17 **Abstract**

18

19 Brown carbon (BrC) aerosol could impact atmospheric radiative forcing and play a cru-  
20 cial role in atmospheric photochemistry. In this study, fine particulate matter (PM<sub>2.5</sub>)  
21 filter samples were collected synchronously in four capital cities of Northwest China  
22 during the winter season (December 2019–January 2020): Lanzhou (LZ), Xining (XN),  
23 Yinchuan (YC), and Urumqi (UR), which are represented as energy-producing and  
24 heavy manufacturing cities in China. The primary aim of the study is to explore the  
25 optical properties, sources, and chemical processes of water-soluble BrC (WS-BrC).  
26 The average mass absorption efficiency at 365 nm (MAE<sub>365</sub>) of WS-BrC at these four  
27 cities was  $1.24 \pm 0.19$  m<sup>2</sup>/g (XN),  $1.19 \pm 0.12$  m<sup>2</sup>/g (LZ),  $1.07 \pm 0.23$  m<sup>2</sup>/g (YC), and  
28  $0.78 \pm 0.16$  m<sup>2</sup>/g (UR), respectively. The properties of WS-BrC were further investi-  
29 gated by an acid-base titration experiment. The results showed that the MAE<sub>365</sub> values  
30 in all cities increased with higher pH values (2–11), while the fluorescence intensities  
31 of water extracts fluctuated with pH values, being stronger under both highly acidic and  
32 basic conditions. The sensitivity to pH variation was most pronounced in the WS-BrC  
33 samples from YC and LZ, indicating the important contribution of acid/base functional  
34 group compounds in these locations. Additionally, the study revealed significant photo-  
35 enhancement (LZ) or photo-bleaching (YC and UR) phenomena of WS-BrC in differ-  
36 ent cities. These results suggest that the sources and/or chemical processes of WS-BrC  
37 varied among the cities.

38

39 The sources and chemical processes of WS-BrC were further explored by a combina-  
40 tion of parallel factor analysis (PARAFAC) on excitation-emission matrix (EEM) spec-  
41 tra of WS-BrC and positive matrix factorization analysis (PMF) on high-resolution  
42 mass spectra of water-soluble organic aerosol (OA). Six PARAFAC components were  
43 identified, including three humic-like substances (two LO-HULIS and one HO-HULIS),  
44 two protein-like (PLS) or phenol-like substances, and one undefined substance. Four  
45 PMF factors were identified, including a water-soluble primary OA (WS-POA), a less

46 oxidized oxygenated OA associated with coal combustion-induced WSOA (LO-OOA),  
47 and two highly oxidized oxygenated OAs resulting from photochemical oxidation and  
48 aqueous-phase oxidation transformations (HO-OOA1 and HO-OOA2). WS-POA was  
49 determined to be the most significant source of light absorption, accounting for 30%–  
50 60% based on multiple linear regression models, and it showed a significant correlation  
51 with PLS and LO-HULIS components. The loss of light absorption of WS-POA was  
52 found to occur through its conversion to LO-OOA and HO-OOAs through photochem-  
53 ical or aqueous reactions, with HO-OOAs being significantly correlated with the HO-  
54 HULIS component. These processes can be clearly illustrated by integrating optical  
55 properties and chemical composition using Van Krevelen diagram and EEM plot.

## 58 **1. Introduction**

59

60 Brown carbon (BrC) is a certain fraction of organic aerosols that absorb light in the  
61 ultraviolet and visible (UV-Vis) ranges (Andreae and Gelencsér, 2006; Laskin et al.,  
62 2015). The light absorption of BrC displays a strong wavelength-dependence which can  
63 be characterized by a higher value ( $\geq 2$ ) of the absorption Ångström exponent (AAE)  
64 (Laskin et al., 2015). The significant effects of BrC on climate and atmospheric chem-  
65 istry have been characterized previously. Wang et al. (2018) estimate the global mean  
66 absorption direct radiative effect (DRE) of BrC is  $+0.048\text{W/m}^2$  using the GEOS-Chem  
67 chemical transport model. The absorption of solar radiation due to BrC can also affect  
68 the formation of ozone and radicals of  $\bullet\text{OH}/\bullet\text{HO}_2$  and corresponding atmospheric chem-  
69 ical reactions (Mok et al., 2016; Baylon et al., 2018).

70

71 Biomass combustion is a major global source of primary BrC, as biomass is widely  
72 used for residential heating and cooking and is also produced during wildfires  
73 (Washenfelder et al., 2015; Lin et al., 2017; Zeng et al., 2020). Coal combustion is  
74 another important source of primary BrC, particularly in urban areas during the winter  
75 heating period (Tan et al., 2016; Hu et al., 2020; Yuan et al., 2021; Deng et al., 2022).  
76 In addition to primary sources, secondary BrC is formed through various reaction path-  
77 ways, such as gas-phase photo-oxidation of aromatic volatile organic compounds  
78 (VOCs), and nighttime aqueous-phase formation of aromatic nitration products in the  
79 atmospheric condensed phase (Lin et al., 2015; Vidovic et al., 2018; Liu et al., 2019).  
80 The chemical compositions and light absorption of BrC can vary significantly due to  
81 atmospheric aging. For instance, BrC can photobleaching through photolysis reactions  
82 in the presence of  $\bullet\text{OH}$  radical and  $\text{O}_3$ , or darken via the formation of nitrated organic  
83 compounds (Lin et al., 2015; Zhao et al., 2015; Moise et al., 2015; Li et al., 2020a).  
84 Furthermore, atmospheric conditions such as changes in pH, air temperature, and rela-  
85 tive humidity can affect the light absorption characteristics of BrC (Song et al., 2013;  
86 Moise et al., 2015; Phillips et al., 2017; Qin et al., 2020).

87

88 The solvent extracts from filter samples have been widely used to assess the absorbing  
89 properties of BrC (Zhang et al., 2017; Wu et al., 2019; Xu et al., 2020b; Zou et al.,  
90 2023). Water-soluble BrC is only a portion of BrC, which accounts for approximately  
91 half of the total light absorption by solvent-extractable organic aerosols in urban areas  
92 (Cheng et al., 2017; Huang et al., 2018; Chen et al., 2020b), and exceeds half and even  
93 up to 90% in remote areas (Zhu et al., 2018; Li et al., 2022). The aerosol extracts are  
94 measured offline using a UV-Vis spectrometer to determine the light absorption of BrC  
95 (Hecobian et al., 2010). Excitation-emission matrix spectroscopy (EEMs) was recently  
96 used to reveal similar chemical structures and photochemical features, as well as to  
97 trace the sources of BrC chromophores (Chen et al., 2016; Tang et al., 2020). A few  
98 recent studies have characterized BrC compounds by combining high-resolution mass  
99 spectrometry and UV-vis spectroscopy (Lin et al., 2017; Wang et al., 2019; Huang et  
100 al., 2020; Ni et al., 2021), which facilitates the assessment of the chemical composition  
101 of BrC chromophores at the molecular level. Recent studies have identified the major  
102 water-soluble BrC species, including humic-like substances, phenols, nitroaromatics,  
103 and oxygenated aromatics (Cai et al., 2020; Qin et al., 2022a; Jiang et al., 2022; Zhou  
104 et al., 2022).

105

106 In recent years, cities in Northwest China have experienced more severe air pollution  
107 due to rapid economic development and intensive anthropogenic activities, especially  
108 in the capital cities of this region. Despite previous research on the chemical composi-  
109 tions and source apportionment of atmospheric aerosols (Xu et al., 2014; Xu et al., 2016;  
110 Tan et al., 2016; Xu et al., 2020a; Zhang et al., 2021a), the current understanding of the  
111 optical properties and formation mechanisms of brown carbon over Northwest China is  
112 quite limited and deserves more attention. This study aims to characterize the optical  
113 properties of water-soluble BrC (WS-BrC) by collecting PM<sub>2.5</sub> filter samples from four  
114 capital cities in Northwest China and analyzing them using a suite of instruments. In  
115 particular, the study focused on the contribution of primary and secondary sources of

116 atmospheric water-soluble chromophores and the related chemical processes. This ob-  
117 jective could be accomplished by combining data from Excitation-Emission Matrices  
118 Spectroscopy (EEMs) and High-Resolution Aerosol Mass Spectrometry (HR-AMS).

119

## 120 **2. Methods**

121

### 122 2.1. Filter samples collection at the four cities

123

124 PM<sub>2.5</sub> filter samples were collected synchronously from four capital cities in Northwest  
125 China, namely Yinchuan (YC), Xining (XN), Urumqi (UR), and Lanzhou (LZ), from  
126 5th December 2019 to 20th January 2020 (Figure 1). The sampling sites were located  
127 on building rooftops and situated within the cultural and educational districts of each  
128 city, away from significant pollution sources. Filter samples were collected by a mid-  
129 volume PM<sub>2.5</sub> sampler (Laoying Ltd., model 2030) with a flow rate of 100 L/min in YC  
130 (sample IDs: 1–14), by a low-volume PM<sub>2.5</sub> sampler (Wuhan Tianhong Instrument Co  
131 Ltd., TH-16E) with a flow rate of 16.7 L/min in XN and UR (sample IDs: 15–28 and  
132 IDs: 29–42), and by a low-volume aerosol sampler (BGI, model PQ 200) with a flow  
133 rate of 16.7 L/min in LZ (sample IDs: 43–56). Fine particles were collected onto quartz  
134 filters with a 90-nm diameter (Whatman, UK) in YC and with a 45-nm diameter (PALL  
135 Life Sciences, USA) in other cities, which had pre-baked at 550 °C for five hours to  
136 eliminate carbonaceous particles. Blank filter samples were obtained from each site by  
137 leaving the filters in the sampler for ten minutes without sampling. Each filter was  
138 wrapped in aluminum foil and frozen at –20 °C until analysis. The daily average con-  
139 centration of PM<sub>2.5</sub>, SO<sub>2</sub>, NO<sub>2</sub>, CO, O<sub>3</sub>, and meteorological data (air temperature and  
140 relative humidity) were obtained from the nearest station of the National Environmental  
141 Monitoring Net sites (<http://www.cnemc.cn/>) for comparison. Figure 1 also illustrates  
142 the energy consumption structure of industrial enterprises in four cities, with YC, UR,  
143 and LZ being energy production cities, and XN being a heavy manufacturing city (Shan  
144 et al., 2018). The energy consumption data for 2019 was obtained from the Statistical

