16 **Abstract.** Carbon monoxide (CO) concentrations in the troposphere are decreasing globally, with Africa as an  
17 exception. Yet, the region is understudied, with a deficit of ground-based observations and highly uncertain CO  
18 emission inventories. This paper reports multi-year observational CO data from the Mt. Kenya Global Atmosphere  
19 Watch (GAW) station, as well as summertime CO isotope observations from both Mt. Kenya and Nairobi, Kenya.  
20 The CO variability at Mt. Kenya is characterized by slightly increased concentrations during dry periods and a  
21 strong influence of short-term pollution events. While some data gaps and differences in instrumentation  
22 complicate decadal-scale trend analysis, a small long-term increase is resolved. High pollution events are  
23 consistent with isotopic signal from downwind savanna fires. The isotope fingerprint of CO in Nairobi indicate an  
24 overwhelming dominance (near 100 %) of primary emissions from fossil fuel combustion with implications for  
25 air pollution policy. In contrast, the isotope signature of CO intercepted at the large footprint Mt. Kenya region  
26 suggests at least 70 % primary sourced, with a predominance likely from, savanna fires in Africa. Taken together,  
27 this study provides quantitative constraints of primary vs secondary CO in the eastern Africa region and in urban  
28 Nairobi, with implications for satellite-based emission inventories as well as for chemical-transport and climate-  
29 modelling.

## 30 1. Introduction

31 Carbon monoxide (CO) is the dominant sink for the hydroxyl radical (OH), accounting for over 50% consumption  
32 of OH in the atmosphere (Lelieveld et al., 2016). It therefore influences the atmosphere's oxidation and cleansing  
33 capacity and, by extension, chemically regulates the atmospheric lifetime and abundance of other reactive gases  
34 such as methane and halocarbons (Lelieveld et al., 2016; Zheng et al., 2019). As such, CO is an indirect greenhouse  
35 gas with a net positive warming effect on climate (Szopa et al., 2021). In addition to climate effects, CO is a  
36 precursor to the formation of ground-level ozone, with implications for human health (Chen et al., 2021; WHO,  
37 2016; Zhang et al., 2019). Anthropogenic activities such as biomass burning and fossil fuel combustion are  
38 important contributors to the global CO budget, in addition to atmospheric reactions, e.g., oxidation of  
39 hydrocarbons (Duncan et al., 2007; Zheng et al., 2019). However, the CO source contributions, mole fractions,  
40 and atmospheric residence time are spatially variable, complicating the source-sink assessment.

41 Global CO levels have been declining over the past two decades, but Africa is an exception. The key source of  
42 information on CO trends in the African region is satellite-based observations that show an increase in CO mole  
43 fractions (Buchholz et al., 2021; Hedelius et al., 2021; Zheng et al., 2019). However, the ground-truthing of the  
44 satellite observations is challenged by a deficit of atmospheric observatories and scant continuous long-term  
45 observations in the region (DeWitt et al., 2019; Henne et al., 2008b; Kulmala, 2018). Exacerbating this  
46 observational deficit, regional CO emission inventories are not well-defined as the continent possesses a unique  
47 CO emission profile, different from other regions such as Europe and South Asia (Crippa et al., 2018; Dasari et  
48 al., 2021; Hedelius et al., 2021). To advance our understanding of trends in CO over Africa and its source  
49 contributions, long-term CO measurements and isotope-based source apportionment studies are required but data  
50 availability is scarce.

51 The isotopic composition of CO provides insights into the relative strengths of regional CO sources and  
52 atmospheric processing (Brenninkmeijer, 1993; Dasari et al., 2021; Henne et al., 2008b; Röckmann et al., 2002).  
53 A particular source of CO possesses a characteristic isotopic signature, with the isotopic composition of the  
54 ambient CO reflecting that of the combined sources, sinks, and atmospheric ageing (Brenninkmeijer and  
55 Röckmann, 1997; Dasari et al., 2021; Popa et al., 2014; Röckmann et al., 1998, 2002). For example, CO from  
56 primary sources (fossil combustion and biomass burning) has a more enriched  $\delta^{18}\text{O}$  signature (above +12 ‰)  
57 compared to that of secondary-formed CO, e.g., from oxidation of  $\text{CH}_4$  (at ~0 ‰) and non-methane hydrocarbons  
58 (NMHC), at  $\sim 2.4 \pm 2.4$  ‰ (Brenninkmeijer and Röckmann, 1997).

