton can be related to the formation
418 of new particles in the Antarctic Ocean. Biogenic DMS was found to be a precursor of NPF in coastal

419 Antarctica (Yu and Luo, 2010).

420 Although sea-ice algae bloom underneath the sea-ice cannot be captured by satellite-estimates of
421 biological activity, the air mass exposure to chlorophyll and DMSP for sea-ice NPF events were 2.0 and
422 2.8 times lower than those of marine NPF events. This could be explained by volatile iodine compounds
423 released from ice-covered areas in Antarctica (Jokinen et al; 2018; Saiz-Lopez et al., 2007); however,
424 iodine compounds were not measured during our study period. Previously, iodine compounds were found
425 in large concentrations in and above the sea ice of the Weddell Sea in Antarctica during spring and
426 summer (Atkinson et al., 2012). Roscoe et al. (2015) also confirmed that iodine compounds may
427 contribute to the secondary production of a significant number of particles measured at Halley and
428 Neumayer on the Antarctic coast.

429 In our study, sea-ice NPF events occurred frequently in January (middle of austral summer) and
430 September (early austral spring) (Figure 4). We compared the JR, GR, and CS values for the sea-ice NPF
431 cases observed between January and September (Figure S4) because of their notable differences in ice
432 coverage. In Antarctica, the minimum ice coverage is observed in February and the maximum in
433 September (Parkinson and Cavalieri, 2012). Our results showed that JR, GR, and CS values were much
434 higher in January than in September, indicating different NPF processes. The January events occurred
435 under low ice-coverage conditions, similar to previous studies from polar areas such as Svalbard
436 (Dall'Osto et al., 2017) and Greenland (Dall'Osto et al., 2018). Both studies showed that NPF events are
437 related to biogenic precursors released by open water and melting sea-ice regions, particularly during the
438 summer. In contrast, the September events occurred under high ice-coverage conditions. The monthly
439 median values of solar radiation showed that solar radiation intensity was very low from May to August
440 and then started to increase from September (Table 1). During the September events, median solar
441 radiation intensity was found to be 63 Wm^{-2} . It is therefore possible that elevated sea-ice concentrations
442 under sufficient solar radiation around Antarctica lead to an increase in the concentration of halogen
443 species, resulting in the production of newly formed particles. Solar photooxidation of frozen iodine-
444 containing solution has been shown to accelerate gas-phase iodine concentrations (Kim et al., 2016).

445 The most intensive NPF event was observed in multiple air masses, although the oceanic biological
446 activity was lower than that in the oceanic air mass. This indicated that terrestrial sources from continental
447 Antarctica, in addition to both DMS (mainly from the ocean) and iodine (mainly from sea ice), may have
448 contributed to NPF. First, previous studies have reported that precursors emitted from seabird colonies
449 are linked to NPF (Schmale et al., 2013; Weber et al., 1998). The Chottaebawi area in the southwestern
450 part of King George Island (around 2 km away from our observation site) is an important penguin colony
451 in the Antarctic region (Lee et al., 2009), while the cape area near King Sejong Station is abundantly
452 populated by flying seabirds such as skua. Given the proximity and abundance of seabird colonies at King
453 Sejong Station, seabird colony emissions are the likely sources of NPF. Second, biogenic emissions from
454 vegetation in the Antarctic Peninsula, mainly composed of relatively small and sparse patches of lichens
455 and mosses (Miranda et al., 2020), could be associated with NPF and growth. Kim et al. (2006) studied
456 plant communities on the Barton Peninsula around King Sejong Station in the maritime Antarctic and
457 concluded that ~47% of the investigated area was covered by vegetation although generally sparse. Finally,
458 biogenic precursors from meltwater ponds in continental Antarctica have also been suggested (Kyrö et
459 al., 2013) as a possible source of aerosol production (Weller et al., 2018). Overall, our data suggest that
460 complex interconnected ecosystems across ocean, sea ice, and land can lead to an enhancement in
461 Antarctic NPF.