145 Yearbook sharing platform (<https://www.yearbookchina.com/>).

146

## 147 2.2. Chemical analysis

148

149 The chemical components of the samples were analyzed using multiple instruments.  
150 Firstly, a piece of each filter (0.50 cm<sup>2</sup>) was analyzed for organic carbon (OC) and ele-  
151 mental carbon (EC) contents using a Thermal/Optical carbon analyzer (DRI Model  
152 2015A, Desert Research Institute, USA) with the IMPROVE-A method (Chow et al.,  
153 2007). One-quarter of each filter from YC and half of each filter from other cities were  
154 extracted in 30ml of Milli-Q water (18.2 M Ω·cm) using an ultrasonic bath for 40  
155 minutes. Ice was added to the ultrasonic bath to minimize chemical reactions and evap-  
156 oration loss during sonication. Water-insoluble residuals were eliminated by filtering  
157 extracts via a 0.45-μm PTFE syringe filter (Pall Life Sciences, USA). The concentra-  
158 tions of water-soluble inorganic ions (WSIIs) (Cl<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, NH<sub>4</sub><sup>+</sup>, Na<sup>+</sup>, K<sup>+</sup>, Ca<sup>2+</sup>,  
159 and Mg<sup>2+</sup>) were analyzed using two 881 compact ion chromatography systems  
160 (Metrohm, Herisau, Switzerland). The operation details can be found elsewhere (Xu et  
161 al., 2015). WSOC was analyzed using a TOC analyzer (Elementar Vario TOC cube,  
162 Hanau, Germany) with the method of total inorganic carbon (TIC) subtracted from total  
163 carbon (TC) (Xu et al., 2015; Zhang et al., 2017).

164

## 165 2.3. Analysis by ultraviolet-visible absorption spectroscopy

166

167 The absorption spectra of water extracts in the 200–700 nm wavelength range were  
168 obtained using a UV-visible absorption spectrophotometer (UV-2700; Shimadzu,  
169 Kyoto, Japan) at 1 nm intervals with Milli-Q water as the reference. The absorption  
170 spectra were corrected by subtracting the average absorbance between 690–700 nm  
171 (A<sub>700</sub>) from the absorbance at wavelength λ.

172

173 The light absorption coefficient at a given wavelength (Abs<sub>λ</sub>, M/m) of water extracts is

174 calculated as follows:

$$175 \quad \text{Abs}_\lambda = (A_\lambda - A_{700}) \times \frac{V_1}{V_a \cdot l} \times \ln(10) \quad (1)$$

176 where  $A_\lambda$  is the absorbance at wavelength  $\lambda$ ;  $V_1$  is the extract volume (30 mL),  $V_a$  is

177 the volume of air passing through the filter, and  $l$  is the optical path length, 5 cm.

178

179 The mass absorption efficiency ( $\text{MAE}_\lambda$ ,  $\text{m}^2/\text{g}$ ) of water extracts can be derived as

180 follows:

$$181 \quad \text{MAE}_\lambda = \frac{\text{Abs}_\lambda}{C_{\text{WSOC}}} \quad (2)$$

182 where  $C_{\text{WSOC}}$  represents the mass concentration of WSOC in the extract. For simplic-

183 ity, the absorption at 360–370 nm (mean 365 nm) is used to characterize the absorption

184 of BrC (Hecobian et al., 2010).

185

186 The spectral dependence of light absorption fits a power law as follows:

$$187 \quad \text{Abs}_\lambda = K \cdot \lambda^{-\text{AAE}} \quad (3)$$

188 where  $K$  is a constant related to light absorption, and the absorption Ångström exponent

189 (AAE) can be fitted at the range of 300–400 nm.

190

191 The imaginary part  $k$  of the particle refractive index represents the light absorption by

192 aerosols and can be calculated as follows (Liu et al., 2013):

$$193 \quad k_\lambda = \frac{\text{MAE}_\lambda \times \lambda \times \rho}{4\pi} \quad (4)$$

194 where  $\rho$  ( $\text{g}/\text{cm}^3$ ) is estimated as  $\rho = (12 + \text{H}/\text{C} + 16 \times \text{O}/\text{C}) / (7 + 5 \times \text{H}/\text{C} + 4.15 \times \text{O}/\text{C})$

195 (Kuwata et al., 2012).

196

197 The direct radiative forcing of WS-BrC is estimated by the simple forcing efficiency

198 model (SFE). The wavelength-dependent  $\text{SFE}_{\text{Abs}}$  (W/g) of WS-BrC is calculated using

199 the following equation (Bikkina and Sarin, 2019):

$$200 \quad \frac{d\text{SFE}_{\text{Abs}}}{d\lambda} = D \frac{dS(\lambda)}{d\lambda} \tau_{\text{atm}}^2 (1 - F_C) \times 2\alpha_S \times \text{MAE}_\lambda \quad (5)$$

201 where  $S(\lambda)$  represents the wavelength-dependent solar irradiance, obtained from ASTM

202 G173–03 reference spectra. Additionally,  $\tau_{\text{atm}}$  refers to atmospheric transmission (0.79);  
203  $D$  is assigned the value of 0.5, representing the proportion of daylight hours;  $F_C$  is set  
204 to 0.6, representing the cloud proportion;  $\alpha_s$  is fixed at 0.19 for the global average, rep-  
205 resenting the surface albedo (Chen and Bond, 2010).

206

#### 207 2.4. EEM fluorescence spectra analysis

208

209 The three-dimensional excitation-emission matrix spectroscopy (EEMs) of the samples  
210 were obtained using an F-7100 fluorescence spectrometer (Hitachi High-Technologies,  
211 Japan). The EEMs were measured in the range of 200 to 400 nm with 5 nm intervals  
212 for excitation and 250 to 550 nm with 1 nm intervals for emission. The inner filter effect  
213 was reduced by diluting the extracts until their absorbance was below 0.1 at 254 nm  
214 (Ohno, 2002). The original EEMs were processed following: (1) subtracting the Milli-  
215 Q water spectrum to reduce background influence, (2) interpolating to eliminate the  
216 interference signals of the Rayleigh scattered light, then (3) adjusting the fluorescence  
217 intensity by dividing the Raman peak area of Milli-Q water at  $\text{Ex} = 350$  nm to remove  
218 instrument dependency (Lawaetz and Stedmon, 2009).

219

220 The obtained fluorescence intensities (unit of RU) were further processed using parallel  
221 factor analysis (PARAFAC) to group potentially similar chemical components. This  
222 process was conducted using the MATLAB 2016b software combined with the DOM-  
223 Fluor and drEEM toolboxes (Murphy et al., 2013). The 6-component model was even-  
224 tually chosen from 2- to 10-component PARAFAC models because the residual errors  
225 decreased markedly when the number of components increased from 2 to 6 (Figure S1).  
226 In addition, the 6-component model has reasonable spectra of each fluorescent compo-  
227 nent.

228

229 Furthermore, the fluorescence properties of the water extracts were examined through  
230 the fluorescence indices. The humification index (HIX) was calculated by the ratio of

231 the integrated fluorescence emission intensity in the region of 435–480 nm to 300–345  
232 nm under the excitation wavelength of 255 nm. The biological index (BIX) was calcu-  
233 lated by the ratio of the emission intensity of 380 nm to 430 nm under the excitation  
234 wavelength of 310 nm (Zsolnay et al., 1999; Mcknight et al., 2001; Yang et al., 2020b).  
235 The average fluorescence intensities (AFI) can be calculated in the region of 200–400  
236 nm for excitation wavelengths and 250–550 nm for emission wavelengths.

237

238 The apparent fluorescence quantum yields (AQY) can be calculated as follows:

$$239 \quad \text{AQY}_\lambda = \frac{\int \text{FI}(\lambda_{\text{Ex}}, \lambda_{\text{Em}}) d\lambda_{\text{Em}}}{\text{UVA}(\lambda_{\text{Ex}}) \int d\lambda_{\text{Em}}} \Big|_{\text{Ex}} \quad (6)$$

240 where FI represents the fluorescence intensity (RU) at each excitation (200–400 nm)  
241 and emission (250–550 nm) wavelength.

242

## 243 2.5. pH titration experiment

244

245 To investigate the variation of light-absorbing and fluorescent properties of ambient  
246 aerosols under the influence of pH, we selected samples with higher WSOA concentra-  
247 tions at each city and recorded their UV-vis absorption and fluorescence spectra at dif-  
248 ferent pH settings. The water extracts were adjusted to pH 2 using 2 M HCl and then  
249 titrated with 0.1 M NaOH to different pH values until the pH reached 11, as measured  
250 by a pH meter (Orion Star A111, Thermo Fisher Scientific, Waltham, MA, USA). The  
251 pH meter was calibrated with buffer solutions of pH 4.01, 7.00, and 10.01 during the  
252 measurement.

253

## 254 2.6. HR-AMS Measurements

255

256 Offline measurements by high-resolution time-of-flight aerosol mass spectrometry  
257 (HR-AMS) were conducted to analyze the ion group, elemental ratio, and oxidation  
258 properties of water-soluble organic aerosol (WSOA). Each sample was atomized with  
259 argon (purity: 99.9999%) to eliminate interference from CO<sub>2</sub> in the air. The generated

260 aerosol was passed through a silica gel diffusion dryer to remove water vapors, and the  
261 aerosol particles were then sampled into an HR-AMS instrument (Aerodyne Inc.,  
262 Billerica, MA, USA) through an aerodynamic lens inlet. The HR-AMS was operated in  
263 both V- and W-mode. Deionized water was aerosolized and analyzed in the same pro-  
264 cedures between every two samples. Elemental ratios, including O/C, H/C, N/C, and  
265 OM/OC, were determined based on high-resolution mass spectra ( $m/z$  up to 120) and  
266 the Improved-Aiken (I-A) method (Canagaratna et al., 2015). The elemental contribu-  
267 tions of C, O, H, and N reported are mass-based, and more details can be found else-  
268 where (Xu et al., 2013). Positive matrix factorization (PMF) was performed on high-  
269 resolution mass spectra of WSOA at four cities to identify the potential source factors  
270 of WSOA, and four factors were ultimately decomposed. A detailed description of PMF  
271 can be found in Zhao et al. (2022).