59 Additional source information can be obtained from the  $\delta^{13}\text{C}$  signatures. CO formed from methane oxidation is  
60 strongly depleted in  $^{13}\text{C}$  ( $\delta^{13}\text{C} = -51.9 \pm 1.6$ ‰) in contrast to, for example, CO emitted from burning of  $\text{C}_4$  plants  
61 ( $\delta^{13}\text{C} = -14.0 \pm 3.8$ ‰),  $\text{C}_3$  plants ( $\delta^{13}\text{C} = -26.9 \pm 4.9$ ‰) or fossil combustion at  $-27.8 \pm 1.5$ ‰ (Brenninkmeijer  
62 et al., 1999). However, the kinetic isotope effect (KIE) during the CO-OH reaction (the main atmospheric CO  
63 removal mechanism) results in the enrichment of  $\delta^{13}\text{C}$  by 4-5 ‰ and more depleted  $\delta^{18}\text{O}$  signatures (by ~10 ‰)  
64 in the lower troposphere (Brenninkmeijer et al., 1999; Röckmann et al., 1998). Overall, isotope forensics can  
65 provide valuable data on CO emissions in remote and urban locations in Africa, especially considering that the  
66 region is largely understudied, with very few ground-based CO observations and highly uncertain emission  
67 inventories.

68 This study investigates the long-term trends in CO mole fractions at Mt. Kenya GAW station, a high-altitude  
69 monitoring site in equatorial East Africa well suited to intercept the regional emission footprint. Online CO mole  
70 fractions measurements have been going on at the observatory since 2002, albeit with large data gaps due to  
71 technical challenges. Flask-based measurements carried out at Mt. Kenya at different periods by NOAA (2003-  
72 2011) were used for gap filling. The online and NOAA flask-measured CO data were obtained from the WMO's  
73 World Data Centre for Greenhouse Gases (WDCGG) database. After the CO measurements from Cape Point,  
74 South Africa, this is likely the longest-running data available in sub-Saharan Africa and provides observational  
75 constraints of the region's long-term trend in CO. The present study additionally provides stable isotope  
76 composition data of CO to resolve source attribution of the observed higher summertime CO amount fraction.  
77 Furthermore, the data are compared to previously obtained and unpublished isotope data from Mt. Kenya (1996-  
78 1997; earlier unpublished work by Röckmann and Brenninkmeijer) and that of an urban site in Nairobi in summer  
79 2021 to provide further insights into regional CO sources. This dataset is unprecedented in the region and facilitates  
80 improved understanding of the regional CO emission trends and source attribution.

## 81 **2. Methodology**

### 82 **2.1 Measurement sites**

83 Ambient air sampling was conducted at a remote mountain site, the Mt. Kenya Global Atmospheric Watch (GAW)  
84 station, and in Nairobi city. The Mt. Kenya GAW station is located on the north-western slope of Mt. Kenya  
85 ( $0.062^{\circ}$  S,  $37.297^{\circ}$  E, at 3678 m MSL) in eastern equatorial Africa. The station description, site selection and  
86 representativeness, and meteorological characterization are detailed by Henne et al. (2008a, 2008b). In brief, the  
87 station lies within a nature conservancy, the Mount Kenya National Park, and contributes to the World  
88 Meteorological Organization GAW programme. The closest human settlements and roadways are over 17 km  
89 away, and the nearest town (Nanyuki) is at 1900 m MSL. A small touristic infrastructure, the Old Moses Camp, is  
90 situated 300 m below and ca. 1.9 km to the NNW of the station. The second site, in the megacity of Nairobi,  
91 Kenya, was a rooftop measurement site ( $\sim 17$  m above ground level; 1690 m asl.;  $1.279^{\circ}$  S,  $36.817^{\circ}$  E). As described  
92 previously, the Nairobi site is representative of the city's ambient conditions (Kirago et al., 2022b).