462 **3.3.3. NPF as a source of CCN**

463 For a given SS of 0.4%, the median CCN number concentrations were rather similar 184, 144, and
464 178 cm⁻³ for ocean, sea ice, and multiple air masses, respectively (Figure 9h). Of the 83 NPF events, CCN
465 concentrations increased by 2–268% (median 44%) following 1 to 36 hours (median 8 hours) after NPF
466 events. The median increase in CCN concentrations was 44 %, 34 %, and 107 % for ocean, sea ice, and
467 multiple air masses, respectively. NPF can be an important source of CCN in Antarctica, and the highest
468 CCN enhancement was observed when air masses passed through multiple regions, followed by ocean
469 and sea-ice regions. Moreover, we newly calculated CCN increase rate, which defined as the change rates
470 of representative CCN concentrations (CCN₁(t₁) and CCN₂(t₂)) with the highest CCN concentrations at

471 certain times (t_1 and t_2), when elevated CCN concentration was observed during the NPF. The CCN rate
472 varied from 1.4 to 76.7 $\text{cm}^{-3} \text{hr}^{-1}$, with a median value of 10.2 $\text{cm}^{-3} \text{hr}^{-1}$. Our results provide the first direct
473 evidence of CCN production resulting from an NPF event in the Antarctic atmosphere, based on
474 simultaneous measurements of particle number size distribution (e.g., diameter ranges of 2.5–300 nm)
475 and CCN number concentrations in real time throughout the year.

476 We also compared CCN activity and critical diameter for the three selected periods (Figure 9i and
477 j). The median values of CCN activity, i.e. the ratio of the number concentration of particles that activated
478 to become CCN at a given supersaturation to the total number concentration or particles larger than 10
479 nm (CN_{10}), were similar (about 5%) in three different air masses. The critical diameter (D_c), the diameter
480 at which the integration of aerosol size distribution from the largest particle diameter to the lowest one
481 matches the measured CCN concentration, was determined using the measured aerosol size distribution,
482 CN_{10} , and CCN concentrations (Furutani et al., 2018). The median D_c value at 0.4% supersaturation was
483 estimated to be 41 nm, 32 nm, and 37 nm for ocean, sea ice, and multiple air masses, respectively. These
484 results agreed well with those reported in previous studies that determined D_c at the Finnish Antarctic
485 Research Station, Aboa (Kyrö et al., 2013), a clean subarctic background site (Komppula et al., 2005),
486 and over remote Southern Ocean around Antarctica (Fossum et al., 2018; Fossum et al., 2020). For
487 instance, Kyrö et al. (2013) found the smallest D_c at 48 nm. The median D_c , as suggested by Komppula
488 et al. (2005), varied from 50–128 nm (average 80 nm). The D_c value for maritime polar and marine
489 modified continental Antarctic air masses were 71 and 59 nm, respectively (Fossum et al., 2020).

490

491 **4. Conclusions**

492 We measured the number size distribution of 2.5–300 nm particles and CCN number concentrations
493 at King Sejong Station in the Antarctic Peninsula continuously from January 1 to December 31, 2018.
494 The annual median values of N_{NUC} , N_{AIT} , and N_{ACC} were 52.4 cm^{-3} , 65.9 cm^{-3} , and 21.7 cm^{-3} , respectively.
495 Overall, clear annual and seasonal patterns of particle number concentrations in all size classes were
496 observed (high concentrations in summer and low concentrations in winter). Furthermore, the monthly

497 CN₁₀ value was positively correlated with the monthly N_{NUC}, implying that summer maximum particle
498 concentrations could be largely influenced by newly formed particles in the Antarctic atmosphere. Among
499 meteorological parameters, the elevated N_{NUC} values (i.e., indicators of NPF events) were more likely to
500 be accompanied by high solar radiation, high temperature, and low RH, regardless of wind speed.

501 NPF events were identified based on size distribution data measured using two SMPSs. During the
502 pristine and clean periods, 97 events (26% of observation days) with elevated N_{NUC} were observed. NPF
503 events occurred more frequently in summer than in any other season. Based on air mass back-trajectory
504 analysis, we distinguished three different types of NPF events: marine (80 cases), sea ice (12 cases), and
505 multiple (3 cases). Marine NPF events were frequent and weak (N_{NUC}, 220 cm⁻³; FR = 1.2 × 10⁻² cm⁻³ s⁻¹;
506 GR = 0.8 nm hr⁻¹) and occurred when the air mass exposure to oceanic phytoplankton was high
507 (chlorophyll, 0.2 mg m⁻³; DMSP, 18 nmol L⁻¹). The photooxidation of biogenic DMS in the Antarctic
508 atmosphere could be a major contributor to marine NPF events. In contrast, sea-ice NPF events (N_{NUC},
509 343 cm⁻³; FR, 3.6 × 10⁻² cm⁻³ s⁻¹; GR, 0.7 nm h⁻¹) were observed when the air mass exposure to oceanic
510 phytoplankton was relatively low (chlorophyll, 0.1 mg m⁻³; DMSP, 7 nmol L⁻¹), which may be due to
511 volatile iodine compounds released from ice-covered areas. Strong NPF events (N_{NUC}, 516 cm⁻³; FR, 3.2
512 × 10⁻² cm⁻³ s⁻¹; GR, 0.9 nm hr⁻¹) were associated with multiple air masses, indicating complex
513 interconnected ecosystems leading to an enhancement in Antarctic NPF.

