16 **Abstract.** Carbon monoxide (CO) concentrations in the troposphere are decreasing globally, with Africa as an
17 exception. Yet, the region is understudied, with a deficit of ground-based observations and highly uncertain CO
18 emission inventories. This paper reports multi-year observational CO data from the Mt. Kenya Global Atmosphere
19 Watch (GAW) station, as well as summertime CO isotope observations from both Mt. Kenya and Nairobi, Kenya.
20 The CO variability at Mt. Kenya is characterized by slightly increased concentrations during dry periods and a
21 strong influence of short-term pollution events. While multi-year data gaps complicate decadal-scale trend analysis,
22 no overall long-term shift can be resolved. High pollution events are consistent with isotopic signal from downwind
23 savanna fires. The isotope fingerprint of CO in Nairobi indicate an overwhelming dominance (near 100%) of
24 primary emissions from fossil fuel combustion - with implications for air pollution policy. In contrast, the isotope
25 signature of CO intercepted at the large footprint Mt. Kenya region suggests at least 70% primary sourced, with a
26 predominance likely from, savanna fires in Africa. Taken together, this study provides quantitative constraints of
27 primary vs secondary CO in the eastern Africa region and in urban Nairobi, with implications for satellite-based
28 emission inventories as well as for chemical-transport and climate- modelling.

29 **1. Introduction**

30 Carbon monoxide (CO) is the dominant sink for the hydroxyl radical (OH), accounting for over 50% consumption
31 of OH in the atmosphere (Lelieveld et al., 2016). It therefore influences the atmosphere's oxidation and cleansing
32 capacity and, by extension, chemically regulates the atmospheric lifetime and abundance of other reactive gases
33 such as methane and halocarbons (Lelieveld et al., 2016; Zheng et al., 2019). As such, CO is an indirect greenhouse
34 gas with a net positive warming effect on climate (Szopa et al., 2021). In addition to climate effects, CO is a
35 precursor to the formation of ground-level ozone, with implications for human health (Chen et al., 2021; WHO,
36 2016; Zhang et al., 2019). Anthropogenic activities such as biomass burning and fossil fuel combustion are
37 important contributors to the global CO budget, in addition to atmospheric reactions, e.g., oxidation of
38 hydrocarbons (Duncan et al., 2007; Zheng et al., 2019). However, the CO source contributions, mole fractions,
39 and atmospheric residence time are spatially variable, complicating the source-sink assessment.

40 Global CO levels have been declining over the past two decades, but Africa is an exception. The key source of
41 information on CO trends in the African region is satellite-based observations that show an increase in CO mole
42 fractions (Buchholz et al., 2021; Hedelius et al., 2021; Zheng et al., 2019). However, the ground-truthing of the
43 satellite observations is challenged by a deficit of atmospheric observatories and scant continuous long-term
44 observations in the region (DeWitt et al., 2019; Henne et al., 2008b; Kulmala, 2018). Exacerbating this
45 observational deficit, regional CO emission inventories are not well-defined as the continent possesses a unique
46 CO emission profile, different from other regions such as Europe and South Asia (Crippa et al., 2018; Dasari et
47 al., 2022; Hedelius et al., 2021). To advance our understanding of trends in CO over Africa and its source
48 contributions, long-term CO measurements and isotope-based source apportionment studies are required but data
49 availability is scarce.

50 The isotopic composition of CO provides insights into the relative strengths of regional CO sources and
51 atmospheric processing (Brenninkmeijer, 1993; Dasari et al., 2022; Henne et al., 2008b; Röckmann et al., 2002).
52 A particular source of CO possesses a characteristic isotopic signature, with the isotopic composition of the
53 ambient CO reflecting that of the combined sources, sinks, and atmospheric ageing (Brenninkmeijer and
54 Röckmann, 1997; Dasari et al., 2022; Popa et al., 2014; Röckmann et al., 1998, 2002). For example, CO from
55 primary sources (fossil combustion and biomass burning) has a more enriched $\delta^{18}\text{O}$ signature (above +12‰)
56 compared to that of secondary-formed CO, e.g., from oxidation of CH_4 (at ~0‰) and non-methane hydrocarbons
57 (NMHC), at $-2.4 \pm 2.4\text{‰}$ (Brenninkmeijer and Röckmann, 1997).