### 93 **2.2 Ambient air sampling**

94 Glass flask sampling was conducted in August 2021 at the Mt. Kenya GAW station and in Nairobi with an in-  
95 house assembled portable sampler consisting of a diaphragm pump (KNF Neuberger N86E) connected with 1/4"  
96 Dekabon tubing. The sampler design, glass flask pre-conditioning protocol and sampling procedure are previously  
97 described (Dasari et al., 2021). Briefly, the sampler was designed to fill two pre-conditioned glass flasks (Normag,  
98 1L) simultaneously, that is, each sample was collected in duplicates. Ambient air was drawn at a flow rate of  $2 \text{ L}$   
99  $\text{min}^{-1}$  and dried through a magnesium perchlorate trap. First, the glass flasks were flushed for 20 minutes before  
100 compressing the dried air to an absolute pressure of  $\sim 1.7$  bar. At Mt. Kenya GAW station, 21 nighttime (02:00h  
101 local time) and six daytime (14:00h local time) air sample sets were collected. Nine sample pairs were collected  
102 in Nairobi (every second day; daytime only; 14:00h local time). The filled glass flasks were sent to the Institute  
103 for Marine and Atmospheric Research Utrecht (IMAU), Utrecht University, for processing and stable isotope  
104 analysis of CO.

### 105 **2.3 Measurements of CO mole fractions and stable isotopes ( $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ ) composition of CO**

106 The CO mole fraction and stable isotopic composition measurements of the collected glass flask samples were  
107 performed at IMAU, Utrecht University. A continuous-flow isotope ratio mass spectrometry (CF-IRMS, Thermo  
108 Scientific Delta V Advantage) system was used, applying a previously described measurement protocol (Pathirana  
109 et al., 2015). In brief, the sample gas was introduced into the analytical system using an automated multi-port unit,  
110 via a mass flow controller and under ultra-high-purity helium flow. Here, the air sample was directed through a  
111 trap with Ascarite (8 - 20 mesh, Thermo Scientific™) followed by magnesium perchlorate (Sigma-Aldrich), to  
112 remove  $\text{CO}_2$  and water. A subsequent cryogenic trap (liquid  $\text{N}_2$ ,  $-196^\circ\text{C}$ ) was used to remove the remaining traces  
113 of  $\text{CO}_2$ ,  $\text{N}_2\text{O}$  and hydrocarbons. The CO in the clean air matrix was then oxidized to  $\text{CO}_2$  using Schütze reagent  
114 ( $\text{I}_2\text{O}_5/\text{H}_2\text{SO}_4$  mixture on granular silica gel) synthesized in-house. Subsequently, the CO-derived  $\text{CO}_2$  was cryo-  
115 trapped in liquid- $\text{N}_2$ , while other residual gases (e.g.,  $\text{O}_2$  and  $\text{N}_2$ ) were pumped out. The sample was further purified  
116 on a GC column, dried via a Nafion dryer, and subsequently transferred to the CF-IRMS via an open split inlet for  
117 stable isotopes ( $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$ ) analysis.(Pathirana et al., 2015) The original CO amount fraction was deduced  
118 from the quantity of the derived  $\text{CO}_2$ .

119 The isotopic composition is expressed as per mil (‰) enrichment or depletion of the isotope ra-tio in the sample  
120 relative to that of international standard materials, which in these cases are the Vienna PeeDeeBelemnite (V-PDB)  
121 standard for  $\delta^{13}\text{C}$ -CO, and the Vienna Standard Mean Ocean Water (V-SMOW) for  $\delta^{18}\text{O}$ -CO measurements  
122 (Brenninkmeijer et al., 1999; Pathirana et al., 2015). A reference cylinder with atmospheric air with known isotopic  
123 composition and mole fraction ( $\delta^{13}\text{C} = -30.25$  ‰;  $\delta^{18}\text{O} = +7.10$  ‰;  $\text{CO} = 180$  ppb) was used for calibration.  
124 Periodical measurements of "target" gases were used to monitor the precision and accuracy of the measurements,  
125 as well as the long-term stability of the analytical system (Pathirana et al., 2015). In addition, blank runs (without  
126 injecting the sample or reference gas) were performed to assess the background  $\text{CO}_2$ , mainly from the Schütze  
127 reagent. The typical 1-sigma measurement reproducibility during the time of these analyses is estimated at 0.12‰  
128 for  $\delta^{13}\text{C}$  and 0.16 ‰ for  $\delta^{18}\text{O}$ .