272

273 In addition, the mass concentration of WSOA can be calculated as follows:

$$274 \quad \text{WSOA} = \text{WSOC} \times (\text{OM/OC}) \quad (7)$$

275

### 276 **3. Results and discussions**

277

#### 278 **3.1. Overview of the field observations**

279

280 Figure 2 presents an overview of the time series of meteorological conditions (air tem-  
281 perature, relative humidity (RH), and precipitation),  $\text{Abs}_{365}$ , AFI, as well as the mass  
282 concentrations of WSIs, WSOA, and EC in the four cities. The weather during the  
283 study was generally sunny, cold, and dry (Figure 2a). For instance, the average ( $\pm 1\sigma$ )  
284 daily air temperature was  $-3.2 \pm 3.4$  °C at YC,  $-4.4 \pm 2.2$  °C at XN,  $-9.2 \pm 3.7$  °C at  
285 UR, and  $-3.8 \pm 2.5$  °C at LZ, respectively, and the average ( $\pm 1\sigma$ ) RH was  $62.4 \pm 15.8\%$   
286 at YC,  $56.1 \pm 14.7\%$  at XN, and  $58.1 \pm 9.7\%$  at LZ. At UR, there were relatively higher  
287 RH conditions ( $83.9 \pm 6.6\%$ ), and frequent foggy weather and two snowfall events were  
288 observed mainly due to the invasion of cold and wet air mass from the Arctic Ocean

289 during winter (Yang et al., 2020a). Both the cold/wet and cold/dry weather conditions  
290 in our study facilitated the study of different chemical processes.

291

292 The mass concentrations of chemical species of PM<sub>2.5</sub>, as well as their mass fractions,  
293 varied dynamically during the sampling period in four cities (Figure 2c and 2d). Heavy  
294 pollution (the daily average PM<sub>2.5</sub> mass concentration higher than 150 μg/m<sup>3</sup>) occurred  
295 frequently in UR, followed by YC (Figure 1). These heavy pollution events, such as the  
296 sample ID of 10–13 and 36–40, commonly occurred under high RH conditions (Figures  
297 2a and 2c), which were favorable for the secondary generation of atmospheric particu-  
298 late matter (Sun et al., 2013). Therefore, the contribution of secondary inorganic ions  
299 (SNA: sulfate + nitrate + ammonium) showed an important contribution to the recon-  
300 structed PM<sub>2.5</sub> mass (WSOA + EC + WSIs) with an average of 53.0 ± 12.7%, 41.6 ±  
301 11.5%, 67.3 ± 7.8%, and 41.8 ± 7.3%, respectively, in YC, XN, UR, and LZ, and could  
302 be as high as 65.6–76.9% during heavy pollution period at YC and UR (Figure  
303 2d). WSOA was also a major component of PM<sub>2.5</sub> accounting for 31.4 ± 5.5%, 40.6 ±  
304 5.4%, 21.8 ± 4.6%, and 37.7 ± 4.1% at YC, XN, UR, and LZ, respectively. The mass  
305 contribution of EC was comparable in four cities (5.8–8.9%). The higher contribution  
306 of SNA at YC and UR, in contrast with the higher contribution of WSOA at XN and  
307 LZ, likely suggested their different sources and chemical processes. The contributions  
308 of WSOA and SNA at XN and LZ in our study were comparable with those in Xi'an,  
309 another megacity in Northwest China, during wintertime (Huang et al., 2014), while  
310 YC and UR showed greater similarity with cities in East China, such as Beijing, Tianjin,  
311 and Jinan, where relatively wet condition during wintertime (Lei et al., 2021; Zhang et  
312 al., 2021c; Dao et al., 2022).

313

314 The ratio of WSOC/OC is commonly used to predict the potential contribution of sec-  
315 ondary organic aerosol to total organic aerosol (Psichoudaki and Pandis, 2013). Overall,  
316 WSOC showed a strong correlation with OC ( $R^2 = 0.84$ ) with a linear slope of 0.55 for  
317 all samples from four cities (Figure S3). The slope values varied among the cities, with

318 YC and UR having higher values (0.61 and 0.59) than XN and LZ (0.54 and 0.52),  
319 suggesting a potentially higher secondary OA formation in YC and UR. The WSOC/OC  
320 values in our study were within the range reported in other cities during winter, such as  
321 Xi'an (0.50 and 0.53) (Zhang et al., 2018; Liu et al., 2020), Beijing (0.54) (Ni et al.,  
322 2022), and Guangzhou (0.55) (Tao et al., 2022). Significant correlations among corre-  
323 lations among WSOC, OC, EC, Cl<sup>-</sup>, K<sup>+</sup> and SNA were found in four cities, indicating  
324 the primary and secondary sources of water-soluble organic compounds (Figure S2,  
325 Table S3). Furthermore, the Abs<sub>365</sub> and AFI values varied with WSOC concentration,  
326 and we observed significant correlation between them ( $R^2_{\text{Abs Vs. WSOC}} = 0.87$ ;  $R^2_{\text{AFI Vs.}}$   
327  $\text{wsoc} = 0.61$ ). These findings suggest indicating an important contribution of WS-BrC  
328 chromophores to WSOC.

329

### 330 3.2. Bulk optical properties of WS-BrC

331

332 Figure 3a presents the average MAE spectra of WSOA from various cities. XN and LZ  
333 exhibited significantly higher MAE<sub>365</sub> values ( $1.22 \pm 0.18$  and  $1.19 \pm 0.12$  m<sup>2</sup>/g) com-  
334 pared to YC ( $1.02 \pm 0.23$  m<sup>2</sup>/g) and UR ( $0.78 \pm 0.16$  m<sup>2</sup>/g) (t-test,  $P < 0.01$ ) (Table 1).  
335 When compared with previous studies during wintertime, the MAE<sub>365</sub> values in XN and  
336 LZ were comparable to those in Beijing (1.21–1.26) (Du et al., 2014; Cheng et al., 2016;  
337 Li et al., 2020b); the MAE<sub>365</sub> values in YC were close to those in Guangzhou ( $0.93 \pm$   
338  $0.06$  m<sup>2</sup>/g), and in Nanjing ( $1.04$  m<sup>2</sup>/g) (Fan et al., 2016; Chen et al., 2018); and the  
339 MAE<sub>365</sub> values in UR were similar to those in Yangzhou ( $0.75 \pm 0.29$  m<sup>2</sup>/g) (Chen et  
340 al., 2020b). In addition, the imaginary refractive index at 365 nm ( $k_{365}$ ) for WS-BrC  
341 showed the same trend as MAE<sub>365</sub>, i.e., XN ( $0.034 \pm 0.007$ ) > LZ ( $0.031 \pm 0.007$ ) > YC  
342 ( $0.029 \pm 0.009$ ) > UR ( $0.023 \pm 0.007$ ) (Table 1). Overall, the  $k_{365}$  values in this study  
343 were comparable to those reported in other urban areas, such as Kanpur in central India  
344 during winter (0.042) (Choudhary et al., 2021) and Jinan in northern China during  
345 spring (0.035) (Wen et al., 2021); however, they were higher than those reported in the  
346 Himalayan cryosphere during winter (0.009–0.026) (Choudhary et al., 2022) and in the  
347 northeast margin of Qinghai-Tibetan Plateau during summer (0.022) (Xu et al., 2020b).

348 Previous studies indicated that photochemical aging decreased the  $k$  values for BrC  
349 aerosols (Laskin et al., 2015; Sumlin et al., 2017).

350

351 AAE denotes the wavelength dependence of light absorption of BrC, an important op-  
352 tical parameter that can be used to infer the chemical properties of BrC (Andreae and  
353 Gelencsér, 2006). In this study, the AAE values at YC, XN, and UR were  $6.8 \pm 0.7$ ,  $7.1$   
354  $\pm 0.4$ , and  $6.9 \pm 0.3$ , respectively. Significantly lower AAE was observed ( $6.4 \pm 0.5$ ) at  
355 LZ (t-test,  $P < 0.01$ ) (Table 1). Our AAE values fell within the range of values reported  
356 in other cities during winter for PM<sub>2.5</sub> water extracts calculated in the same wavelength  
357 range, such as at Nanjing (6.8) (Chen et al., 2018), Beijing (7.3 and 7.5) (Du et al., 2014;  
358 Cheng et al., 2016), and Guangzhou ( $6.7 \pm 0.1$ ) (Fan et al., 2016). Previous studies have  
359 suggested that higher AAE values may be associated with primary biomass combustion  
360 emissions and/or SOA formation. For instance, Chen and Bond (2010) emphasized that  
361 particles from smoldering of various wood have higher values of 7–16. Lambe et al.  
362 (2013) indicated that secondary BrC generated in the laboratory also has a higher AAE  
363 value (5.2–8.8). Therefore, the differences in AAE values among the four cities may  
364 indicate their different sources or/and chemical compositions.

365

366 Saleh (2020) proposed an optical-based classification of BrC using the space of MAE<sub>405</sub>  
367 vs. AAE, which is linked with their physicochemical properties (i.e., molecular sizes  
368 and solubility) and atmospheric aging (i.e., photo-enhancement or photo-bleaching).  
369 Almost all samples in this study fell into the region of W-BrC (Weakly absorptive BrC),  
370 similar to ambient samples from other studies (Zhou et al., 2021; Xu et al.,  
371 2022). However, a few samples at UR fell into the region of VW-BrC (Very weakly  
372 absorptive BrC). Furthermore, the WS-BrC in YC exhibited a broader range than in  
373 other three cities, indicating multiple sources and/or processes for WS-BrC in this  
374 city. Higher AAE and MAE<sub>405</sub> values were found in XN, which could be associated  
375 with biomass-burning emissions. Additionally, WS-BrC in LZ was the closest to the  
376 region of M-BrC (Moderately absorptive BrC) among the four cities, and the different

377 positions among them could be related to their chemical processes in each city. For  
378 instance, upon examining the relationship between MAE<sub>365</sub> and the O/C ratio, a positive  
379 correlation was observed only in LZ, while negative relationships were observed in  
380 other three cities (Figure 10). The chemical processes of WS-BrC are discussed in detail  
381 in section 3.7.