514 To investigate the connection between newly formed particles and CCN production, we compared
515 CCN properties for the three air mass categories. The median CCN number concentrations at a given SS
516 of 0.4% were 184, 144, and 178 cm⁻³ for ocean, sea ice, and multiple air masses, respectively. Of the 83
517 events, an increase in CCN concentrations after the NPF events was detected, ranging from 2–268 %
518 (median 44 %). The median increase in CCN concentrations was 44 %, 34 %, and 107 % for ocean, sea
519 ice, and multiple air masses, respectively. NPF events led to increased CCN concentrations at King Sejong
520 Station. The median value of D_c at a supersaturation of 0.4% was estimated to be 41 nm, 32 nm, and 37
521 nm for ocean, sea ice, and multiple air masses, respectively. This study is the first to report CCN
522 production resulting from NPF events in the Antarctic atmosphere in the Antarctic Peninsula. However,

523 further detailed measurements of the chemical properties of aerosol particles and precursors during NPF
524 events are required to better understand the contribution of these compounds to the formation and growth
525 of aerosol particles and to explore their impacts on CCN formation in the remote Antarctic environment.

526

527 **Data availability**

528 The data analyzed in this publication will be readily provided upon request to the corresponding author
529 (yjyoon@kopri.re.kr).

530

531 **Author contributions**

532 JP and YJY designed the study. JP, HK, YG, EJ, K-TP, SP, and YJY analyzed data. JP wrote the
533 manuscript. CHJ, DC, and CO'D all commented on and discussed the manuscript.

534

535 **Competing interests**

536 The authors declare that they have no conflict of interest.

537

538 **Acknowledgments**

539 We would like to thank the many technicians and scientists of the overwintering crews. This work was
540 supported by the KOPRI project (PE23030).

^a N_{NUC} , N_{AIT} , and N_{ACC} represent the particle number concentrations in the nucleation mode (3–25 nm), Aitken mode (25–100 nm), and accumulation mode (100–300 nm).

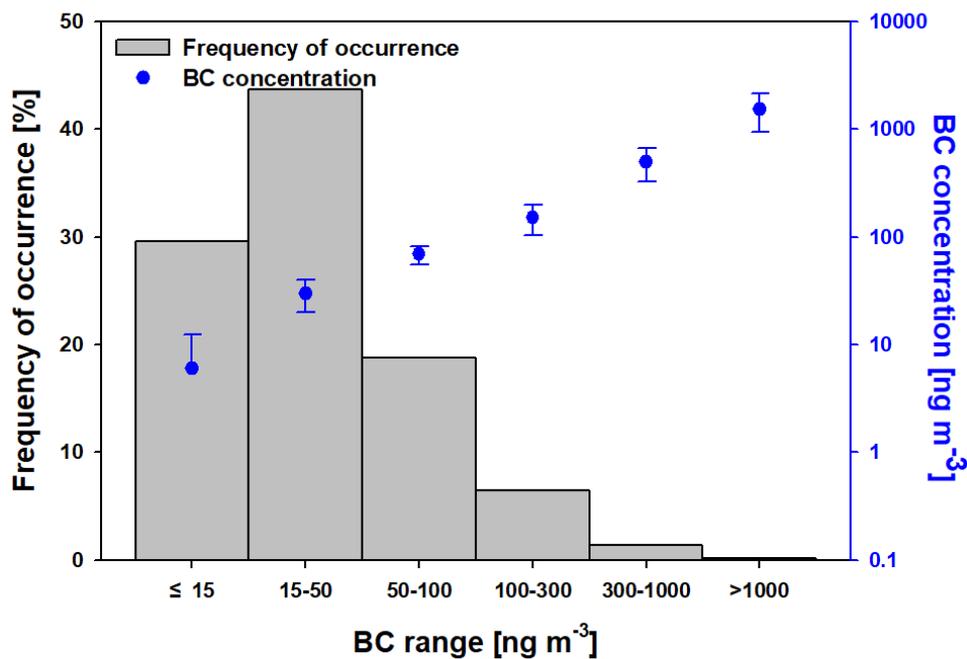

Figure 1. Frequency of occurrence of BC mass concentration for six types of Antarctic Peninsula air-pollution levels classified from four-year BC data.