### 129 **2.4 Sampling and isotopic characterization of CO for the 1996/97 campaign**

130 High-volume air samples were collected between July and September 1996 on an exploratory mission around  
131 Mount Kenya following the ring road A2/B6, and branching off towards the mountain to locations where sufficient  
132 power was available for sample collection. During this campaign and later incidental samplings in 1997 air samples  
133 of approximately 500 L volume were compressed into 5 L aluminium cylinders using a modified RIX compressor  
134 (Mak and Brenninkmeijer, 1994). Unfortunately, records of precise locations have been lost. The filled cylinders  
135 were sent to the Max Planck Institute for Chemistry in Mainz, Germany, for CO isotope analysis on a high-volume  
136 extraction unit (Brenninkmeijer et al., 1999; Röckmann et al., 2002). A high CO concentration calibration gas (269  
137 ppm) that was used during the 1996/7 measurements has been preserved and is regularly measured in the lab of  
138 Utrecht University to assure scale compatibility.

## 139 2.5 Long-term CO mole fractions at the Mt. Kenya GAW station

140 High-resolution CO data from Mt. Kenya GAW station are available from the WMO World Data Centre for  
141 Greenhouse Gases (WDCGG; <https://gaw.kishou.go.jp/>). A continuous time series is available for the 2002-2006  
142 and 2020-2021 periods, with some large gaps attributable mainly to power outages and data quality issues.  
143 Between 2010 and 2015, the station was disconnected from the power grid following a bush fire, while  
144 performance audits revealed the CO analyzer to be in poor working condition between 2015-2019  
145 (decommissioned in 2020), compromising the data quality (Zellweger et al., 2020). Over time, the CO  
146 measurements were made using different CO analyzers (Thermo Electron Corporation TEI 48C-TL in 2002-2006,  
147 Horiba APMA360 in 2010-2019, and Picarro G2401 in 2020-2021).

148 The instrument calibration, quality control protocols, and data treatment procedures are discussed elsewhere  
149 (Henne et al., 2008b; Zellweger et al., 2009, 2020). In brief, ambient air was drawn into the CO instrument using  
150 1/4" Teflon (till 2019) and 1/4" Synflex 1300 (after 2019) tubings at a flow rate of 4 l/min via a Nafion drier to  
151 remove moisture and a particulate filter. The air inlet was about 7 m above ground and protected against rain, snow  
152 and direct wind. These instruments were installed and calibrated by the Swiss Federal Institute for Materials  
153 Science and Technology (Empa) in collaboration with the Federal Office of Meteorology and Climatology  
154 MeteoSwiss, and operated by the Kenya Meteorological Department (KMD). The instrument calibration and  
155 performance audits are conducted regularly by the GAW World Calibration Center hosted at Empa (Zellweger et  
156 al., 2020). In addition, flask-based CO data from Mt. Kenya GAW station by NOAA Global Monitoring labora-  
157 tory and published in the WDCGG database was used in this study (Petron, 2023).

## 158 2.6 Trajectory and statistical modelling

159 The air mass back trajectories (10 days; arrival height of 100 m above ground level) were calculated to identify  
160 the air mass source region. The NOAA Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPPLIT,  
161 version 4) and GDAS ( $1^\circ \times 1^\circ$ ) archived meteorological datasets were used (Stein et al., 2015). The Bayesian  
162 Markov chain Monte Carlo (MCMC) model was used to quantitatively constrain CO fractional contributions and  
163 account for source end member variability and measurement uncertainties (Dasari et al., 2021). The MCMC  
164 simulations were carried out with MATLAB R2020 with 1,000,000 runs and 10,000 runs for sample burn-in and  
165 a data thinning of 100.