58 Additional source information can be obtained from the $\delta^{13}\text{C}$ signatures. CO formed from methane oxidation is
59 strongly depleted in ^{13}C ($\delta^{13}\text{C} = -51.9 \pm 1.6\text{‰}$) in contrast to, for example, CO emitted from burning of C_4 plants
60 ($\delta^{13}\text{C} = -14.0 \pm 3.8\text{‰}$), C_3 plants ($\delta^{13}\text{C} = -26.9 \pm 4.9\text{‰}$) or fossil combustion at $-27.8 \pm 1.5\text{‰}$ (Brenninkmeijer et
61 al., 1999). However, the kinetic isotope effect (KIE) during the CO-OH reaction (the main atmospheric CO
62 removal mechanism) results in the enrichment of $\delta^{13}\text{C}$ by 4-5‰ and more depleted $\delta^{18}\text{O}$ signatures (by ~10‰) in
63 the lower troposphere (Brenninkmeijer et al., 1999; Röckmann et al., 1998). Overall, isotope forensics can provide
64 valuable data on CO emissions in remote and urban locations in Africa, especially considering that the region is
65 largely understudied, with very few ground-based CO observations and highly uncertain emission inventories.

66 This study investigates the long-term trends in CO mole fractions at Mt. Kenya GAW station, a high-altitude
67 monitoring site in equatorial East Africa well suited to intercept the regional emission footprint. Online CO mole
68 fractions measurements have been going on at the observatory since 2002, albeit with large data gaps due to
69 technical challenges. Flask-based measurements carried out at Mt. Kenya at different periods by NOAA (2003-
70 2011) were used for gap filling. The online and NOAA flask-measured CO data were obtained from the WMO's
71 World Data Centre for Greenhouse Gases (WDCGG) database. After the CO measurements from Cape Point,
72 South Africa, this is likely the longest-running data available in sub-Saharan Africa and provides observational
73 constraints of the region's long-term trend in CO. The present study additionally provides stable isotope
74 composition data of CO to resolve source attribution of the observed higher summertime CO amount fraction.
75 Furthermore, the data are compared to previously obtained and unpublished isotope data from Mt. Kenya (1996-
76 1997; earlier unpublished work by Röckmann and Brenninkmeijer) and that of an urban site in Nairobi in summer
77 2021 to provide further insights into regional CO sources. This dataset is unprecedented in the region and facilitates
78 improved understanding of the regional CO emission trends and source attribution.

79 **2. Methodology**

80 **2.1 Measurement sites**

81 Ambient air sampling was conducted at a remote mountain site, the Mt. Kenya Global Atmospheric Watch (GAW)
82 station, and in Nairobi city. The Mt. Kenya GAW station is located on the north-western slope of Mt. Kenya (0.062
83 °S, 37.297 °E, at 3678 m MSL) in eastern equatorial Africa. The station description, site selection and
84 representativeness, and meteorological characterization are detailed by Henne et al. (2008a, 2008b). In brief, the
85 station lies within a nature conservancy, the Mount Kenya National Park, and contributes to the World
86 Meteorological Organization GAW programme. The closest human settlements and roadways are over 17 km
87 away, and the nearest town (Nanyuki) is at 1900 m MSL. A small touristic infrastructure, the Old Moses Camp, is
88 situated 300 m below and ca. 1.9 km to the NNW of the station. The second site, in the megacity of Nairobi,
89 Kenya, was a rooftop measurement site (~17 m above ground level; 1690 m asl.; 1.279° S, 36.817° E). As described
90 previously, the Nairobi site is representative of the city's ambient conditions (Kirago et al., 2022b).