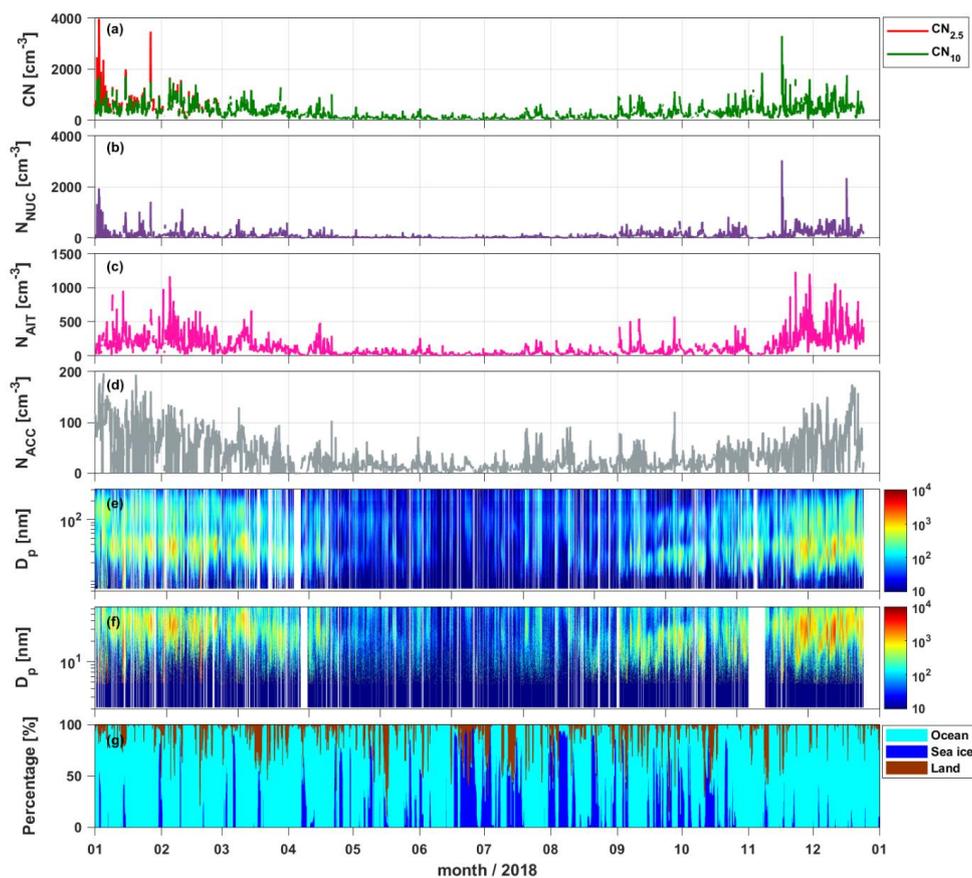

Figure 2. Time series of 1 h averages for (a) total aerosol (CN_{2.5} and CN₁₀), (b) nucleation mode (N_{NUC}; 3–25 nm), (c) Aitken mode (N_{AIT}; 25–100 nm), and (d) accumulation mode (N_{ACC}; 100–300 nm); contour plots of the size distributions measured using (e) standard and (f) nano-SMPS; and (g) residence time of air masses passing over ocean, sea ice, and land. CN_{2.5} and CN₁₀ represent total number concentration of particles > 2.5 (measured using TSI 3776 CPC) and 10 nm (measured using TSI 3772 CPC), respectively.

