15 **Abstract**

16 Timely, continuous, and dynamics-based estimates of PM_{2.5} emissions with a high temporal
17 resolution can be objectively and optimally obtained by assimilating observed surface PM_{2.5}
18 concentrations using flow-dependent error statistics. The annual dynamics-based estimates of
19 PM_{2.5} emission averaged over mainland China for years 2016-2020 without biomass burning
20 emissions are 7.66, 7.40, 7.02, 6.62 and 6.38 Tg, respectively, which are very closed to the values
21 of MEIC. Annual PM_{2.5} emissions in China have consistently decreased of approximately 3% to
22 5% from 2017 to 2020. Significant PM_{2.5} emission reductions occurred frequently in regions with
23 large PM_{2.5} emissions. COVID-19 could cause a significant reduction of PM_{2.5} emissions in the
24 north China plain and northeast of China in 2020. The magnitudes of PM_{2.5} emissions were greater
25 in the winter than in the summer. PM_{2.5} emissions show an obvious diurnal variation that varies
26 significantly with the season and urban population. Compared to the diurnal variations of PM_{2.5}

27 emission fractions estimated based on diurnal variation profiles from US and EU, the estimated
28 PM_{2.5} emission fractions are 1.25% larger during the evening, the morning peak is 0.57% smaller
29 in winter and 1.05% larger in summer, and the evening peak is 0.83% smaller. Improved
30 representations of PM_{2.5} emissions across time scales can benefit emission inventory, regulation
31 policy and emission trading schemes, particularly for especially for high temporal resolution air
32 quality forecasting and policy response to severe haze pollutions or rare human events with
33 significant socioeconomic impacts.

34

35 **1. Introduction**

36 Anthropogenic emissions have imposed essential influences on the earth system, from
37 hourly air quality and human health to long-time climate and environment. To reduce
38 anthropogenic emissions, the Chinese government has enforced the Clean Air Action (2013) since
39 2013. Studies to date that evaluated the emission controls and understood the climate responses
40 from emission reductions often have used either a fixed meteorology with emission changes or
41 *vice versa* (Li et al., 2019a; Li et al., 2021, Zhai et al., 2021). Estimated emissions from empirical
42 extrapolation were commonly applied to analyze the meteorological-chemical mechanisms and
43 associated social-economic impacts from occasional events like the 2015 China Victory Day
44 Parade and Coronavirus Disease 2019 (COVID-19) pandemic (Wang et al., 2017; Liu et al., 2020;
45 Huang et al., 2020; Zhu et al., 2021). But to better understand both long-term and short-term
46 influences from emission changes, the continuous, up-to-date, and high temporal-/spatial-
47 resolution emission estimates with coherent interactions of meteorology and emission changes are
48 needed.

49 The complex contributions from energy production, industrial processes, transportation,
50 and residential consumptions have imposed great challenges to accurately estimate the emissions.
51 The emission inventories created by the traditional bottom-up techniques were typically outdated
52 from the present day due to the lack of accurate and timely statistics, and often with coarse
53 temporal resolutions from monthly to annual (Zhang et al., 2009; Li et al., 2014; Janssens-
54 Maenhout et al., 2015; Zheng et al., 2018). Alternatively, update-to-date emission estimates with
55 high temporal-spatial resolutions could be provided by top-down techniques (Miyazaki et al.,
56 2017), but most emissions estimated by top-down techniques were intermittent and analyzed at

57 monthly scale or longer longer (Zhang et al., 2016; Jiang et al., 2017; Qu et al., 2017; Cao et al.,
58 2018; Müller et al., 2018; Chen et al., 2019; Li et al., 2019b; Miyazaki et al., 2020). Moreover,
59 emissions updated by the top-down techniques based on satellite observations could be insufficient
60 to capture realistic near-surface characteristics (Li et al., 2019b; Liu et al., 2011; Choi et al., 2020).