91 **2.2 Ambient air sampling**

92 Glass flask sampling was conducted in August 2021 at the Mt. Kenya GAW station and in Nairobi with an in-
93 house assembled portable sampler consisting of a diaphragm pump (KNF Neuberger N86E) connected with 1/4"
94 Dekabon tubing. The sampler design, glass flask pre-conditioning protocol and sampling procedure are previously
95 described (Dasari et al., 2022). Briefly, the sampler was designed to fill two pre-conditioned glass flasks (Normag,
96 1L) simultaneously. Ambient air was drawn at a flow rate of 2 L min⁻¹ and dried through a magnesium perchlorate
97 trap. First, the glass flasks were flushed for 20 minutes before compressing the dried air to an absolute pressure of
98 ~1.7 bar. At Mt. Kenya GAW station, 21 nighttime (02:00h local time) and six daytime (14:00h local time) air
99 sample sets were collected. Nine sample pairs were collected in Nairobi (every second day; daytime only; 14:00h
100 local time). The filled glass flasks were sent to the Institute for Marine and Atmospheric Research Utrecht (IMAU),
101 Utrecht University, for processing and stable isotope analysis of CO.

102 **2.3 Measurements of CO mole fractions and stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) composition of CO**

103 The CO mole fraction and stable isotopic composition measurements of the collected glass flask samples were
104 performed at IMAU, Utrecht University. A continuous-flow isotope ratio mass spectrometry (CF-IRMS, Thermo
105 Scientific Delta V Advantage) system was used, applying a previously described measurement protocol (Pathirana
106 et al., 2015). In brief, the sample gas was introduced into the analytical system using an automated multi-port unit,
107 via a mass flow controller and under ultra-high-purity helium flow. Here, the air sample was directed through a
108 trap with Ascarite (8 - 20 mesh, Thermo Scientific™) followed by magnesium perchlorate (Sigma-Aldrich), to
109 remove CO_2 and water. A subsequent cryogenic trap (liquid N_2 , -196°C) was used to remove the remaining traces
110 of CO_2 , N_2O and hydrocarbons. The CO in the clean air matrix was then oxidized to CO_2 using Schütze reagent
111 ($\text{I}_2\text{O}_5/\text{H}_2\text{SO}_4$ mixture on granular silica gel) synthesized in-house. Subsequently, the CO-derived CO_2 was cryo-
112 trapped in liquid- N_2 , while other residual gases (e.g., O_2 and N_2) were pumped out. The sample was further purified
113 on a GC column, dried via a Nafion dryer, and subsequently transferred to the CF-IRMS via an open split inlet for
114 stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) analysis.(Pathirana et al., 2015) The original CO amount fraction was deduced
115 from the quantity of the derived CO_2 .

116 The isotopic composition is expressed as per mil (‰) enrichment or depletion of the isotope ratio in the sample
117 relative to that of international standard materials, which in these cases are the Vienna PeeDeeBelemnite (V-PDB)
118 standard for $\delta^{13}\text{C}$ -CO, and the Vienna Standard Mean Ocean Water (V-SMOW) for $\delta^{18}\text{O}$ -CO measurements
119 (Brenninkmeijer et al., 1999; Pathirana et al., 2015). A reference cylinder with atmospheric air with known isotopic
120 composition and mole fraction ($\delta^{13}\text{C} = -30.25\text{‰}$; $\delta^{18}\text{O} = +7.10\text{‰}$; $\text{CO} = 180$ ppb) was used for calibration.
121 Periodical measurements of "target" gases were used to monitor the precision and accuracy of the measurements,
122 as well as the long-term stability of the analytical system (Pathirana et al., 2015). In addition, blank runs (without
123 injecting the sample or reference gas) were performed to assess the background CO_2 , mainly from the Schütze
124 reagent. The typical 1-sigma measurement reproducibility during the time of these analyses is estimated at 0.12‰
125 for $\delta^{13}\text{C}$ and 0.16‰ for $\delta^{18}\text{O}$.