382

383 We estimated the integrated mean SFE values of WS-BrC within the 300–700 nm range  
384 (SFE<sub>300-700</sub>) due to the abrupt decrease of solar spectral energy below 300 nm and the  
385 negligible absorption of solar radiation by BrC above 700 nm. SFE<sub>300-700</sub> was larger at  
386 XN ( $4.42 \pm 0.72$  W/g) and LZ ( $4.35 \pm 1.01$  W/g) than at YC ( $3.72 \pm 0.90$  W/g) and UR  
387 ( $2.97 \pm 0.6$  W/g) (Table 1), indicating their stronger light-absorbing capacity of WS-  
388 BrC. The SFE values in this study were similar to those in Hong Kong during winter  
389 (4.4 W/g) (Zhang et al., 2020), slightly higher than those in Jinan during spring (3.3  
390 W/g) (Wen et al., 2021), but only half of those in laboratory biomass burning samples  
391 (7.7–8.3 W/g) (Lei et al., 2018).

392

### 393 3.3. Fluorescence Indices

394

395 Fluorescence indexes, such as HIX and BIX, have been used in recent years to study  
396 the source and chemical processes of atmospheric organic aerosols (Lee et al., 2013; Fu  
397 et al., 2015; Qin et al., 2018; Deng et al., 2022). The HIX indicates the degree of  
398 humification of WSOA, and it increases significantly upon aging (Lee et al., 2013; Fan  
399 et al., 2020). The BIX is broadly in contrast with HIX and is known as the freshness  
400 index. A higher BIX value implies a higher contribution of freshly released organics,  
401 while a lower value indicates greater degrees of aging (Lee et al., 2013; Wen et al.,  
402 2021).

403

404 Table 1 shows that the HIX and BIX values were  $1.85 \pm 0.36$  and  $1.28 \pm 0.14$  at UR,  
405  $1.32 \pm 0.23$  and  $1.48 \pm 0.11$  at YC,  $1.29 \pm 0.27$  and  $1.49 \pm 0.15$  at XN, and  $1.16 \pm 0.18$

406 and  $1.52 \pm 0.11$  at LZ, respectively. The highest HIX value and lowest BIX value were  
407 found in UR, indicating a higher degree of aging/oxidation of WS-BrC. On the other  
408 hand, the lower HIX and higher BIX values observed in LZ suggest a high contribution  
409 of freshly emitted BrC. These results were consistent with the results of the MAE<sub>365</sub>  
410 discussed earlier.

411

412 The HIX exhibits a significant negative correlation with BIX across all the data ( $R^2 =$   
413  $0.86$ , slope =  $2.19$ ) (Figure 4a). In Figure 4b, a comparison is presented between our  
414 findings and other datasets derived from laboratory or ambient aerosols in different  
415 cities throughout China. These datasets can be roughly categorized into three zones,  
416 distinguished by the gray, pink, and blue dashed boxes. The freshly introduced materials  
417 generated from the laboratory (gray box) were located at a much lower position than  
418 those of ambient samples. Differences also existed in ambient samples, with higher  
419 (lower) BIX (HIX) values from our samples (pink box) than those from Eastern China  
420 (blue box) (Qin et al., 2018; Yue et al., 2019; Wen et al., 2021; Deng et al., 2022), which  
421 suggested that our samples are generally less aged than those from Eastern cities,  
422 although the position of UR fell within the overlapped range between these two zones.

423

#### 424 3.4. Influence of pH on optical properties

425

426 Recent studies have shown that the optical properties of BrC vary depending on pH,  
427 which is important for modeling its climate-forcing effect, as the general assumption of  
428 a neutral state for aerosol in models may not be accurate (Phillips et al., 2017). We  
429 investigated the effect of pH on the absorption and fluorescence spectra of WSOA for  
430 our samples (Figures 5 and 6). The absorption spectra showed a significant increase in  
431 absorbance with the increasing pH values (from 2 to 10). The integrated absorbance  
432 (300–450 nm) increased by 66.6%, 55.2%, 43.4%, and 25.3% in YC, LZ, XN, and UR  
433 at pH 10 relative to pH 2 (Figure S4). The MAE<sub>365</sub> increased with increasing pH values  
434 (slope =  $0.03$ – $0.07$ ), while the AAE decreased (slope =  $-0.15$  to  $-0.40$ ) (Figure S5).

435 Notably, the light absorption spectra in YC and LZ exhibited greater sensitivity to pH  
436 variation, evident from their steeper slopes. Previous studies have observed variations  
437 in light absorbance as a function of pH, attributing these changes to the  
438 protonation/deprotonation of carboxyl/phenolic functional groups and/or alterations in  
439 macromolecular conformation (Lin et al., 2017; Phillips et al., 2017; Xu et al., 2020b;  
440 Qin et al., 2020; Qin et al., 2022a). The different sensitivity of WS-BrC to pH at our  
441 sampling sites suggested variations in chemical compositions among them, which could  
442 be further investigated through fluorescence spectra.

443

444

445 The EEM spectra exhibited the highest fluorescent intensity values at pH = 2 and tended  
446 to decrease with increasing pH. However, for the YC and UR samples, the fluorescent  
447 intensity at pH = 10 slightly increased compared to that at pH = 7 (Figure 6). The  
448 underlying mechanism behind the variations in fluorescence intensity with pH values  
449 may be related to the rigid properties of fluorophores. Specifically, the formation of  
450 hydrogen bonds at lower pH values could give the aggregates a stronger rigid planar  
451 conformation and enhance fluorescence efficiency (Ghosh and Schnitzer, 1981; Mei et  
452 al., 2009). As pH values increased, the repulsion among generated anions disrupts  
453 hydrogen bonding, leading to a more open conformation. The increased conformational  
454 flexibility enhanced light absorption while depressing fluorescence. This explained  
455 why the light absorbance of WSOC increased under basic conditions while the  
456 fluorescence intensity increased under acidic conditions. In addition, in Figure 6, the  
457 turning point of fluorescence intensity at pH 2–4 and pH 7–10 may be related to  
458 acidic/basic groups bound to the fluorophore cores (Cox et al., 1999; Milne et al., 2001;  
459 Phillips et al., 2017), and the position variation of the fluorescence peak ( $\lambda_{Em}$ ) can  
460 further reveal the types of acidic/basic groups (Qin et al., 2022a; Qin et al., 2022c). At  
461 XN and LZ, the  $\lambda_{Em}$  redshifted at pH 2–4, indicating the deprotonation of electron-  
462 donating groups (e.g.,  $-OH$  and  $-NH_2$ ), while the  $\lambda_{Em}$  blueshifted at pH 4–7, indicating  
463 the deprotonation of electron-withdrawing groups (e.g.,  $-COOH$ ,  $-C=O$ , and  $-NO_2$ ).

464 At LZ, the  $\lambda_{Em}$  further redshifted at pH 7–10, suggesting another electron-donating  
465 group. In contrast, at YC and UR, the  $\lambda_{Em}$  redshifted in pH 2–7 and then blueshifted in  
466 pH 7–10, suggesting that the deprotonation of electron-donating and electron-  
467 withdrawing groups was different from that of LZ.

468

469 To identify the potential dominant chemical components of WS-BrC responsible for the  
470 pH dependency, we analyzed several fluorescence peaks associated with specific chem-  
471 ical constituents across different pH values (Chen et al., 2003; Fellman et al., 2010).  
472 These peaks including peak A ( Ex/Em = 225–250/356–440 nm), was classified as  
473 humic-like fluorophores (Fu et al., 2015; Qin et al., 2018); peak T (Ex/Em = 270–  
474 280/330–355 nm) and peak B (Ex/Em = 270–280/290–310 nm), were classified as  
475 protein-like fluorophores (Chen et al., 2003; Birdwell and Engel, 2010); and peak M  
476 (Ex/Em = 310–320/380–420 nm), was categorized as oxygenated organic substances  
477 (Chen et al., 2003; Qin et al., 2022b). As shown in Figure 7, peak A dominated the  
478 variation, contributing 78.5%, 69.1%, 74.1%, and 61.2% of the total variation of all  
479 fluorescence peaks in YC, XN, UR, and LZ, respectively. In comparison, other peaks  
480 showed moderate variations in the four cities, ranging from 8.3% to 12.4% for peak M,  
481 11.2% to 17.9% for peak T, and 1.6% to 7.6% for peak B. The variation trend of peak  
482 A was highly consistent with the trends of the average fluorescence efficiency  
483 (AFI/TOC) and the average apparent quantum yield (AQY) over the entire Ex/Em range  
484 at each city (Figures 7 and S7). These results suggested that the major fluorophores in  
485 all the samples are humic-like compounds. Note that although the dominant  
486 contribution comes from the humic-like compound (Peak A) in all the samples, the  
487 chemical composition of humic-like compounds among the cities is somewhat different,  
488 as indicated by the distinct AQY peak shapes of this peak (Figure S6). These differences  
489 can be further elucidated using the PARAFAC model.

490

491 3.5. Fluorescent Components

492

493 Using the PARAFAC model, we identified six chromophore components (C1–C6) from  
494 EEMs (Figure 8 and Table S2). C1 displayed a primary peak (Ex/Em) at 230 nm/375  
495 nm and a secondary peak at 320 nm/375 nm, while C5 exhibited two similar peaks at  
496 210 nm/373 nm and 280 nm/373 nm, albeit with a blueshift. These two chromophores  
497 were identified as less oxygenated humic-like substances (LO-HULIS), typically  
498 associated with combustion sources (Chen et al., 2016; Chen et al., 2020a; Chen et al.,  
499 2021). Therefore, we speculated that C5 is likely a primary chromophore, while a  
500 redshift of C1 suggests that C1 is a secondary product (Matos et al., 2015; Wang et al.,  
501 2020). C2 exhibited a fluorescence peak at (255 nm/364 nm) and has been observed in  
502 previous studies on fossil burning aerosol but has not been defined (Tang et al., 2020;  
503 Chen et al., 2020a). C3, peaking at 240 nm/300 nm (Ex) and 414 nm (Em) and was  
504 regarded as a highly oxygenated humic-like chromophore (HO-HULIS), commonly  
505 considered as a secondary formation (Chen et al., 2016; Yan and Kim, 2017; Cao et al.,  
506 2021). Notably, Hawkins et al. (2016) and Aiona et al. (2017) discovered that the fluo-  
507 rescence generated by the aqueous-phase reaction of aldehydes with ammonium sulfate  
508 or amines highly matched the HULIS fluorescence peak (Ex < 250/~300 nm, Em > 400  
509 nm) in WSOA of ambient aerosol. C4 (Ex = 225/275 nm and Em = 338 nm) and C6  
510 (Ex = 220 nm, Em = 292 nm) both peaked at a short wavelength and were usually  
511 characterized as protein-like fluorophores (PLS) (Yan and Kim, 2017; Wu et al., 2019;  
512 Chen et al., 2020a; Chen et al., 2021), but could also be phenol-like substances or other  
513 aromatic compounds, especially for urban ambient aerosol samples (Barsotti et al.,  
514 2016; Chen et al., 2020a; Cao et al., 2021; Deng et al., 2022). The average relative  
515 contributions of chromophores were dominated by HULIS chromophores (C1, C3, and  
516 C5) with a total contribution of 56.5–68.4%, followed by PLS chromophores (C4 and  
517 C6) (16.5–22.3%), and then the undefined chromophores (C2) (14.9–20.8%) (Figure  
518 2e). Additionally, significant differences existed in the relative content of each fluores-  
519 cent component among the four cities. For example, the content of C1 was higher in  
520 YC (38.4% vs. 28.7–31.0% in the other three cities) (t-test,  $P < 0.01$ ), the contents of  
521 C2 and C4 were higher in LZ (20.8% and 21.1%) than in other three cities (14.7–16.2%

522 and 11.2–18.6%) (t-test,  $P < 0.01$ ), and the content of C3 was significantly higher in  
523 UR than in YC, XN and LZ (28.6% vs. 18.8–19.4%) (t-test,  $P < 0.01$ ).