61 Given the development of observation networks and advanced data assimilation strategies,
62 timely and dynamics-based emission estimates with high temporal resolution can be achieved by
63 harmonically constraining the atmospheric-chemical model with dense observations of trace gas
64 compounds through an optimal assimilation methodology. The ensemble Kaman smoother (EnKS)
65 (Whitaker et al., 2002; Peters et al., 2007; Peng et al., 2015), as a four-dimensional (4D)
66 assimilation algorithm, makes use of chemical observations from past to future to provide an
67 optimal estimate of source emissions, and it can capture the “error of the day” and construct fine
68 emission characteristics with high temporal-spatial resolutions by using short-term ensemble
69 forecasts (Kalnay, 2002). Since 2013, the fine particulate matter pollution (PM_{2.5}, particles smaller
70 than 2.5 µm in diameter) as the most urgent threat to public health has been persistently decreased,
71 and ground-based observations of PM_{2.5} have been progressively increased (Huang et al., 2018).
72 Thus by harmonically assimilating dense surface PM_{2.5} observations into an atmospheric-chemical
73 model through an EnKS, hourly estimates of PM_{2.5} emission that were continuously cycled for
74 years 2016-2020 are presented in this study.

75 The timely estimated emissions can provide guidance for emission inventories that usually
76 have time lags and emission trading schemes that often require up-to-date source emissions. Based
77 on the dynamics-based estimated emissions with harmonic combination of the model and
78 observations, better evaluation of the emission controls and more comprehensive understanding of
79 the consequent climate responses can be obtained. The high temporal-resolution estimated
80 emissions can reveal features of emissions that are absent from the traditional ones with coarse
81 temporal resolutions. Moreover, the timely and dynamics-based emission estimates with high
82 temporal resolution are essential for regional air quality modeling, especially for the occurrence of
83 severe haze pollutions associated with timely evaluation for the impact on public health (Attri et
84 al., 2001; Wang et al., 2014; Ji et al., 2018; Wang et al., 2020; Liu et al., 2021) and events that
85 lead to large changes of emissions and significant socioeconomic impacts such as the COVID-19
86 pandemic (Huang et al., 2020; Le et al., 2020).

87 2. Data assimilation and experimental design

88 The estimate of PM_{2.5} emission can be successfully constrained by the PM_{2.5} concentration
89 observations through an ensemble Kalman filter (EnKF; Peng et al., 2017, 2018, 2020). For a
90 retrospective ‘reanalysis’ mode here, all available PM_{2.5} concentration observations, including
91 those data collected after the analysis time, can be used. Thus a EnKS, a direct generalization of
92 the EnKF, is applied to incorporate PM_{2.5} concentration observations both before and after the
93 analysis time, aiming to provide an optimal estimate of the PM_{2.5} emission. In simple words, The
94 emissions are updated by current and future observations though EnKS, while the concentrations
95 are updated by current observations though EnKF. Detailed procedures of the EnKS are described
96 in section 2.1.

97 2.1 An ensemble Kalman smoother to update the source emission

98 The ensemble priors of source emissions \mathbf{e}^f is created by multiplying a scaling factor λ^f
99 to the prescribed emission \mathbf{e}^p (Peng et al., 2017, 2018, 2020), where the superscript f denotes priors.
100 Given a time-invariant \mathbf{e}^p , the update of \mathbf{e}^f is equivalent to the update of λ^f . Due to a time lag,
101 the prior scaling factor at time $t-1$ (λ_{t-1}^f) is updated by chemical observations at time t (\mathbf{y}_t^c). At time
102 $t-1$, the prior scaling factor for the i^{th} member is written as

$$103 \lambda_{i,t-1}^f = \frac{1}{M} \left[\left(\beta \frac{\mathbf{c}_{i,t-1}^f}{\bar{\mathbf{c}}_{t-1}^f} + 1 - \beta \right) + \sum_{j=t-M}^{t-2} \lambda_{i,j|j+t-1}^a \right]. \quad (1)$$

104 The first term is the concentration ratio given by the prior of the chemical fields ($\mathbf{c}_{i,t-1}^f$) normalized
105 by the ensemble mean ($\bar{\mathbf{c}}_{t-1}^f$), where β is an inflation factor used to compensate the insufficient
106 ensemble spread (Peng et al., 2017). Through using the concentration ratio, each ensemble member
107 of the source emissions naturally has the spatial correlations given by the chemical fields. The
108 second term is the mean of the posterior scaling factors at previous assimilation cycles, where the
109 superscript a denotes posteriors, M is the length of smoothing, and the subscript $j+1:t-1$ indicates
110 that the scaling factor at time j is updated by future observations from $j+1$ to $t-1$. The assimilation
111 of future observations will be described below.