## 166 3. Results and Discussion

### 167 3.1 CO mole fractions at Mt. Kenya GAW Station and Nairobi

168 The results of the CO observations at Mt. Kenya GAW station, both online and flask measurements, are presented  
169 in Figure 1. Part of the data (2002 - 2006) has been comprehensively discussed previously (Henne et al., 2008b).  
170 Overall, peak CO mole fractions were observed during the dry periods (SI Figure S1). Assessment of the long-  
171 term CO trend, following the approach by Thoning and Tans (1989), reveal a small but statistically significant  
172 positive decadal trend of  $6.7 \pm 0.4$  ppb/10 yrs. This statistical model is based on a fit function that includes a linear  
173 term, a quadratic term, as well as first and second harmonics. For comparison, simple linear regression gives a  
174 similar decadal rate of  $6.2 \pm 0.6$  ppb/10 yrs (for uncertainty estimation, see Kirago et al., 2022a). Like many types

175 of environmental data, the present CO data display a lognormal-like concentration distribution, suggesting  
176 influence by exponential processes such as sink kinetics (Andersson, 2021). This may influence trend analysis.  
177 Similarly to linear regression, regression of log-transformed data also gives a significant positive rate, which  
178 suggests that the skewed concentration profile has little influence on trend estimation. However, given the large  
179 data gaps and different measurement techniques, such interpretations should not be over-emphasized.  
180 Nevertheless, the increasing trend here constrained for ground observations of CO is qualitatively consistent with  
181 satellite retrievals and model estimates for sub-Saharan Africa (Buchholz et al., 2021; Hedelius et al., 2021; Zheng  
182 et al., 2019).

183 The observed CO levels, ranging between 55 – 250 ppb, are comparable to those previously recorded at Mt. Kenya  
184 station (Henne et al., 2008b), but lower than CO concentrations reported at the Rwanda Climate Observatory -  
185 another remote site also in Eastern Africa, possibly with a stronger and more direct influence of savanna burning  
186 episodes (DeWitt et al., 2019). The daytime and nighttime ambient flask CO concentrations were comparable,  
187 similar to observation from Picarro-measured CO measurements though with a slight daytime elevation (SI Figure  
188 S1). During the nighttime, the station stands above the atmospheric boundary layer, hence reduced influence from  
189 local sources. Overall, changes in source strength, air mass transport pathways and meteorological parameters such  
190 as planetary boundary layer thickness are likely to be key drivers of the observed temporal variations. In Nairobi,  
191 the CO concentrations during August 2021 range between 200 – 700 ppb ( $\sim 0.2 - 0.8 \text{ mg m}^{-3}$ , assuming average  
192 weather conditions), well within the WHO recommended short-term (24-h average) air quality guideline level of  
193  $4 \text{ mg m}^{-3}$  (WHO, 2021). While CO is not a major direct health concern in Nairobi nor in other urban settings  
194 (Chen et al., 2021), it affects the presence of health-detrimental components such as ground-level ozone and  
195 secondary aerosols.

196 Back-trajectories calculated with the HYSPLIT model were combined with the CO data to learn more about source  
197 regions incident with elevated CO mole fractions. Air masses originating from different geographical areas, such  
198 as from eastern Africa, Arabian Peninsula, northern Africa, South Asia, and south-eastern Africa, as well as cleaner  
199 air masses from the Indian Ocean, are intercepted at Mt. Kenya GAW station (Figure 2). This underlines the  
200 suitability of Mt. Kenya GAW station to capture both the regional and intercontinental footprints. The elevated  
201 summertime (June - August) CO mole fractions are linked to the arrival of south-easterly airmasses, coinciding  
202 with large-scale savanna fires in southern Africa and Madagascar. The air masses shift north-easterly during winter  
203 (December - March), and coincide with savanna fires in northern Africa (Andersson et al., 2020; Kirago et al.,  
204 2022a). Although the intercepted air masses do not directly flow over West-Central Sub-Saharan Africa, where  
205 most fires occur, the atmospheric residence time of CO is sufficient for regional and intercontinental mixing. Air  
206 masses with elevated CO loadings from South Asia and the Arabian Peninsula are also intercepted during winter.  
207 High wintertime CO amount fractions have been reported from a South Asian receptor site in the northern Indian  
208 Ocean (Dasari et al., 2021). Taken together, the seasonal variability in CO mole fraction can partly be explained  
209 by regional emission events, combined with a contribution from other geographical source regions such as South  
210 Asia.