126 **2.4 Sampling and isotopic characterization of CO for the 1996/97 campaign**

127 The 1996/97 high-volume air samples were collected on an exploratory mission around Mount Kenya following
128 the ring road A2/B6, and branching off towards the mountain to locations where sufficient power was available
129 for sample collection. During this campaign and later incidental samplings, air samples of approximately 500 L
130 volume were compressed into 5 L aluminium cylinders using a modified RIX compressor (Mak and
131 Brenninkmeijer, 1994). Unfortunately, records of precise locations have been lost. The filled cylinders were sent
132 to the Max Planck Institute for Chemistry in Mainz, Germany, for CO isotope analysis on a high-volume extraction
133 unit (Brenninkmeijer et al., 1999; Röckmann et al., 2002). A high CO concentration calibration gas (269 ppm) that
134 was used during the 1996/7 measurements has been preserved and is regularly measured in the lab of Utrecht
135 University to assure scale compatibility.

136

137 **2.5 Long-term CO mole fractions at the Mt. Kenya GAW station**

138 High-resolution CO data from Mt. Kenya GAW station are available from the WMO World Data Centre for
139 Greenhouse Gases (WDCGG; <https://gaw.kishou.go.jp/>). A continuous time series is available for the 2002-2006
140 and 2020-2021 periods, with some large gaps attributable mainly to power outages and data quality issues.
141 Between 2010 and 2015, the station was disconnected from the power grid following a bush fire, while
142 performance audits revealed the CO analyzer to be in poor working condition between 2015-2019
143 (decommissioned in 2020), compromising the data quality (Zellweger et al., 2020). Over time, the CO
144 measurements were made using different CO analyzers (Thermo Electron Corporation TEI 48C-TL in 2002-2006,
145 Horiba APMA360 in 2010-2019, and Picarro G2401 in 2020-2021).

146 The instrument calibration, quality control protocols, and data treatment procedures are discussed elsewhere
147 (Henne et al., 2008b; Zellweger et al., 2009, 2020). In brief, ambient air was drawn into the CO instrument using
148 1/4" Teflon (till 2019) and 1/4" Synflex 1300 (after 2019) tubings at a flow rate of 4 l/min via a Nafion drier to
149 remove moisture and a particulate filter. The air inlet was about 7 m above ground and protected against rain, snow
150 and direct wind. These instruments were installed and calibrated by the Swiss Federal Institute for Materials
151 Science and Technology (Empa) in collaboration with the Federal Office of Meteorology and Climatology
152 MeteoSwiss, and operated by the Kenya Meteorological Department (KMD). The instrument calibration and
153 performance audits are conducted regularly by the GAW World Calibration Center hosted at Empa (Zellweger et
154 al., 2020).

155 **2.6 Trajectory and statistical modelling**

156 The air mass back trajectories (10 days; arrival height of 100 m above ground level) were calculated to identify
157 the air mass source region. The NOAA Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPPLIT,
158 version 4) and GDAS ($1^\circ \times 1^\circ$) archived meteorological datasets were used (Stein et al., 2015). The Bayesian
159 Markov chain Monte Carlo (MCMC) model was used to quantitatively constrain CO fractional contributions and
160 account for source end member variability and measurement uncertainties (Dasari et al., 2022). The MCMC
161 simulations were carried out with MATLAB R2020 with 1,000,000 runs and 10,000 runs for sample burn-in and
162 a data thinning of 100.

163 **3. Results and Discussion**

164 **3.1 CO mole fractions at Mt. Kenya GAW Station**

165 The results of the continuous CO observations at Mt. Kenya GAW station, both online and flask measurements,
166 are presented in Figure 1. Part of the data (2002 - 2006) has been comprehensively discussed previously (Henne
167 et al., 2008b), and here it will be only compared to the 2021 period with respect to a general long-term trend.
168 Overall, peak CO mole fractions were observed during the dry periods (SI Figure S1). However, the seasonal
169 variations are not pronounced; the intra-seasonal peak-to-peak amplitude is larger than the variations between
170 different seasons, implying a strong influence of short-term pollution events. Meanwhile, no clear multi-year trend

171 in CO concentrations were detected (the rate of the long-term trend is ~ 0 ppb/year), albeit the large data gaps and
172 different measurement techniques precludes a detailed analysis.