112 The ensemble square-root filter (EnSRF) (Peng et al., 2017) is used to update λ_{t-1}^f by
 113 assimilating \mathbf{y}_t^c . For the scaling factor at time $t-1$, posterior ensemble mean is given by

$$114 \quad \bar{\lambda}_{t-1}^a = \bar{\lambda}_{t-1}^f + \rho \circ \mathbf{P}_{t-1,t}^{ec} \mathbf{H}_t^{cT} \left(\mathbf{H}_t^c \mathbf{P}_t^c \mathbf{H}_t^{cT} + \mathbf{R}_t^c \right)^{-1} \left(\mathbf{y}_t^c - H_t^c \bar{\mathbf{c}}_t^f \right), \quad (2)$$

115 and posterior ensemble perturbations are given by

$$116 \quad \lambda_{i,t-1}^a = \lambda_{i,t-1}^f - \rho \circ \mathbf{P}_{t-1,t}^{ec} \mathbf{H}_t^{cT} \left[\left(\sqrt{\mathbf{H}_t^c \mathbf{P}_t^c \mathbf{H}_t^{cT} + \mathbf{R}_t^c} \right)^{-1} \right]^T \left[\sqrt{\left(\mathbf{H}_t^c \mathbf{P}_t^c \mathbf{H}_t^{cT} + \mathbf{R}_t^c \right) + \sqrt{\mathbf{R}_t^c}} \right]^{-1} \mathbf{H}_t^c \lambda_{i,t-1}^f, \quad ,$$

117 (3)

118 where $\mathbf{P}_{t-1,t}^{ec}$ denotes the background error covariance matrix of λ_{t-1}^f and \mathbf{c}_t^f , \mathbf{P}_t^c indicates the
 119 background error covariance matrix of \mathbf{c}_t^f , H_t^c , \mathbf{H}_t^c and \mathbf{R}_t^c are the observation forward operator,
 120 Jacobian matrix and observation error covariance matrix of the chemical fields at time t , ρ is the
 121 localization matrix and \circ denotes the Schur (elementwise) product.

122 By applying the ensemble Kalman smoother (EnKS) (Whitaker et al., 2002; Peters et al.,
 123 2007), the chemical observation \mathbf{y}_t^c is also assimilated to update the posterior scaling factor at
 124 previous assimilation cycles $j (j = t - K, \dots, t - 2)$. After assimilating the future chemical
 125 observation at time t , posterior ensemble mean of the scaling factor at j is given by

$$126 \quad \bar{\lambda}_{j|j+1:t}^a = \bar{\lambda}_{j|j+1:t-1}^a + \rho \circ \mathbf{P}_{j|j+1:t-1,t}^{ec} \mathbf{H}_t^{cT} \left(\mathbf{H}_t^c \mathbf{P}_t^c \mathbf{H}_t^{cT} + \mathbf{R}_t^c \right)^{-1} \left(\mathbf{y}_t^c - H_t^c \bar{\mathbf{c}}_t^f \right), \quad (4)$$

127 and posterior ensemble perturbations are given by

$$128 \quad \lambda_{i,j|j+1:t}^a = \lambda_{i,j|j+1:t-1}^a - \rho \circ \mathbf{P}_{j|j+1:t-1,t}^{ec} \mathbf{H}_t^{cT} \left[\left(\sqrt{\mathbf{H}_t^c \mathbf{P}_t^c \mathbf{H}_t^{cT} + \mathbf{R}_t^c} \right)^{-1} \right]^T \left[\sqrt{\left(\mathbf{H}_t^c \mathbf{P}_t^c \mathbf{H}_t^{cT} + \mathbf{R}_t^c \right) + \sqrt{\mathbf{R}_t^c}} \right]^{-1} \mathbf{H}_t^c \lambda_{i,t-1}^f, \quad (5)$$

129 where $\mathbf{P}_{j|j+1:t-1,t}^{ec}$ denotes the background error covariance matrix of $\lambda_{j|j+1:t-1}^a$ and \mathbf{c}_t^f . After (2)-(5),
 130 the updated $\lambda_{j|j+1:t}^a$, $j (j = t - M + 1, \dots, t - 1)$ will be used to construct the prior scaling factor at next
 131 time $t+1$ (1).