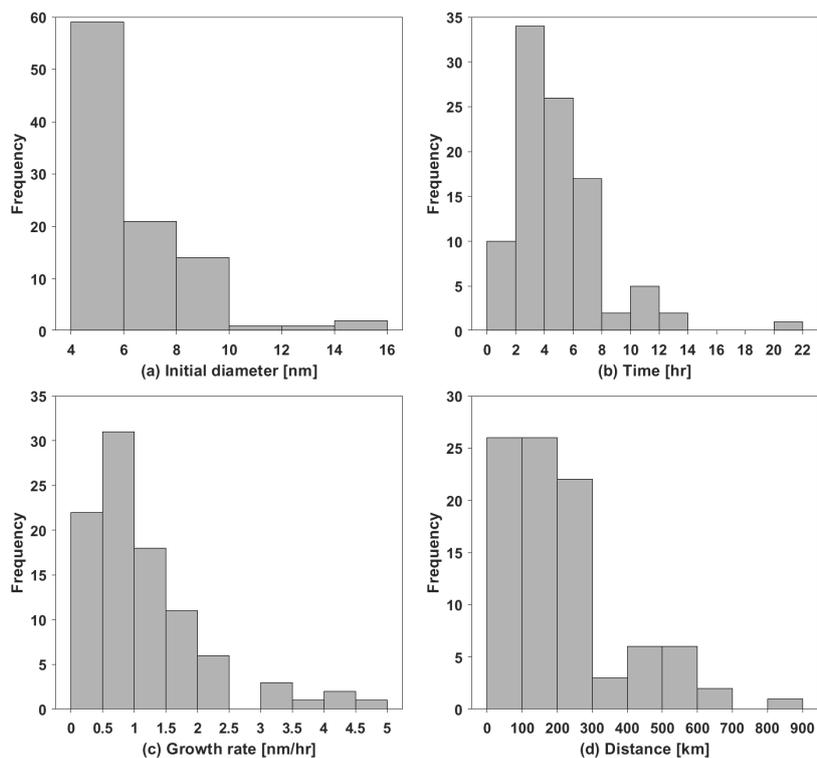

Figure 3. Frequency of (a) initial diameter of particles, (b) duration time, (c) growth rate, and (d) extension for the NPF event. Two NPF cases were excluded when the wind speed was higher than 10 ms^{-1} .

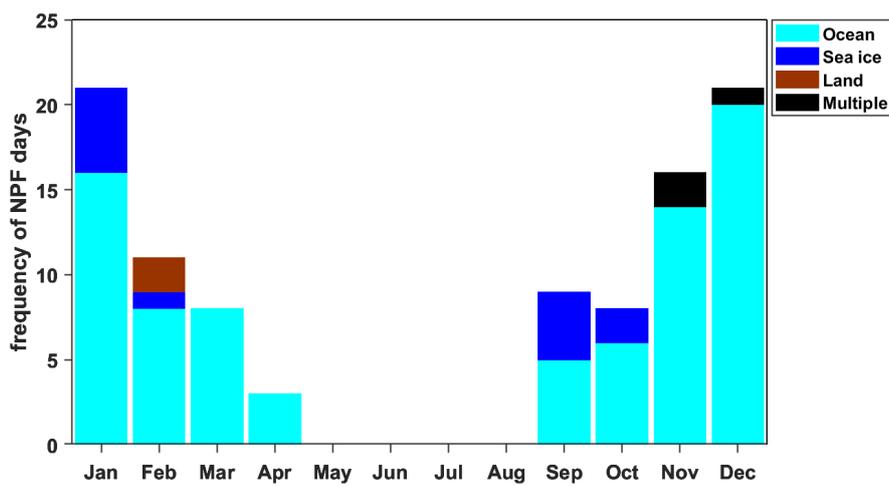

Figure 4. Seasonal variations in the number of NPF days by air mass origin.

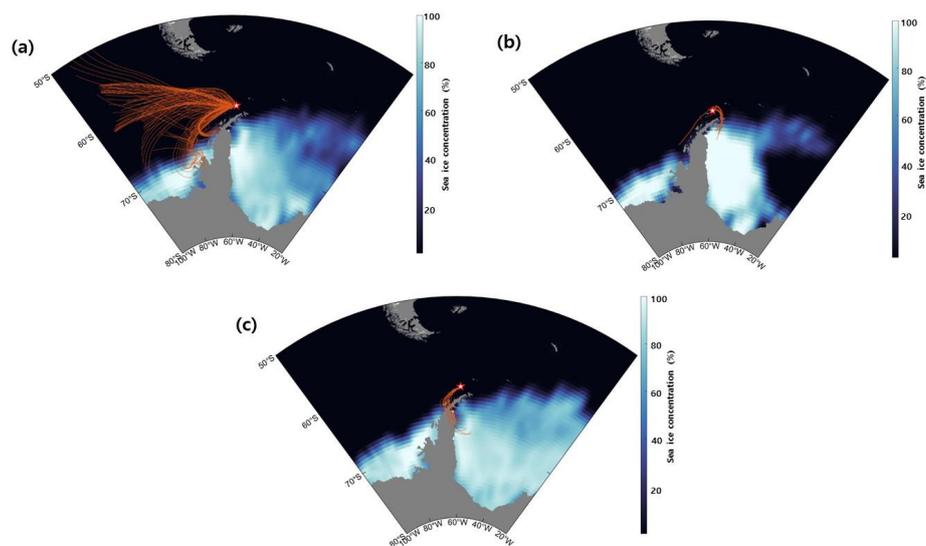

Figure 5. Air mass back trajectories for arrival at 50 m for the four case study NPF events: (a) marine, (b) sea ice, and (c) multiple.