### 211 3.2 Isotopic constraints of sources to CO from Mount Kenya and Nairobi

212 The stable isotope composition of CO ( $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$ ) for ambient samples from Mt. Kenya GAW station during  
213 August 2021 varied temporally with the CO mole fractions (SI Figure S2). The  $\delta^{13}\text{C}$  ranged between  $-31.5\text{‰}$  to -  
214  $28.0\text{‰}$ , while  $\delta^{18}\text{O}$  ranged between  $2.5$  to  $10.0\text{‰}$  (SI Figure S2). However, there were no distinct temporal or  
215 diurnal trends in the recorded isotopic values (both daytime and night-time samples were measured). The air  
216 masses were consistently southeasterly during the three weeks study period (SI Figure S3). Comparable  $\delta^{18}\text{O}$   
217 composition was observed in 1996/97 samples (ranged between  $3.7$  to  $10.4\text{‰}$ ), but was more enriched in  $\delta^{13}\text{C}$  (-  
218  $28.4\text{‰}$  to  $-26.6\text{‰}$ ). The isotopic composition in the Mt. Kenya background region was distinct from that of the  
219 urban Nairobi location that recorded highly enriched  $\delta^{18}\text{O}$  values ( $17.5 \pm 2.2\text{‰}$ ; SI Figure S2).

220 The Keeling plot approach provides insights into the regional CO sources. Here, a linear relationship is observed  
221 between the isotope signatures and the inverse of the CO amount fractions ( $\delta^{13}\text{C}$  vs  $1/[\text{CO}]$  and  $\delta^{18}\text{O}$  vs  $1/[\text{CO}]$ )  
222 both at Mt. Kenya and in Nairobi (Figure 3). This implies that the CO dynamics in this system can be described  
223 by a two-component mix-ture; a relatively stable background fraction and a regional varying source (Dasari et al.,  
224 2021; Keeling, 1958). The y-axis intercept in this relation represents the source signature. At Mt. Kenya, analysis  
225 of the recently-obtained dataset (2021) reveals the stable isotopes signature of the source of  $\delta^{18}\text{O} = 14.0 \pm 1.2\text{‰}$   
226 and  $\delta^{13}\text{C} = -27.7 \pm 0.6\text{‰}$ . For the samples collected during the 1996/97 campaign, the  $\delta^{18}\text{O}$  signature is very  
227 similar and indistinguishable ( $\delta^{18}\text{O} = 14.2 \pm 2.1\text{‰}$ ), while the source is more enriched in  $^{13}\text{C}$  ( $\delta^{13}\text{C} = -24.7 \pm 0.7$   
228  $\text{‰}$ ; Figure 4). The latter suggests differences in the relative strengths of the contributing sources, possibly a  
229 relatively higher contribution from  $\text{C}_4$  plants burning or a relatively smaller influence of secondary CO from  
230 atmospheric reactions during the 1996/97 campaign. It should be kept in mind that the 1990s samples were obtained  
231 at a lower altitude location on the slopes of Mt. Kenya.  $\text{C}_4$  plants like maize and sugarcane are commonly grown  
232 in Kenya, while also biomass usage (including crop residuals for household energy) and agricultural burning are  
233 prevalent in the region (World Bank, 2011). In Nairobi, a clearly distinct source signature is noted, especially for  
234  $\delta^{18}\text{O}$  ( $\delta^{13}\text{C} = -26.0 \pm 0.4\text{‰}$  and  $\delta^{18}\text{O} = 22.9 \pm 0.8\text{‰}$ ; Figures 4). The highly enriched  $\delta^{18}\text{O}$  source signature in  
235 Nairobi indicates almost exclusively high temperature combustion sources, while a mixed source regime (both  
236 combustion sources and CO emanating from atmospheric reactions) is observed at Mt. Kenya; these can be  
237 quantitatively resolved using an isotopic mass balance approach

238 The source signatures can be used to quantitatively constrain the fractional contributions of CO in the regional  
239 background and urban atmosphere (Dasari et al., 2021). However, information was available for only two isotopes,  
240  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$ , against five potential sources that can contribute to the overall CO isotopic signature ( $\text{C}_3$  plants,  
241 fossil,  $\text{C}_4$  plants,  $\text{CH}_4$  oxidation and NMHC oxidation), yielding a mathematically under-determined scenario.  
242 Furthermore, the weak linear correlation for  $\delta^{13}\text{C}$  in the Keeling plot ( $\delta^{13}\text{C}$  vs  $1/[\text{CO}]$ ;  $R^2 = 0.34$  for Mt. Kenya)  
243 limits its application in the statistical model. Therefore, only  $\delta^{18}\text{O}$  signatures were here modelled ( $R^2 = 0.64$  for  
244 both Mt. Kenya;  $R^2 = 0.89$  for Nairobi;  $P < 0.05$ ). Hence, the CO sources were partitioned into two major classes:  
245 primary/combustion (fossil,  $\text{C}_3$  and  $\text{C}_4$  biomass) and secondary (i.e., oxidation of methane and NMHC).