132 As a Monte Carlo approach, the EnKS uses the forecast-analysis error covariances based
133 on ensemble forecasts / analyses to compute the Kalman gain matrix with time lags, to incorporate
134 observations from the past to the future. The first iteration of EnKS is equivalent to EnKF that
135 assimilates observations up to the analysis time. The following iterations of EnKS assimilate
136 observations in the future to update the state at the analysis time. The hourly forecasts of PM_{2.5}
137 concentration from the cycling assimilation experiment matched the independent observed
138 quantities (Figure 1). Therefore, the ability of EnKS to retrieve the source emissions has been
139 demonstrated. Previous studies also showed that simulations forced by the posterior emissions
140 could produce improved forecasts for PM_{2.5}, SO₂, and NO₂ than those with a priori emissions
141 (Peng et al., 2020).

142 **2.2 WRF-Chem model, observations and emissions**

143 To simulate the transport of aerosol and chemical species, the WRF-Chem model version
144 3.6.1 (Grell et al., 2005) that has the meteorological and chemical components fully coupled is
145 used. The model parameterization schemes follow Peng et al. (2017). Figure 2 shows the model
146 domain that covers most east Asia regions. Horizontal grid spacing is 45 km with 57 vertical levels
147 and model top at 10 hPa.

148 Experiments are conducted for each year from 2016 to 2020 separately. The 6-h
149 meteorological observations, including all in-situ observations and cloud motion vectors from the
150 National Centers for Environmental Prediction (NCEP) Global Data Assimilation System (GDAS;
151 http://www.emc.ncep.noaa.gov/mmb/data_processing/prepbuftr.doc/table_2.htm), are assimilated
152 every 6 h. The hourly observed chemical quantities, which contain PM₁₀, PM_{2.5}, SO₂, NO₂, O₃,
153 and CO from the Ministry of Ecology and Environment of China (<https://aqicn.org/map/china/cn/>),
154 are assimilated every hour. Figure 2 shows the assimilated chemical observation network, which
155 has 560 randomly chosen stations from 1576 stations in total. The thinning of observations is
156 applied to avoid correlated errors of observations. The spatial autocorrelation of the thinning of
157 observations is close to the original observations (Peng et al., 2017). The observation priors are
158 computed by the “observer” portion of the Grid-point Statistical Interpolation system (GSI) (Kleist
159 et al., 2009).

160 The hourly and time-invariantly prescribed anthropogenic emissions are obtained from the
161 EDGAR-HTAP (Emission Database for Global Atmospheric Research for Hemispheric Transport

162 of Air Pollution v2.2) v2.2 inventory (Janssens-Maenhout et al., 2015), in which the Chinese
163 emissions are derived from MEIC in 2010 (Lei et al., 2011; Li et al., 2014). Natural emissions,
164 including the biogenic (Guenther et al., 1995), dust (Ginoux et al., 2001), dimethyl sulfide and sea
165 salt emissions (Chin et al., 2000), are computed online.

166 2.3 Assimilation and ensemble configurations

167 The $PM_{2.5}$ emission directly gives the primary $PM_{2.5}$, and then the primary $PM_{2.5}$ along
168 with other precursor emissions could contribute to the secondary $PM_{2.5}$. The observations of $PM_{2.5}$
169 concentrations that contain both primary and secondary $PM_{2.5}$, are used to constrain the $PM_{2.5}$
170 emission through data assimilation. Thus the correlations between the concentration observations
171 and source emissions might be contaminated by the secondary $PM_{2.5}$. Since the secondary
172 formation process can be captured by the WRF-Chem model, the impact of the secondary $PM_{2.5}$
173 is indirectly considered. The detailed updated state variables with the according observations
174 follow Peng et al. (2018). The concentrations and emissions of $PM_{2.5}$, NH_3 , and $PM_{2.5}$ precursors
175 (SO_2 and NO) that have observations (~~SO_2 and NO~~), are updated by the observed quantities,
176 respectively. Besides, NH_3 concentrations and emissions are constrained by $PM_{2.5}$ observations,
177 however, but the VOC that are also $PM_{2.5}$ precursors are not updated due to the lack of direct and
178 limited observations. One possible way to untangle the impact of secondary $PM_{2.5}$ on the estimates
179 of $PM_{2.5}$ emission is to jointly estimate the source emission, primary and secondary $PM_{2.5}$ given
180 the concentration observations.