173 The observed CO levels, ranging between 55 – 250 ppb, are comparable to those previously recorded at Mt. Kenya
174 station (Henne et al., 2008b), but lower than CO concentrations reported at the Rwanda Climate Observatory -
175 another remote site also in Eastern Africa, possibly with a stronger and more direct influence of savanna burning
176 episodes (DeWitt et al., 2019). Overall, changes in source strength, air mass transport pathways and meteorological
177 parameters such as planetary boundary layer thickness are likely to be key drivers of the observed temporal
178 variations.

179 Back-trajectories calculated with the HYSPLIT model were combined with the CO data to learn more about source
180 regions incident with elevated CO mole fractions. Air masses originating from different geographical areas, such
181 as from eastern Africa, Arabian Peninsula, northern Africa, South Asia, and south-eastern Africa, as well as cleaner
182 air masses from the Indian Ocean, are intercepted at Mt. Kenya GAW station (Figure 2). This underlines the
183 suitability of Mt. Kenya GAW station to capture both the regional and intercontinental footprints. The elevated
184 summertime (June - August) CO mole fractions are linked to the arrival of south-easterly airmasses, coinciding
185 with large-scale savanna fires in southern Africa and Madagascar. The air masses shift north-easterly during winter
186 (December - March), and coincide with savanna fires in northern Africa (Andersson et al., 2020; Kirago et al.,
187 2022a). Although the intercepted air masses do not directly flow over West-Central Sub-Saharan Africa, where
188 most fires occur, the atmospheric residence time of CO is sufficient for regional and intercontinental mixing. Air
189 masses with elevated CO loadings from South Asia and the Arabian Peninsula are also intercepted during winter.
190 High wintertime CO amount fractions have been reported from a South Asian receptor site in the northern Indian
191 Ocean (Dasari et al., 2022). Taken together, the seasonal variability in CO mole fraction can partly be explained
192 by regional emission events, combined with a contribution from other geographical source regions such as South
193 Asia.

194 3.2 Isotopic constraints of sources to CO from Mount Kenya and Nairobi

195 The stable isotope composition of CO ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) for ambient samples from Mt. Kenya GAW station during
196 August 2021 varied temporally and inversely with the CO mole fractions. The $\delta^{13}\text{C}$ ranged between -31.5‰ to $-$
197 28.0‰ , while $\delta^{18}\text{O}$ ranged between 2.5 to 10.0‰ (SI Figure S2). However, there were no distinct temporal or
198 diurnal trends in the recorded isotopic values (both daytime and night-time samples were measured). The air
199 masses were consistently southeasterly during the three weeks study period (SI Figure S3). Comparable $\delta^{18}\text{O}$
200 composition was observed in 1996/97 samples (ranged between 3.7 to 10.4‰), but was more enriched in $\delta^{13}\text{C}$ ($-$
201 28.4‰ to -26.6‰). The isotopic composition in the Mt. Kenya background region was distinct from that of the
202 urban Nairobi location that recorded highly enriched $\delta^{18}\text{O}$ values ($17.5 \pm 2.2\text{‰}$; SI Figure S2).

203 The Keeling plot approach provides insights into the regional CO sources. Here, a linear relationship is observed
204 between the isotope signatures and the inverse of the CO amount fractions ($\delta^{13}\text{C}$ vs $1/[\text{CO}]$ and $\delta^{18}\text{O}$ vs $1/[\text{CO}]$)
205 both at Mt. Kenya and in Nairobi (Figure 3). This implies that the CO dynamics in this system can be described
206 by a two-component mixture; a relatively stable background fraction and a regional source. The y-axis intercept
207 in this relation represents the source signature. At Mt. Kenya, analysis of the recently-obtained dataset (2021)