524

### 525 3.6. Source apportionment of WSOA by PMF analysis

526

527 Four WSOA factors were identified through PMF analysis on the high-resolution mass  
528 spectra of WSOA at four cities, including a water-soluble primary OA (WS-POA), two  
529 highly oxidized oxygenated OA (HO-OOA1 and HO-OOA2), and a less oxidized oxy-  
530 genated OA (LO-OOA) (Figure 9). The mass spectrum of WS-POA was dominated by  
531  $C_xH_y^+$  (51%) fragment ions, followed by  $C_xH_yO_1^+$  (24%),  $C_xH_yO_2^+$  (14%),  $C_xH_yN_p^+$   
532 (6%),  $H_yO_1$  (4%), and  $C_xH_yO_zN_p^+$  (1%). The WS-POA had the lowest O/C (0.47) and  
533 the highest H/C (1.68) among the four factors, but its O/C was much higher than those  
534 of online measurement decomposed POA ( $< 0.1$ ) (Xu et al., 2020a; Zhao et al., 2022). In  
535 addition to oxygen-containing ions, the WS-POA exhibited a few characteristics similar  
536 to those of the online measurement decomposed POA, such as relatively high  $m/z$  at 55  
537 and 57 with the  $m/z$  55-to-57 ratio being 2.67, 60 (fraction of signal = 0.39%), and 115  
538 (fraction of signal = 0.21%), which could be related to cooking, biomass burning, and  
539 coal combustion, respectively. These results suggested that the WS-POA factor in our  
540 study represents mixed primary sources. The mass contribution of WS-POA was  $26.2$   
541  $\pm 19.1\%$ ,  $42.9 \pm 15.2\%$ ,  $30.7 \pm 10.2\%$ , and  $48.8 \pm 9.3\%$  in YC, XN, UR, and LZ, re-  
542 spectively.

543

544 The mass spectrum of LO-OOA also displayed a pronounced signal at  $m/z$  115 (signal  
545 fraction = 0.36%), and its concentration was highly correlated with specific PAH sig-  
546 nals, such as  $C_6H_3^+$ ,  $C_7H_4^+$ ,  $C_8H_5^+$ , and  $C_9H_5^+$  (Figure 9), indicating that LO-OOA was  
547 associated with coal combustion-induced WSOA. However, LO-OOA exhibited signif-  
548 icantly higher  $OS_c$  (-0.05 vs. -0.74 for LO-OOA and WS-POA, respectively), lower  
549  $C_xH_y^+$  ions (33%), and higher combination of oxygenated ions (57% in total), including  
550  $C_xH_yO_1^+$  (32%),  $C_xH_yO_2^+$  (18%),  $H_yO_1$  (4%), and  $C_xH_yO_zN_p^+$  (2%), compared to the

551 primary factor. These implied that LO-OOA likely represented a low oxidation OOA  
552 associated with coal combustion-induced WSOA. The same factor was also observed  
553 in water-soluble aerosol samples from Beijing during winter (Hu et al., 2020). The mass  
554 contribution of LO-OOA was  $25.2 \pm 15.3\%$ ,  $10.9 \pm 3.3\%$ ,  $6.4 \pm 2.3\%$ , and  $7.3 \pm 1.6\%$   
555 in YC, XN, UR, and LZ, respectively.

556

557 The mass spectrum of HO-OOA1 was characterized by a distinct signal at  $m/z$  44,  
558 which accounted for 20.4% of the total signal and was mainly composed of  $\text{CO}_2^+$  (94%).  
559 Additionally, HO-OOA1 exhibited a high O/C value (0.97), indicating its high oxida-  
560 tion. HO-OOA1 was significantly correlated with nitrate and odd oxygen ( $\text{O}_x = \text{O}_3 +$   
561  $\text{NO}_2$ ), which are the products of photochemical processes (Figure S7), suggesting that  
562 HO-OOA1 was photochemically produced (Herndon et al., 2008; Ye et al., 2017). The  
563 mass contribution of HO-OOA1 was  $29.6 \pm 18.1\%$ ,  $37.2 \pm 10.1\%$ ,  $13.4 \pm 10.2\%$ , and  
564  $38.3 \pm 8.5\%$  in YC, XN, UR, and LZ, respectively. The HO-OOA2 exhibited compara-  
565 ble O/C with that of HO-OOA1 (0.99 vs. 0.97), but it had a higher N/C ratio (0.094 vs.  
566 0.041) and a stronger correlation with RH and sulfate than HO-OOA1, suggesting its  
567 potential for aqueous processing production (Sun et al., 2016; Wang et al., 2021). Fur-  
568 thermore, HO-OOA2 exhibited a significant correlation with  $\text{CH}_2\text{O}_2^+$  ( $r = 0.48$ ,  $P <$   
569  $0.01$ ), a typical fragment ion for glyoxal, which could be generated from ring-breaking  
570 in the aqueous-phase oxidation of polycyclic aromatic hydrocarbons (Chhabra et al.,  
571 2010; Wang et al., 2021). The mass contribution of HO-OOA2 were  $19.0 \pm 5.8\%$ ,  $8.9$   
572  $\pm 6.2\%$ ,  $49.5 \pm 7.2\%$ , and  $5.1 \pm 2.7\%$  in YC, XN, UR, and LZ, respectively. Overall,  
573 the WSOA in LZ exhibited the highest contribution of POA. Conversely, the WSOA in  
574 UR had the highest contribution of HO-OOA2, while the WSOA in YC demonstrated  
575 the highest contribution of LO-OOA (Figure 2).

576

577 To further assess the relative light absorption contributions of WSOA from different  
578 sources, the four WSOA factors mentioned above were assigned to  $\text{Abs}_{365}$  using the  
579 multiple linear regression model (MLR), as described in the following equation:

580  $Abs_{365} = a \times [WS-POA] + b \times [LO-OOA] + c \times [HO-OOA1] + d \times [HO-OOA2]$   
581 where [WS-POA], [LO-OOA], [HO-OOA1], and [HO-OOA2] are the mass concentra-  
582 tions of WSOA factors, and a, b, c, and d denote regression coefficients ( $m^2/g$ ), repre-  
583 senting the MAE value for each factor.

584

585 The reconstructed  $Abs_{365}$  fits well with the measured  $Abs_{365}$ , and the slope is close to 1  
586 (Figure S8), indicating the effectiveness of the algorithm. The fitted MAE values were  
587 higher for WS-POA and LO-OOA, with values of 1.34 and 1.33 ( $m^2/g$ ), respectively  
588 (Table S4). These values were comparable to those of FF-POA (fossil-fuel POA) (1.35)  
589 and LO-OOA (1.24) factors previously determined during the winter in Beijing (Wang  
590 et al., 2021). The lower MAE of HO-OOA1 (1.10  $m^2/g$ ) was likely attributed to photo-  
591 bleaching occurring in photochemical processes (Browne et al., 2019; Chen et al.,  
592 2020b; Zhang et al., 2021b). The lowest MAE value for HO-OOA2 (0.58  $m^2/g$ ) sug-  
593 gested a strong photobleaching effect of the aqueous-phase oxidation process (Wang et  
594 al., 2021). The average relative contributions of different WSOA factors to light ab-  
595 sorption are shown in Figure 9c. WS-POA was the most important WS-BrC in our study,  
596 contributing 60%, 51%, 46%, and 30% of  $Abs_{365}$  in LZ, XN, UR, and YC, respectively.  
597 HO-OOA1 also played an important role in the absorption of WS-BrC, contributing  
598 nearly 30% except in UR (only 13%). HO-OOA2 emerged as a significant contributor  
599 to WS-BrC (32%) in UR due to its high-quality contribution (50%), while it was the  
600 least contributing factor to  $Abs_{365}$  in other three cities (only 2–11%). LO-OOA was an  
601 equally important contributor to  $Abs_{365}$  as WS-POA in YC (31% vs. 30%), while the  
602 contribution was around 10% in other three cities.

603

### 604 3.7. Chemical transformations of chromophores

605

606 The light-absorption capacity of BrC is closely related to atmospheric aging processes  
607 and their chemical composition (Lin et al., 2016; Jiang et al., 2022). To understand the

608 relationship between light-absorption properties and chemical processes, several in-  
609 dexes, including O/C, H/C, N/C, and carbon oxidation state (OSc), were investigated  
610 for the relationship with MAE<sub>365</sub> and AAE (Figure 10). The indexes of O/C and OSc,  
611 which reflect the degree of atmospheric aging, were lower in LZ than in other cities  
612 (0.58 vs. 0.64–0.77). A significant positive relationship was observed between O/C and  
613 MAE<sub>365</sub> in LZ ( $r = 0.57$ ), while significant negative relationships were observed in YC  
614 and UR ( $r = -0.70$  and  $-0.53$ ). These findings suggested that the photo-enhancement  
615 phenomenon occurred in LZ, while the photo-bleaching phenomenon took place in the  
616 other three cities. Fitting MAE<sub>365</sub> vs. O/C for all data from the four cities using least-  
617 squares linear regression (Figure S9), the trend changed around an O/C ratio of 0.64:  
618  $MAE_{365} = 1.04 \times O/C + 0.58$  for  $O/C < 0.64$ , and  $MAE_{365} = -1.23 \times O/C + 1.90$  for  
619  $O/C \geq 0.64$ . A similar phenomenon was found by Jiang et al. (2022) in various polar  
620 solvent extracts of PM<sub>2.5</sub> filters from Beijing, which suggested that chemical processing  
621 is dominated by functionalization for the low O/C period, while it is primarily con-  
622 trolled by fragmentation for the high O/C period. Therefore, we inferred that the photo-  
623 enhancement phenomenon in LZ is probably due to the initial aging of fresh WSOA.