246 A Bayesian statistical model, drawing upon the model described in Dasari et al. (2022), was used to estimate the  
247 contribution of secondary ( $f_{\text{secondary}}$ ) vs primary ( $f_{\text{primary}}$ ) CO sources. In this model the relative contributions of  
248 primary vs. secondary CO for the temporally varying source is computed, corresponding to the  $\delta^{18}\text{O}$  values at the  
249 limit where  $1/\text{CO}$  approaches zero (the  $\delta^{18}\text{O}$  intercept in the Keeling plot). First, the source end members for the

250 two fractions were established. Unlike the oxidation of NMHC, the CH<sub>4</sub>-oxidized CO fluxes have little variability  
251 (CH<sub>4</sub> has a long atmospheric lifetime) and largely contribute to the background signal (Dasari et al., 2021; Worden  
252 et al., 2019; Zheng et al., 2019). Therefore, the temporally-varying secondary CO end member was assigned that  
253 of the NMHC oxidation source ( $\delta^{18}\text{O}_{\text{secondary}} = 2.4 \pm 2.4 \text{ ‰}$ ).

254 The primary CO end member is a composite of the three combustion sources; C<sub>4</sub> biomass ( $+20.2 \pm 4.9 \text{ ‰}$ ), C<sub>3</sub>  
255 biomass ( $+16.3 \pm 5.1 \text{ ‰}$ ) and fossil fuel combustion at  $+19.2 \pm 4.9 \text{ ‰}$  (Dasari et al., 2021). Although the relative  
256 contributions are uncertain, the  $\delta^{18}\text{O}$  end members largely overlap. Model estimates show biomass burning in  
257 Africa accounts for 80 – 90 % of the surface CO emissions (Zheng et al., 2018). Similar contributions to black  
258 carbon (different but co-emitted incomplete combustion product) were observed using isotopic constraints with  
259 near-equal contributions from C<sub>3</sub> and C<sub>4</sub> biomass in the eastern Africa background atmosphere (Kirago et al.,  
260 2022c). Therefore, the relative source contributions were estimated at 50% from C<sub>3</sub> biomass and 50 % from C<sub>4</sub>  
261 and fossil sources at Mt. Kenya. Hence, a primary CO end member was established at  $\delta^{18}\text{O}_{\text{primary}} = 18.4 \pm 3.5 \text{ ‰}$ .  
262 In Nairobi, fossil fuel combustion was estimated to contribute to 85% of the CO emission in the city ( $\delta^{18}\text{O}_{\text{primary}} =$   
263  $+19.2 \pm 4.9 \text{ ‰}$ ). Since primary source endmembers largely overlap, the model simulations were generally insen-  
264 sitive to chosen priors, as investigated by sensitivity analysis.

265 A similar  $\delta^{18}\text{O}$  source signature ( $\sim 14.0 \pm 2.1 \text{ ‰}$ ) was observed at the two Mt. Kenya campaigns (1996/97 and  
266 2021). Applying the established endmembers, we estimate the contribution of CO from primary/ combustion  
267 sources at the regional background site to be at least 70 %. In contrast, we found an almost exclusively primary  
268 CO component for the urban Nairobi case. Nairobi is a strong air pollution source region, and the CO loadings  
269 largely reflect the city's CO emissions. CO is, e.g., a precursor to low-level ozone, and thus emissions deteriorate  
270 air quality. Present findings show that air quality policy should target primary emissions, especially from traffic  
271 (Kirago et al., 2022b). In contrast, Mt. Kenya GAW station captures a more regional footprint with a dominant  
272 contribution from savanna fires.