208 reveals the stable isotopes signature of the source of $\delta^{18}\text{O} = 14.0 \pm 1.2\text{‰}$ and $\delta^{13}\text{C} = -27.7 \pm 0.6\text{‰}$. For the samples
209 collected during the 1996/97 campaign, the $\delta^{18}\text{O}$ signature is very similar and indistinguishable ($\delta^{18}\text{O} = 14.2 \pm$
210 2.1‰), while the source is more enriched in ^{13}C ($\delta^{13}\text{C} = -24.7 \pm 0.7\text{‰}$; Figure 4). The latter suggests differences
211 in the relative strengths of the contributing sources, possibly a relatively higher contribution from C_4 plants burning
212 or a relatively smaller influence of secondary CO from atmospheric reactions during the 1996/97 campaign. It
213 should be kept in mind that the 1990s samples were obtained at a lower altitude location on the slopes of Mt Kenya.
214 C_4 plants like maize and sugarcane are commonly grown in Kenya, while also biomass usage (including crop
215 residuals for household energy) and agricultural burning are prevalent in the region (World Bank, 2011). In
216 Nairobi, a clearly distinct source signature is noted, especially for $\delta^{18}\text{O}$ ($\delta^{13}\text{C} = -26.0 \pm 0.4\text{‰}$ and $\delta^{18}\text{O} = 22.9 \pm$
217 0.8‰ ; Figures 4). The highly enriched $\delta^{18}\text{O}$ source signature in Nairobi indicates almost exclusively high
218 temperature combustion sources, while a mixed source regime (both combustion sources and CO emanating from
219 atmospheric reactions) is observed at Mt. Kenya; these can be quantitatively resolved using an isotopic mass
220 balance approach

221 The source signatures can be used to quantitatively constrain the fractional contributions of CO in the regional
222 background and urban atmosphere (Dasari et al., 2022). However, information was available for only two isotopes,
223 $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$, against five potential sources that can contribute to the overall CO isotopic signature (C_3 plants,
224 fossil, C_4 plants, CH_4 oxidation and NMHC oxidation), yielding a mathematically under-determined scenario.
225 Furthermore, the weak linear correlation for $\delta^{13}\text{C}$ in the Keeling plot ($\delta^{13}\text{C}$ vs $1/[\text{CO}]$; $R^2 = 0.34$ for Mt. Kenya)
226 limits its application in the statistical model. Therefore, only $\delta^{18}\text{O}$ signatures were here modelled ($R^2 = 0.64$ for
227 both Mt. Kenya; $R^2 = 0.89$ for Nairobi; $P < 0.05$). Hence, the CO sources were partitioned into two major classes:
228 primary/combustion (fossil, C_3 and C_4 biomass) and secondary (i.e., oxidation of methane and NMHC).

229 A Bayesian statistical model, drawing upon the model described in Dasari et al. (2022), was used to estimate the
230 contribution of secondary ($f_{\text{secondary}}$) vs primary (f_{primary}) CO sources. In this model the relative contributions of
231 primary vs. secondary CO for the temporally varying source is computed, corresponding to the $\delta^{18}\text{O}$ values at the
232 limit where $1/\text{CO}$ approaches zero (the $\delta^{18}\text{O}$ intercept in the Keeling plot). First, the source end members for the
233 two fractions were established. Unlike the oxidation of NMHC, the CH_4 -oxidized CO fluxes have little variability
234 (CH_4 has a long atmospheric lifetime) and largely contribute to the background signal (Dasari et al., 2022; Worden
235 et al., 2019; Zheng et al., 2019). Therefore, the temporally-varying secondary CO end member was assigned that
236 of the NMHC oxidation source ($\delta^{18}\text{O}_{\text{secondary}} = 2.4 \pm 2.4\text{‰}$).