624

625 The variation between MAE<sub>365</sub> and H/C was broadly opposite to that of O/C. A signif-  
626 icant positive correlation between MAE<sub>365</sub> and H/C was observed in YC and UR, sug-  
627 gesting a higher MAE<sub>365</sub> for fresh aerosols. MAE<sub>365</sub> values showed a significantly pos-  
628 itive correlation with N/C in YC, XN, and LZ ( $r = 0.57$ ,  $0.50$ , and  $0.51$ , respectively),  
629 while a weak correlation in UR ( $r = 0.11$ ), indicating that N-containing organic species  
630 are effectively light-absorbing chromophores (Chen et al., 2018). To elucidate the po-  
631 tential chemical composition and sources of N-containing species, a correlation analy-  
632 sis between MAE<sub>365</sub> and N-containing fragment ions was conducted. Higher correlation  
633 coefficients were found for the  $C_xH_yN_p^+$  and  $C_xH_yO_zN_p^+$  family ions, such as  $CHN^+$ ,  
634  $CH_4N^+$ ,  $C_2H_3N^+$ ,  $C_2H_6N^+$ ,  $C_3H_8N^+$ ,  $C_2HNO^+$ ,  $C_2H_2NO^+$ ,  $C_2H_5NO^+$ , and  $C_3H_4NO^+$  (Fig-  
635 ure S10). These ions may be associated with amine, imine, N-heterocyclic compounds  
636 (e.g., imidazole), organonitrates, and nitroaromatic compounds, which have been

637 proven to be important BrC components in ambient aerosol (Farmer et al., 2010; Sun  
638 et al., 2012; Kim et al., 2019; Kasthuriarachchi et al., 2020; Ditto et al., 2022; Jiang et  
639 al., 2022).

640

641 The relationship between AAE and O/C was also investigated. In YC, AAE increased  
642 significantly with rising O/C (slope = 2.62,  $r = 0.55$ ), which could be attributed to the  
643 significant chemical oxidation and the formation of O-containing functional groups  
644 with weakly light-absorbing characteristics of WSOA (Sumlin et al., 2017; Zeng et al.,  
645 2021), resulting in a shift in the absorption spectrum towards UV wavelengths (Zhang  
646 et al., 2013; Mo et al., 2018). Nevertheless, a significant negative relationship between  
647 AAE and O/C was observed in LZ (slope = -1.41,  $r = -0.51$ ). The initial oxidation  
648 occurring in LZ introduced functional groups to form auxochrome or chromophores,  
649 leading to absorption enhancement and an absorption spectrum red-shift (Lin et al.,  
650 2015; Zeng et al., 2021; Jiang et al., 2022). Additionally, the AAE values showed a  
651 roughly decreasing trend with increasing N/C in the four cities, possibly due to the  
652 abundance of N-heteroatoms leading to a red shift in the absorption spectrum (Jiang et  
653 al., 2022).

654

655 Crossing-correlation among fluorescent chromophores and chemical components of  
656 PM<sub>2.5</sub> were performed to infer the possible sources and atmospheric chemical processes  
657 of WS-BrC (Figure 11a). The results revealed that C1, C3, and C6 were tightly  
658 correlated with SNA, particularly sulfate, indicating contributions from secondary pro-  
659 duction sources. In contrast, C2, C4, and C5 exhibited tight correlations with primary  
660 species like EC, K<sup>+</sup>, and Cl<sup>-</sup>, suggesting origins from primary emission sources.  
661 Furthermore, the fluorescent chromophores were assigned to different WSOA factors  
662 based on Pearson's correlation analysis between the relative abundance of the four PMF  
663 factors and the relative content of the six PARAFAC components. For example, C2, C4,  
664 and C5, identified as primary chromophore components, significantly correlated with  
665 WS-POA. C1, characterized as less oxygenated humic-like components, significantly

666 correlated with LO-OOA, representing secondary chromophoric components with less  
667 oxidation. C3, identified as highly oxygenated humic-like components, strongly corre-  
668 lated with HO-OOA2. Notably, there was a significant positive correlation between C3  
669 and HO-OOA1 when excluding UR data (Figure S11). Thus C3 was likely to represent  
670 secondary chromophoric components with a high degree of oxidation, formed through  
671 either aqueous-phase or photochemical oxidation, with different contributions from  
672 these two aging pathways in different cities of our study. C6 exhibited a significant  
673 correlation with HO-OOA2, and the EEM spectra of C6 overlapped highly with phenol  
674 chromophore (Barsotti et al., 2016; Chen et al., 2020a), implying that C6 might be a  
675 phenol-like chromophore and an aqueous-phase oxidation product. Recent studies have  
676 indicated the presence of benzene and its derivatives in atmospheric waters such as  
677 clouds and fog (Raja et al., 2009). Benzene reacts readily with hydroxyl radicals in the  
678 aqueous phase ( $k_{\text{OH}} = 4.7 \times 10^5 \mu\text{M}^{-1} \text{min}^{-1}$ ), which is much faster than its reaction to  
679 other atmospheric radicals such as ozone ( $k_{\text{O}^3} = 6.1 \times 10^{-6} \mu\text{M}^{-1} \text{min}^{-1}$ ) and nitrate radi-  
680 cals ( $k_{\text{NO}_3} = 4.0 \times 10^{-1} \mu\text{M}^{-1} \text{min}^{-1}$ ) or photolysis in the gas phase (Minakata et al., 2009).  
681 Thus, the atmospheric chemistry reaction of benzenes is likely initiated by  $\bullet\text{OH}$  in the  
682 aqueous-phase, leading to the formation of phenol-like chromophores (Borrás and  
683 Tortajada-Genaro, 2012; Heath et al., 2013; Faust et al., 2017).

684

685 By combining the information provided above into a Van Krevelen plot (H:C vs. O:C),  
686 commonly used to illustrate the evolution of organic aerosols (Heald et al., 2010; Ng et  
687 al., 2011; Canagaratna et al., 2015), a tight relationship between the evolution of  
688 chemical processes and the light absorbance of chromophores was clearly revealed.  
689 Note that in the Van Krevelen plot, each WSOA factor is colored by its fitted MAE<sub>365</sub>,  
690 with the size of each WSOA factor representing the average contribution to Abs<sub>365</sub>, and  
691 the PARAFAC components are also assigned to distinct WSOA factors based on their  
692 relevance to each factor. Overall, the aging processes from fresh species (WS-POA) to  
693 LO-OOA and HO-OOAs, along the direction of increasing OSc, were clearly associated  
694 with a photobleaching phenomenon, as evidenced by a decrease/increase in

695 MAE365/AAE values. The slope from WS-POA to each OOA component could be  
696 used to some extent to describe this photobleaching phenomenon, i.e.,  $-0.91$  for WS-  
697 POA & LO-OOA,  $-0.53$  for WS-POA & HO-OOA1, and  $-0.34$  for WS-POA & HO-  
698 OOA2. A lower slope (closer to  $-1$ ) could be related to the addition of carboxylic acid  
699 functional groups, while higher slopes (such as  $-0.5$ ) could be related to the addition of  
700 alcohol/peroxide functional groups. Additionally, the slopes for each dataset from the  
701 four cities exhibited variation:  $-1.01$  at LZ,  $-0.89$  at XN,  $-0.78$  at UR, and  $-0.71$  at YC.  
702 This variation further underscores the different chemical processes and optical  
703 properties in each city.

704

705 Figure 11c displays the EEM profiles of the six PARAFAC components (indicated by  
706 dashed line) along with their fluorescence peak positions (Ex/Em) (represented by cir-  
707 cles C1–C6), as well as their corresponding compound categories. The potential origins  
708 and atmospheric chemical transformations of these chromophores are further revealed  
709 by correlating the PMF results. The classification of the highly oxygenated and less  
710 oxygenated species regions proposed by Chen et al. (2016) closely matches with our  
711 research findings. However, our results are divided into three distinct categories: fresh  
712 species, less oxidized species, and highly oxidized species, with each region circled by  
713 a different shade of brown box in Figure 11c. Note that the chemical transformation of  
714 the loss of primary chromophores (fresh species) and the generation of secondary chro-  
715 mophores (less oxidized and highly oxidized species) can occur through either photo-  
716 chemical oxidation or aqueous-phase oxidation, with different contributions from the  
717 two aging pathways in different cities. Additionally, certain chromophores formed from  
718 high oxidation processes exhibit short emission wavelengths, which were originally  
719 classified as PLS chromophores, providing a reference for determining PLS sources  
720 and processes in future studies.

721

## 722 **4. Conclusions**

723

724 In this study, a comprehensive comparison was conducted regarding the optical prop-  
725 erties, potential sources, and chemical processes of WSOA using atmospheric aerosols  
726 collected from four typical cities, namely Yinchuan (YC), Xining (XN), Urumqi (UR),  
727 and Lanzhou (LZ). The main conclusions and environmental implications are obtained  
728 as follows.