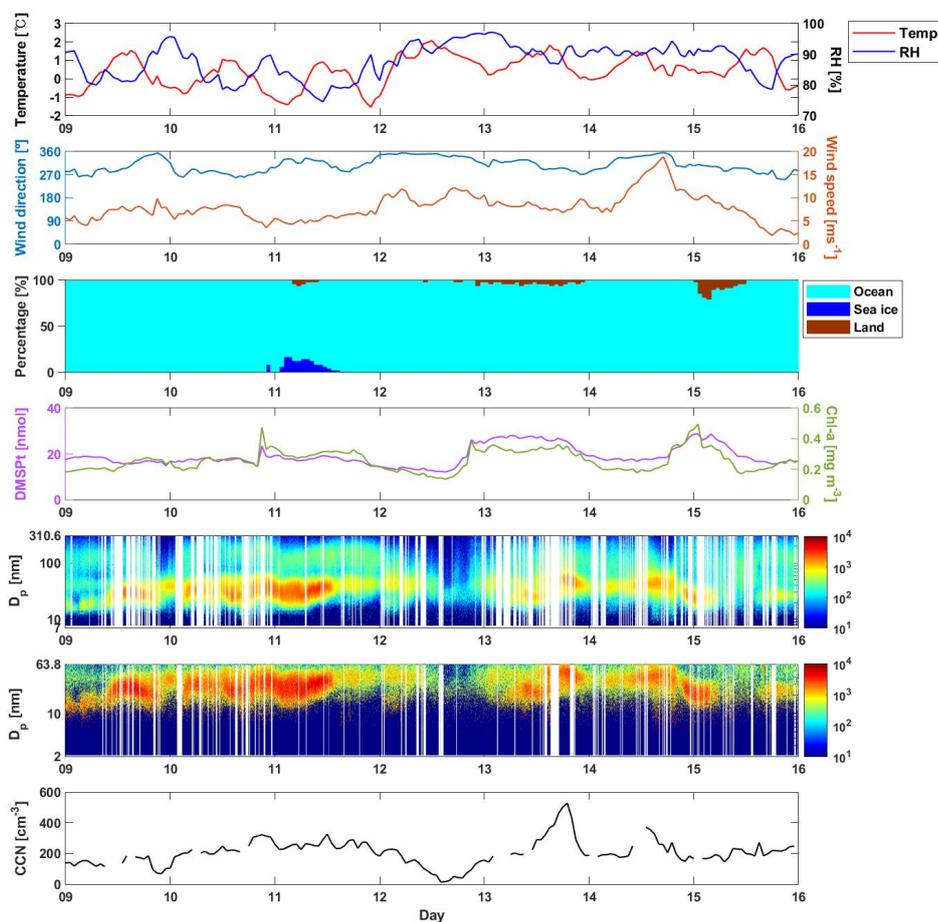

Figure 6. Marine NPF event observed from December 9–15, 2018. From top to bottom, the parameters are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas, number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration.