237 The primary CO end member is a composite of the three combustion sources; C_4 biomass ($+20.2 \pm 4.9\text{‰}$), C_3
238 biomass ($+16.3 \pm 5.1\text{‰}$) and fossil fuel combustion at $+19.2 \pm 4.9\text{‰}$ (Dasari et al., 2022). Although the relative
239 contributions are uncertain, the $\delta^{18}\text{O}$ end members largely overlap. Model estimates show biomass burning in
240 Africa accounts for 80 - 90% of the surface CO emissions (Zheng et al., 2018). Similar contributions to black
241 carbon (different but co-emitted incomplete combustion product) were observed using isotopic constraints with
242 near-equal contributions from C_3 and C_4 biomass in the eastern Africa background atmosphere (Kirago et al.,
243 2022c). Therefore, the relative source contributions were estimated at 50% from C_3 biomass and 50% from C_4 and
244 fossil sources at Mt. Kenya. Hence, a primary CO end member was established at $\delta^{18}\text{O}_{\text{primary}} = 18.4 \pm 3.5\text{‰}$. In
245 Nairobi, fossil fuel combustion was estimated to contribute to 85% of the CO emission in the city ($\delta^{18}\text{O}_{\text{primary}} =$

246 +19.2 ± 4.9‰). Since individual source end members in the primary fraction largely overlap, the model simulations
247 were generally insensitive to chosen priors, as investigated by sensitivity analysis.

248 A similar $\delta^{18}\text{O}$ source signature ($\sim 14.0 \pm 2.1\text{‰}$) was observed at the two Mt. Kenya campaigns (1996/97 and
249 2021). Applying the established endmembers, we estimate the contribution of CO from primary/ combustion
250 sources at the regional background site to be at least 70%. In contrast, we found an almost exclusively primary CO
251 component for the urban Nairobi case. Nairobi is a strong air pollution source region, and the CO loadings largely
252 reflect the city's CO emissions. CO is, e.g., a precursor to low-level ozone, and thus emissions deteriorate air
253 quality. Present findings show that air quality policy should target primary emissions, especially from traffic
254 (Kirago et al., 2022b). In contrast, Mt. Kenya GAW station captures a more regional footprint with a dominant
255 contribution from savanna fires.

256 **4. Conclusion**

257 This study provides ground-observational constraints that broadly supports earlier suggestions that savanna fires
258 are the main emitters and modulators of CO loadings over Sub-Saharan Africa. Albeit data gaps in CO mixing
259 ratios prevent detailed analysis, no clear long-term trend was resolved for the Mt. Kenya GAW station. Isotope-
260 based source apportionment shows that at least two thirds of the CO emitted from East African savanna fires are
261 of primary origins, while for Nairobi primary sources approach 100%. The latter has implications for air quality
262 policy, suggesting primary emissions such as traffic should be targeted, in line with previous findings for BC
263 (Kirago et al., 2022b). These findings put constraints on satellite-based emission inventories and chemical-
264 transport and climate modelling. Overall, this study corroborates earlier findings that in order to reduce the
265 secondary climate warming effect from CO over Sub-Saharan Africa, man-made savanna fires should be reduced
266 (Andersson et al., 2020).

267 **Acknowledgement**

268 This work was supported by research grants from the Swedish Research Council (VR contracts nos. 2013-114,
269 2017-05687 and 2020-05384), the Swedish Research Council for Sustainable Development (FORMAS contract
270 no. 2020-01951), and the Swedish Research Council Distinguished Professor Grant (VR contract no. 2017-
271 01601). Sample analysis was supported by the research grants from European Commission under the Horizon
272 2020 – Research and Innovation Framework Programme, H2020-INFRAIA-2020-1 (grant agreement number
273 101008004).

274 We commend the efforts of the Kenya Meteorological Department (KMD), the Swiss Federal Institute for
275 Materials Science and Technology (Empa), and the Federal Office of Meteorology and Climatology MeteoSwiss
276 for Mt. Kenya GAW Station operations. We appreciate the field and technical support from the staff at the Institute
277 of Nuclear Science & Technology, University of Nairobi and KMD. We commend Prof. Carl Brenninkmeijer and
278 Sergey Gromov for their contribution to science, and contribution to 1996/97 campaign/ data used in this
279 manuscript.