729

730 Firstly, the optical properties of WSOA were found to be influenced by its chemical  
731 composition. The MAE<sub>365</sub>, HIX, and BIX values of XN (1.24 m<sup>2</sup>/g, 1.29, 1.49) and LZ  
732 (1.19 m<sup>2</sup>/g, 1.16, 1.52) were higher, lower, and higher than those of YC (1.07 m<sup>2</sup>/g,  
733 1.32, 1.48) and UR (0.78 m<sup>2</sup>/g, 1.85, 1.28), possibly due to a higher contribution of  
734 fresh WSOA in XN and LZ and a greater degree of humification and aging/oxidation  
735 of WSOA in YC and UR. Secondly, the optical properties of WSOA were found to be  
736 influenced by pH variation. The integrated absorbance (300–450 nm) and MAE<sub>365</sub> ex-  
737 hibited a monotonically increasing trend with rising pH in four cities. The impact of pH  
738 on EEM spectra was much more complex, involving the rigidity and planarity of mol-  
739 ecule structure and the protonation/deprotonation of electron-withdrawing groups (–  
740 COOH and –NO<sub>2</sub>) and electron-donating groups (–NH<sub>2</sub> and –OH) connected to the  
741 fluorophore nuclei. The WSOA in YC and LZ were found to be most sensitive to pH  
742 variation and exhibited distinct trends, indicating that their chemical structures are rich  
743 in different types of acid/base functional groups. Thirdly, changes in the optical prop-  
744 erties of WSOA were observed during aging/oxidation processes. Obvious photo-  
745 bleaching was observed in YC and UR, while photo-enhancement was observed in LZ,  
746 reflecting the role of the initial aging (functionalization) and further oxidation (frag-  
747 mentation) of fresh WSOA on the optical properties of WS-BrC based on the analysis  
748 of optical properties and bulk chemical characteristics. Finally, the analysis combining  
749 chromophores with WSOA factors can be used to illustrate the chemical processes and  
750 optical variation by V-K plot and EEM plot, which is useful for understanding the dom-  
751 inant chemical pathway at each city.

752

753 Overall, this study provides insights into the optical properties, sources, and chemical  
754 transformations of WS-BrC. These insights will provide an important reference for fu-  
755 ture studies to determine the sources and processes of atmospheric chromophores and  
756 further help to estimate the climatic effects of atmospheric aerosols and control carbo-  
757 naceous aerosol pollution.

758

#### 759 **Data availability**

760 The data used in this study can be accessed on request from corresponding author.

761

#### 762 **Author contributions**

763 JX designed the research and MZ, HW, LG and WL collected samples. MZ processed  
764 data, plotted the figures, and wrote the manuscript when JX and XZ gave constructive  
765 discussion. LZ and WZ had an active role in supporting the experimental work. All  
766 authors contributed to the discussions of the results and refinement of the manuscript.

767

#### 768 **Competing interests**

769 The authors declare that they have no conflict of interests.

770

#### 771 **Acknowledgment**

772 This work was partially supported by the National Natural Science Foundation of China  
773 (41977189) and the Key Laboratory of Cryospheric Sciences Scientific Research Foun-  
774 dation (SKLCS-ZZ-2023).

1282 **Figures**

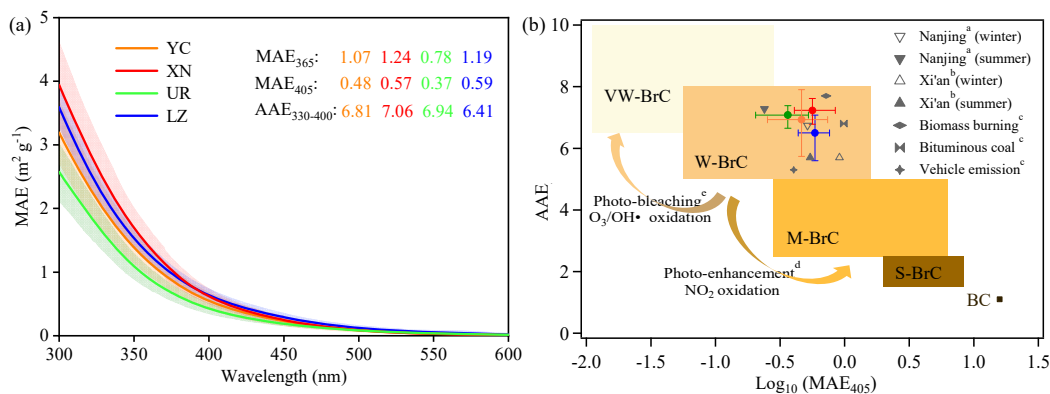

1283  
 1284 Figure 1. Location map for the sampling sites in this study, and the corresponding energy structure  
 1285 in each city and air quality in each city during 2019. The locations of the four cities are also shown  
 1286 the spatial variation of SO<sub>2</sub> concentration in China (resolution of 0.25° × 0.25°), retrieved from OMI  
 1287 satellite data over the whole sampling period of 2019/12-2020/1 (<http://www.satdatafresh.com/>).

1288 Pie charts around the map show the energy consumption structure of industrial enterprises above  
 1289 the designated size during 2019 (China Energy Statistical Yearbook) and the proportion of urban air  
 1290 quality grades during the sampling period at YC, XN, UR, and LZ (<https://www.zq12369.com/>),  
 1291 respectively.

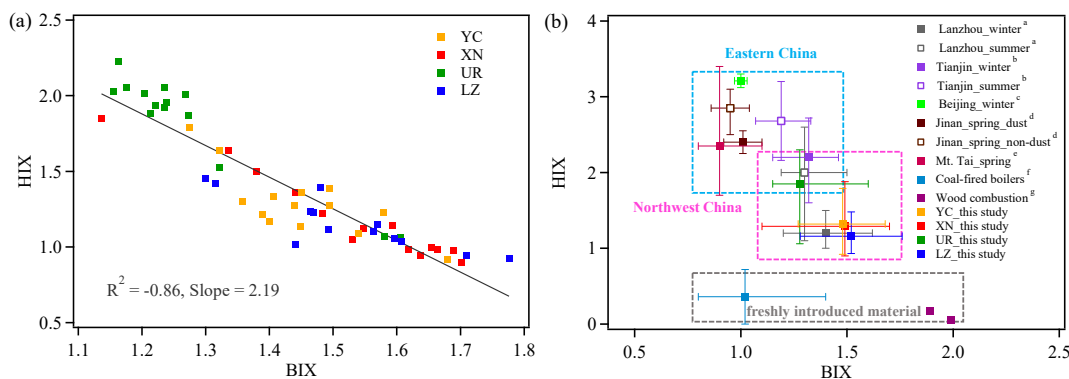

1292  
 1293 Figure 2. Summary of meteorological and aerosol species data. (a) Meteorological condition during  
 1294 the sampling, including air temperature, relative humidity, and precipitation; (b) WSOC concentra-  
 1295 tions, the light-absorption (Abs), and average fluorescence intensity (AFI) of WSOA; (c) the concen-  
 1296 trations of total identified species (WSIIs, WSOA, and EC); (d) The relative abundance of total  
 1297 identified species; (e) The relative abundances of the identified six fluorescent components by  
 1298 PARAFAC analysis; (f) Mass contributions of the factors resolved by PMF analysis on WSOA.  
 1299

1300

1301 Figure 3. (a) The average MAE spectrum and their standard deviations of WS-BrC in each city  
 1302 represented by different colors. (b) Graphical representation of the optical-based BrC classes in the  
 1303  $\log_{10}(\text{MAE}_{405})$ -AAE space (Saleh, 2020). The shaded areas respectively indicate very weakly (VW),  
 1304 weakly (W), moderately (M), and strongly (S) absorbing BrC and absorbing BC. Grey marks indi-  
 1305 cate the data from previous studies about ambient BrC aerosol, i.e., <sup>a</sup>Chen et al. (2018) <sup>b</sup>(Huang et  
 1306 al., 2018) <sup>c</sup>(Tang et al., 2020). The curve with the arrowhead displays the variation tendency of  
 1307 optical properties of the lab-generated BrC aerosol and aged in the presence of  $\text{NO}_3$  or  $\text{O}_3/\text{OH}$  rad-  
 1308 icals, i.e., <sup>d</sup>(Li et al., 2020a) <sup>e</sup>(Browne et al., 2019).

1309

1310

1311 Figure 4. (a) Scatter plots of the humification index (HIX) as a function of the biological index (BIX)  
 1312 for WSOA in four cities. (b) Comparison plot of HIX versus BIX for this study and previous litera-  
 1313 ture, including WSOA from ambient aerosols in Lanzhou <sup>a</sup>(Qin et al., 2018), Tianjin <sup>b</sup>(Deng et al.,  
 1314 2022), Beijing <sup>c</sup>(Qin et al., 2022b), Jinan <sup>d</sup>(Wen et al., 2021), Mt. Tai <sup>e</sup>(Yue et al., 2019), and from  
 1315 coal-fired aerosols <sup>f</sup>(Yang et al., 2020b), and biomass burning aerosols <sup>g</sup>(Fan et al., 2019).

1316

1317 Figure 5. The Influence of pH on absorbance spectra (the insert figure shows the  $\log_{10}(\text{MAE}_{405})$ -

1318 AAE values at different pH).

1319

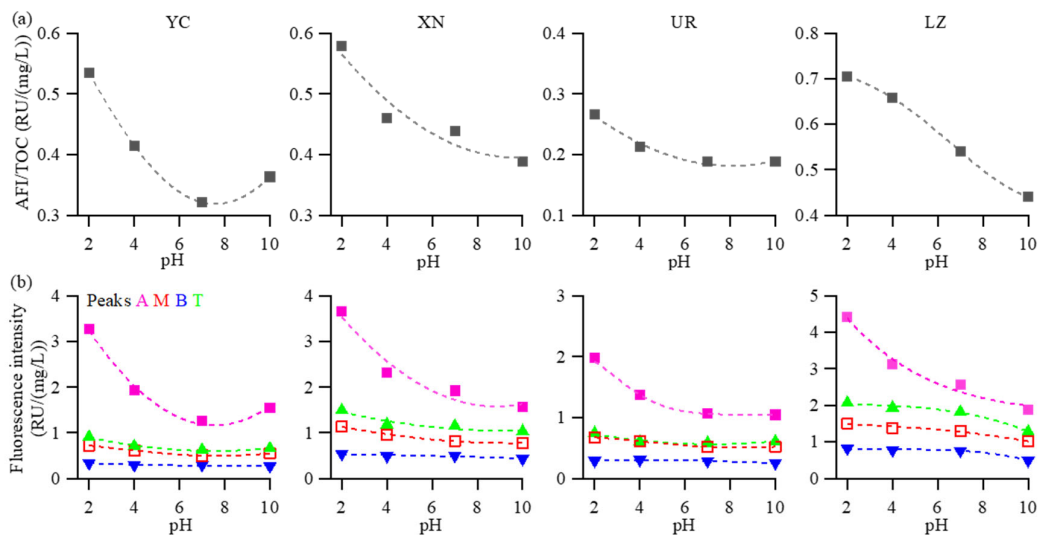

1320

1321

1322

Figure 6. EEM spectra and the fluorescence peak (Ex, Em) of WSOA at different pH values in four cities.