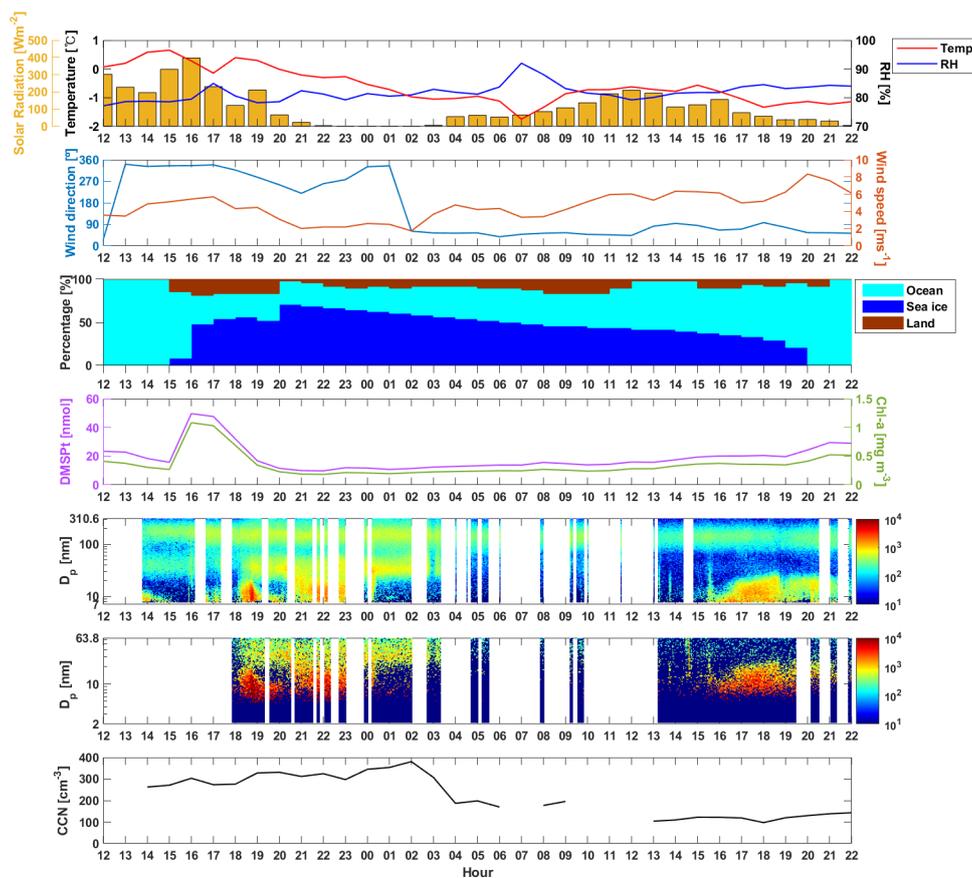

Figure 7. Sea ice NPF event observed from January 2–3, 2018. From top to bottom, the parameters are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas, number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration.