280 We acknowledge the use of data from the World Data Centre for Greenhouse Gases (WDCGG) database
281 (<https://gaw.kishou.go.jp/>), hosted by the World Meteorological Organization. The authors gratefully acknowledge
282 the NOAA Air Resources Laboratory (ARL) for the provision of the HYSPLIT transport and dispersion model
283 and/or READY website (<https://www.ready.noaa.gov>) used in this publication.

284 **Author Contribution**

285 Conceptualization of the study by AA and ÖG. Design and execution of field campaigns by LK, AA, SG and MJG.
286 Management of Mt. Kenya GAW station and instrument calibration by DN, JK, CZ, CF & MS. Isotope analysis
287 by MEP. 1996/97 sampling campaign and sample analysis by TR. Data analysis by LK with support from AA,
288 ÖG, SLH and SG; Manuscript writing by LK with support from co-authors.

289 **Competing interests**

290 The authors declare no competing interests.

393

394 Figure 1: Time series of CO mole fractions at Mt. Kenya GAW station. a) Daily-resolution continuously measured CO
395 mole fraction (Picarro) at Mt. Kenya GAW is represented by black dots. The CO data was retrieved from the WMO's-
396 WDCGG database covering 2002 to 2021. Different instrumentations were used over time, but similar instrumental
397 calibration, quality control, and assurance protocols were applied. Flask-based measurements by NOAA at the station
398 are presented in purple symbols, while flask samples during our 2021 campaign are shown in red symbols. b) Variations
399 in CO mole fractions for the year 2021. The prevailing typical weather conditions are indicated.

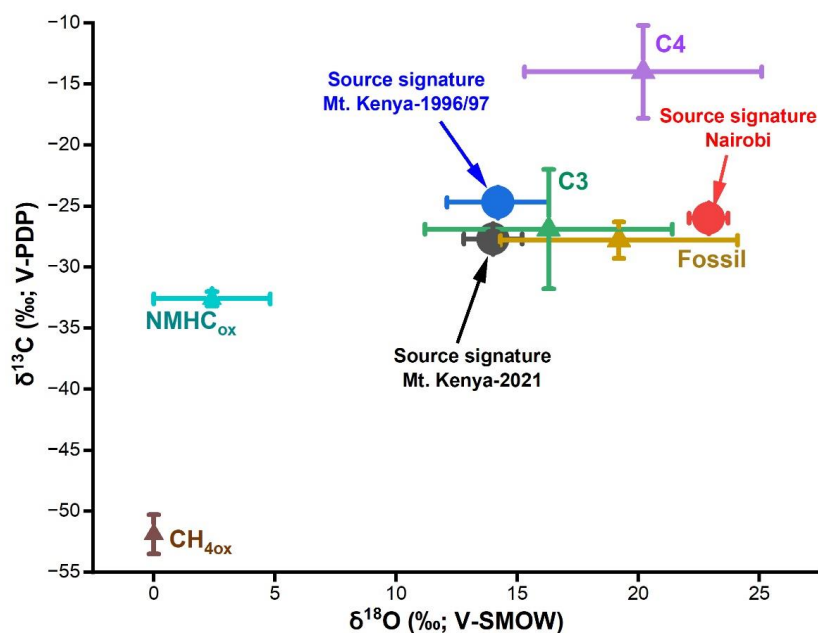

400

401 **Figure 2: Seasonal changes in CO concentration-coded back trajectories intercepted at Mt. Kenya; (a) December –**
402 **February, (b) June – August, (c) March – May, and (d) September – November. Ten days air masses back trajectories**
403 **are calculated at an arrival height of 100 m above ground level.**

404

405 Figure 3: The Keeling relation plots (i.e., isotopic signature vs the inverse of the measured CO mole fraction) for Mt.
 406 Kenya (top panel) and Nairobi (bottom panel). The y-intercept in the Keeling relationship represents the source
 407 signature.

408

409 **Figure 4: Stable isotope ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) source signatures of CO for Nairobi and Mt. Kenya (2021 and 1996/97), and**
410 **the source end members. The source end members are adopted from Brenninkmeijer et al. (1999)**