#### 273 4. Conclusion

274 This study provides ground-observational constraints that broadly supports earlier suggestions that savanna fires  
275 are the main emitters and modulators of CO loadings over Sub-Saharan Africa. Although the data gaps in CO  
276 mixing ratios and mixed instrumentation complicates detailed analysis, a small decadal increase of  $6.7 \pm 0.4 \text{ ppb}/10$   
277 yrs was resolved for the Mt. Kenya GAW station, in agreement with satellite observations and emission inventories  
278 for the Sub-Saharan region (Buchholz et al., 2021; Hedelius et al., 2021; Zheng et al., 2019). Isotope-based source  
279 apportionment shows that at least two thirds of the CO emitted from East African savanna fires are of primary  
280 origins, while for Nairobi primary sources approach 100 %. The latter has implications for air quality policy,  
281 suggesting primary emissions such as traffic should be targeted, in line with previous findings for BC (Kirago et  
282 al., 2022b). These findings put constraints on satellite-based emission inventories and chemical-transport and  
283 climate modelling. Overall, this study corroborates earlier findings that in order to reduce the secondary climate  
284 warming effect from CO over Sub-Saharan Africa, man-made savanna fires should be reduced (Andersson et al.,  
285 2020).

286 **Acknowledgement**

287 This work was supported by research grants from the Swedish Research Council (VR contracts nos. 2013-114,  
288 2017-05687 and 2020-05384), the Swedish Research Council for Sustainable Development (FORMAS contract  
289 no. 2020-01951), and the Swedish Research Council Distinguished Professor Grant (VR contract no. 2017-  
290 01601). Sample analysis was supported by the research grants from European Commission under the Horizon  
291 2020 – Research and Innovation Framework Programme, H2020-INFRAIA-2020-1 (grant agreement number  
292 101008004).

293 We commend the efforts of the Kenya Meteorological Department (KMD), the Swiss Federal Institute for  
294 Materials Science and Technology (Empa), and the Federal Office of Meteorology and Climatology MeteoSwiss  
295 for Mt. Kenya GAW Station operations. We appreciate the field and technical support from the staff at the Institute  
296 of Nuclear Science & Technology, University of Nairobi and KMD. We commend Prof. Carl Brenninkmeijer and  
297 Sergey Gromov for their contribution to science, and contribution to 1996/97 campaign/ data used in this  
298 manuscript.

299 We acknowledge the use of data from the World Data Centre for Greenhouse Gases (WDCGG) database  
300 (<https://gaw.kishou.go.jp/>), hosted by the World Meteorological Organization. The authors gratefully acknowledge  
301 the NOAA Air Resources Laboratory (ARL) for the provision of the HYSPLIT transport and dispersion model  
302 and/or READY website (<https://www.ready.noaa.gov>) used in this publication.

303 **Data availability**

304 Data from this study will be available in the Bolin Centre Database ([bolin.su.se/data/](http://bolin.su.se/data/)).

305 **Author Contribution**

306 Conceptualization of the study by AA. Design and execution of field campaigns by LK, AA, SG and MJG.  
307 Management of Mt. Kenya GAW station and instrument calibration by DN, JK, CZ, CF & MS. Isotope analysis  
308 by MEP. 1996/97 sampling campaign and sample analysis by TR. Data analysis by LK with support from AA,  
309 ÖG, SLH and SG; Manuscript writing by LK with support from co-authors.

310 **Competing interests**

311 The authors declare no competing interests.

312 **Additional information**

313 Supplementary Information (SI) contain the flask-based CO measurement data for the 1996/97 and 2021 sampling  
314 campaigns and the respective stable isotopes of CO (Table S1- S3).

 440 **February, (b) June – August, (c) March – May, and (d) September – November. Ten days air masses back trajectories**  
 441 **are calculated at an arrival height of 100 m above ground level.**

442

443 Figure 3: The Keeling relation plots (i.e., signatures of the two isotopic systems vs the inverse of the measured CO mole  
 444 fraction) for Mt. Kenya (top panel) and Nairobi (bottom panel). The y-intercept in the Keeling relationship represents  
 445 the source signature.

446

447 Figure 4: Stable isotope ( $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$ ) source signatures of CO for Nairobi and Mt. Kenya (2021 and 1996/97), and  
 448 the source end members. The source end members are adopted from Brenninkmeijer et al. (1999).