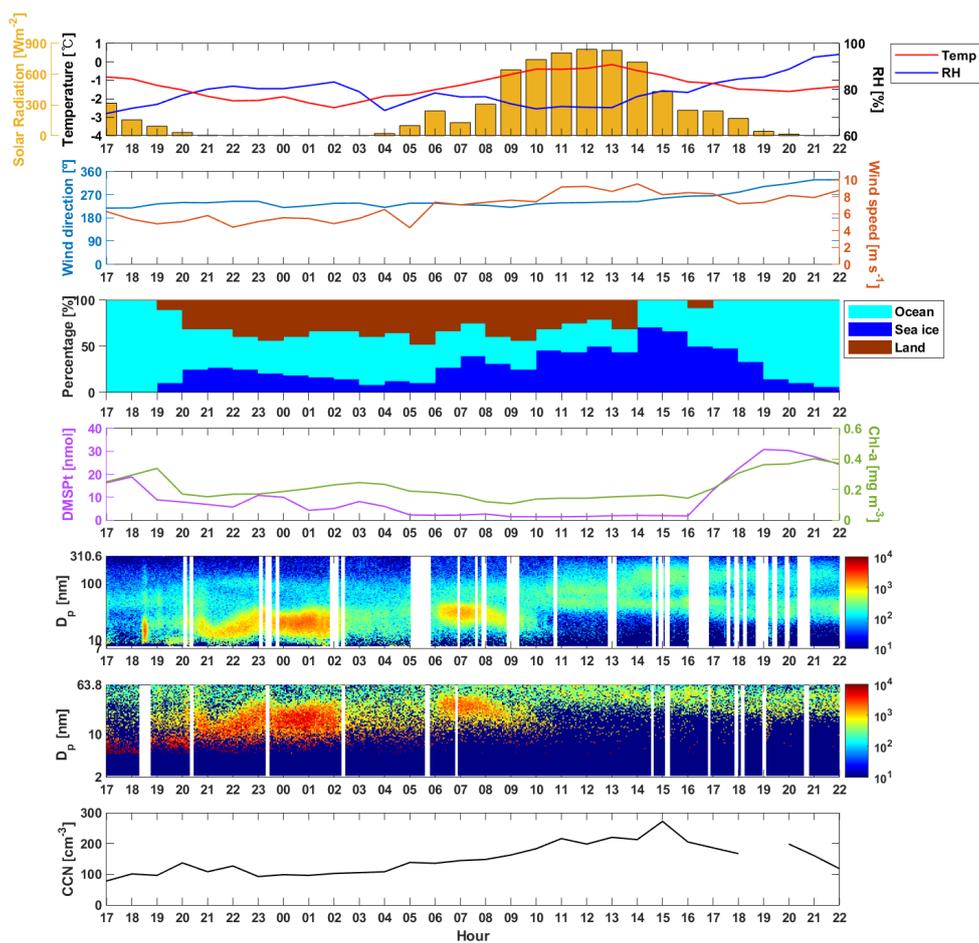

Figure 8. Multiple NPF event observed from November 16–17, 2018. From top to bottom, the parameters are as follows: meteorological variables, the residence time of air masses that passed over the ocean, sea ice and land areas, number size distribution with the standard-SMPS and nano-SMPS, and CCN number concentration.

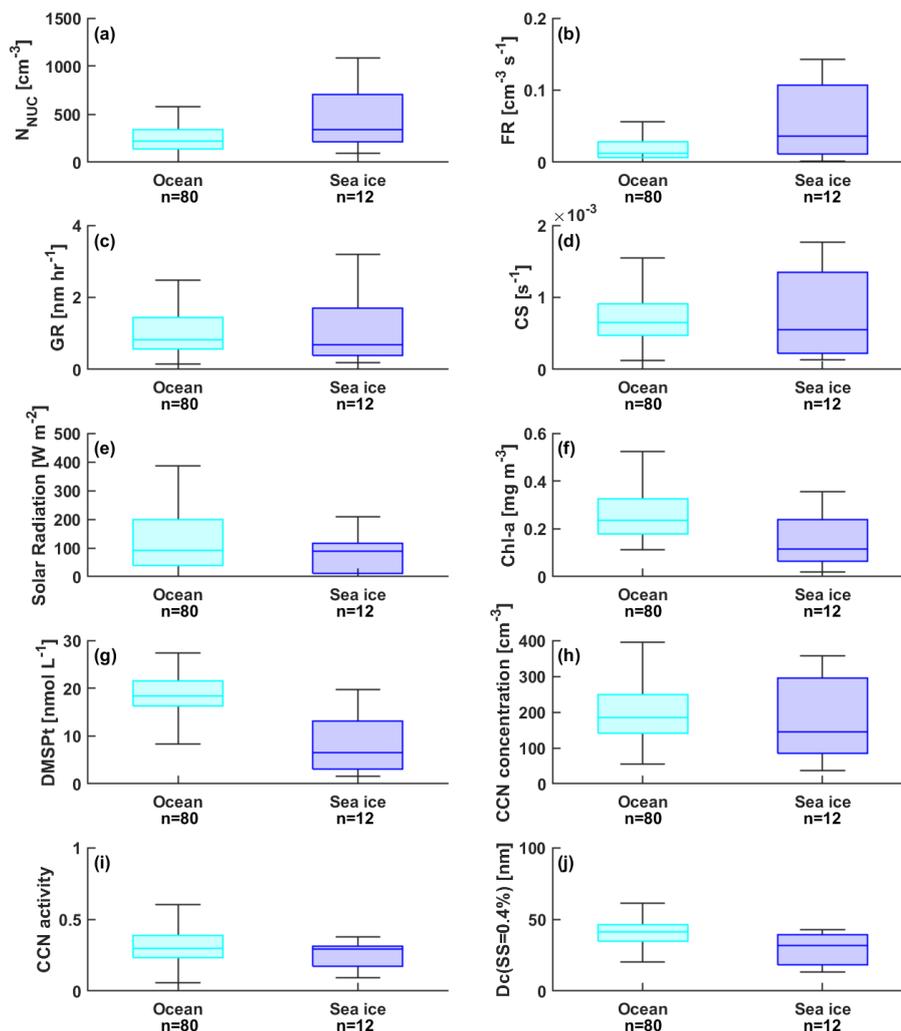

Figure 9. Box plots for (a) number concentration of nucleation-mode particles (N_{NUC}), (b) formation rate for, (c) growth rate (GR), (d) condensation sink (CS), (e) solar radiation, (f) chlorophyll exposure, (g) DMSPt exposure, (h) CCN number concentration, (i) CCN activity, and (j) critical diameter (D_c) for ocean, sea ice, and multiple air masses. Upper/lower box limits and solid lines indicate the 75th/25th percentiles and median, respectively.