1323

1324

1325

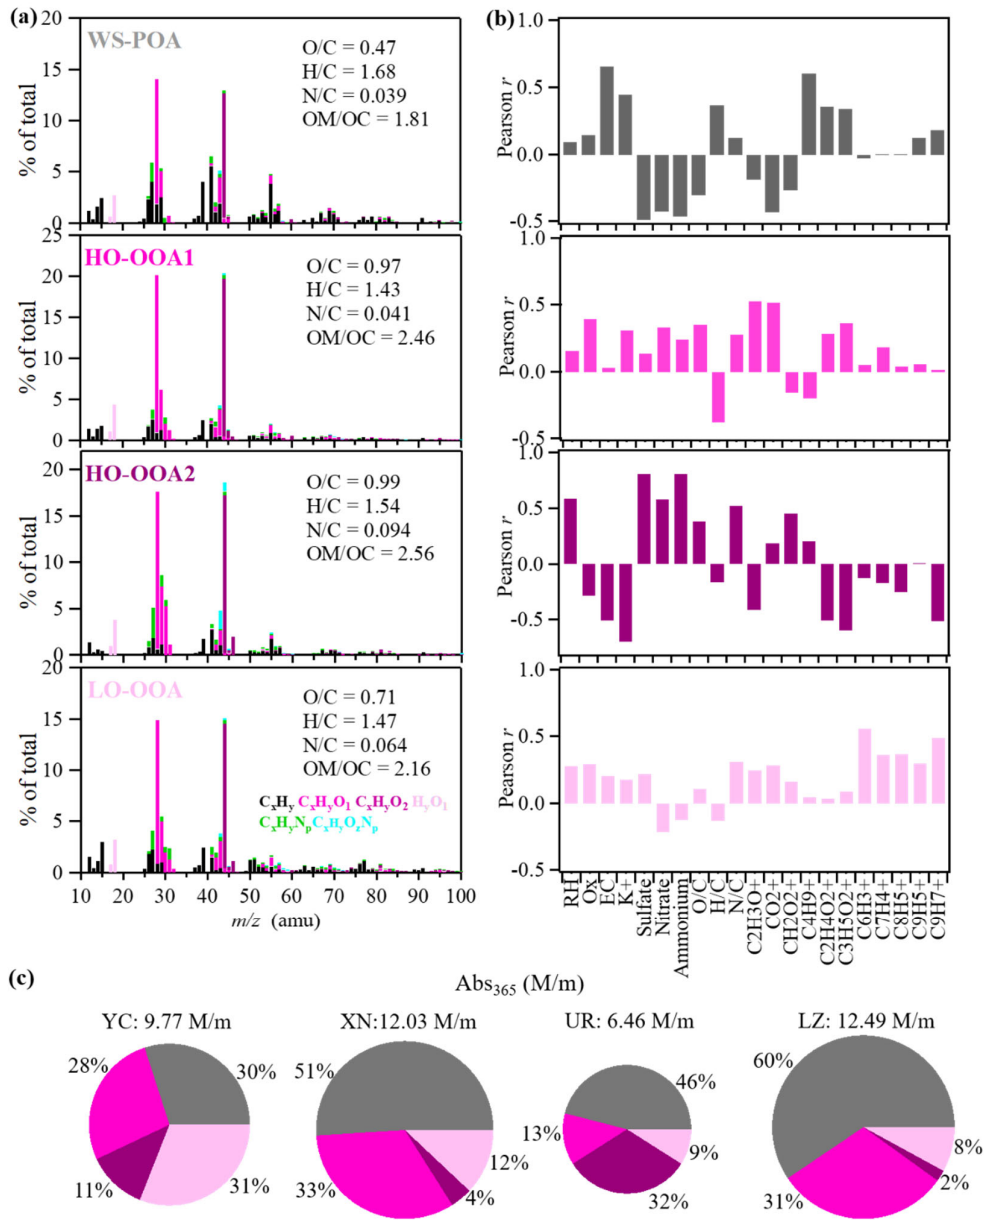

1326

Figure 7. (a) The AFI/TOC and (b) maximum peak intensity of major fluorescence peaks as a function of pH values.

1327  
 1328  
 1329

Figure 8. The EEM components identified by the PARAFAC model for the WSOA.

1330

1331

1332

1333

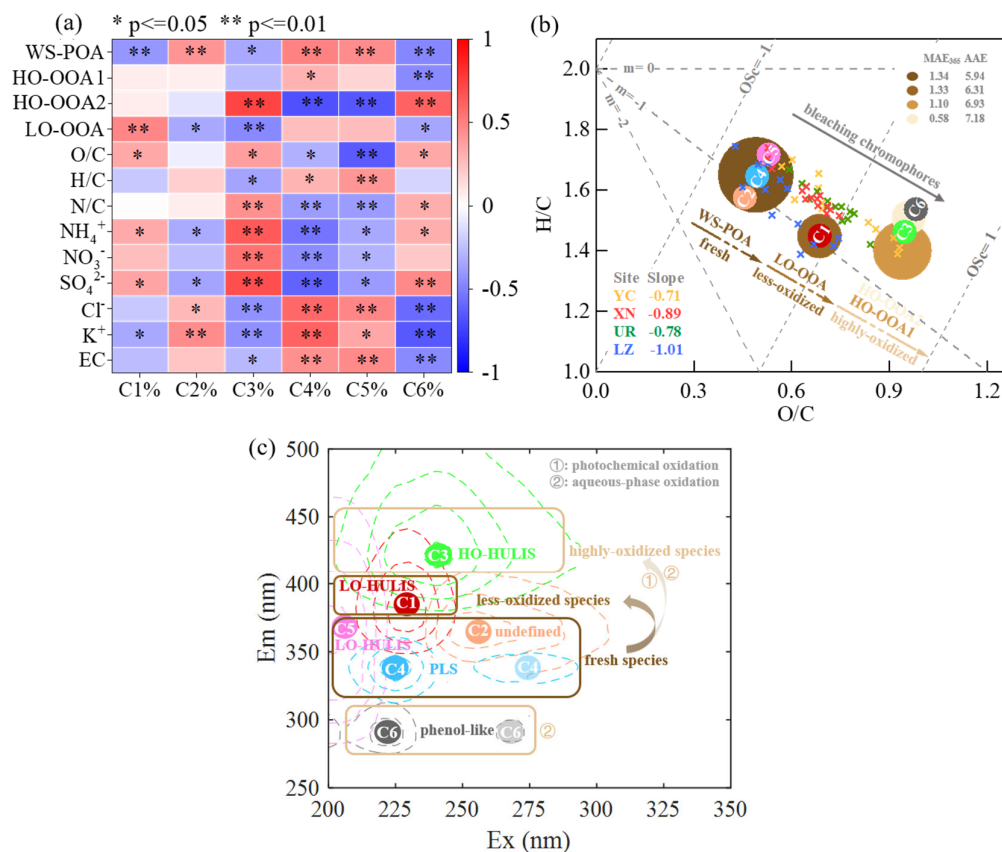

1334

Figure 9. (a) The mass spectra of PMF factors (WS-POA, HO-OOA1, HO-OOA2, LO-OOA), (b) correlations between PMF factors and various tracers, and (c) average contributions of WSOA factors to light absorption at 365 nm.

1335

1336 Figure 10. Scatter plots of MAE<sub>365</sub> (a–d) and AAE (e–h) vs. (a, e) O/C, (b, f) H/C, (c, g) OS<sub>c</sub>, and  
 1337 (d, h) N/C in four cities. The slope and correlation coefficient by fitting the scatter of each group  
 1338 are shown, and the p-test is significant at the 0.05 level when *r* reaches 0.49.  
 1339

1340

1341 Figure 11. The diagram illustrates the aging from fresh species to less oxidized and/or highly-oxi-  
 1342 dized species and the corresponding variation in optical properties. (a) Heatmap of the correlation  
 1343 analysis between the PARAFAC components and PMF factors, with highly significant correlations  
 1344 ( $p < 0.01$ ) are marked by\*\* and significant correlations ( $0.01 < p < 0.05$ ) marked by\*.  
 1345 (b) The Van Krevelen plot (H:C vs. O:C) for ambient WSOA samples and different WSOA factors in this study,

1346 with the slopes of the fitted line for ambient WSOA samples from each city noted in the lower left.  
 1347 The fitted MAE<sub>365</sub> and AAE values for each WSOA factor are noted in the upper right, and each  
 1348 WSOA factor is colored by its MAE<sub>365</sub> value, with fading color indicating bleaching chromophores.  
 1349 The size of the color block represents the average contribution of each WSOA factor to Abs<sub>365</sub>.  
 1350 Based on the correlation coefficients between PARAFAC components and PMF factors, C2, C4,  
 1351 and C5 chromophores were assigned to WS-POA, C1 chromophore were assigned to LO-OOA, and  
 1352 C3 and C6 chromophore were assigned to HO-OOA (HO-OOA1 and HO-OOA2). (c) The Ex-Em  
 1353 plot for fluorescence peak positions (Ex/Em) and the corresponding compounds of these six fluor-  
 1354 ophores.

1355

1356 **Tables**

1357 Table 1. Light-absorbing properties of BrC in PM<sub>2.5</sub> water extract in four cities.

Light absorption property	YC	XN	UR	LZ
AAE	6.81 ± 0.69	7.06 ± 0.44	6.94 ± 0.25	6.41 ± 0.51
Abs <sub>365</sub> (M/m)	9.77 ± 4.74	12.03 ± 3.16	6.46 ± 1.60	12.49 ± 4.94
MAE <sub>365</sub> (m <sup>2</sup> /g)	1.02 ± 0.23	1.22 ± 0.18	0.78 ± 0.16	1.19 ± 0.12
<i>k</i> <sub>365</sub>	0.041 ± 0.007	0.049 ± 0.005	0.034 ± 0.006	0.046 ± 0.008
SFE <sub>300-700</sub> (W/g)	3.72 ± 0.90	4.42 ± 0.72	2.97 ± 0.67	4.35 ± 1.01