181 The National Oceanic and Atmospheric Administration (NOAA) operational EnKF system
182 (https://dtcenter.ucar.edu/com-GSI/users/docs/users_guide/GSIUserGuide_v3.7.pdf), which is an
183 EnSRF and modified with the EnKS feature, is used to assimilate the observations. Ensemble size
184 is set to 50. To combat the sampling error resulted from a limited ensemble size, covariance
185 localization and inflation are applied. The Gaspari and Cohn (GC) (1999) function with a length
186 scale of 675 km is used to localize the impact of observations and mitigate the spurious error
187 correlations between observations and state variables. The constant multiplicative posterior
188 inflation (Whitaker and Hamill 2012) with coefficients 1.12 for all meteorological and chemical
189 variables is applied to enlarge the ensemble spread. The inflation β for advancing the scale factor
190 is 1.2. The smoothing length M for source emissions is 4, and the EnKS lagged length K is 6. The
191 larger the K value, the more future observations are assimilated to constrain the current emission

192 estimate. But the sample estimated temporal correlations could be contaminated by sampling errors
193 and model errors, especially with increased lagged times. Thus, there is a tradeoff between the
194 amount of future observations and accuracy of sample estimated temporal correlations. The choice
195 of $K (=6)$ is determined by sensitivity experiments.

196 At 0000 UTC 26 December of previous year, ensemble initial conditions (ICs) of the
197 meteorological fields are generated by adding random perturbations that sample the static
198 background error covariances (Barker et al., 2012) on the NCEP FNL (Final) analyses (Torn et al.,
199 2006). Ensemble ICs of the chemical fields are 0, and source emissions of each ensemble member
200 are adopted from the EDGAR-HTAP v2.2 inventory with random perturbations of mean 0 and
201 variances of 10% of the emission values. Hourly ensemble lateral boundary conditions (LBCs) are
202 generated using the same fixed-covariance perturbation technique as the ensemble ICs. After 6-d
203 spin up, ensemble data assimilation experiments start cycling for each year.

204 **3. PM_{2.5} emission for years 2016-2020**

205 Starting from the time-invariant source emission PR2010 (Janssens-Maenhout et al., 2015),
206 the dynamics-based estimates of the PM_{2.5} emissions are obtained, which include both the
207 contributions of the anthropogenic and biomass burning emissions. The mean annual PM_{2.5}
208 emissions from biomass burning in China (2003~2017) was 0.51 Tg (Yin et al., 2019). The annual
209 dynamics-based estimates of PM_{2.5} emission (DEPE) averaged over mainland China for years
210 2016-2020 without biomass burning emissions are 7.66, 7.40, 7.02, 6.62 and 6.38 Tg, respectively.
211 The values from the Multi-resolution Emission Inventory (MEIC; Zheng et al., 2018) that does not
212 consider the contributions of biomass burning emissions, are 8.10, 7.60, 6.70, 6.38 and 6.04 Tg,
213 respectively. Thus the annual DEPE are very closed to the values of MEIC. From year 2017 to
214 2020, the estimated annual PM_{2.5} emissions are reduced 3.4%, 8.4%, 13.6% and 16.7%
215 respectively compared to that of year 2016. There has been 3%-5% persistent reduction of annual
216 PM_{2.5} emission from year 2017 to 2020, which demonstrates the effectiveness of China's Clean
217 Air Action (2013) implemented since 2013 and China Blue Sky Defense War Plan (2018) enforced
218 since 2018 with strengthened industrial emission standards, phased out outdated industrial
219 capacities, promoted clean fuels in residential sector and so on (Zhang et al., 2019).

220 The monthly DEPE show reduction of PM_{2.5} emission nearly in each month from years
221 2016 to 2020 (Figure 3a), which further demonstrates the effectiveness of China's national plan.

222 Compared to year 2016, both the reduction amount and reduction ratio of $PM_{2.5}$ emission are more
223 prominent for February, March, June-September, and November than the other months (Figure3b).
224 Given larger magnitudes of $PM_{2.5}$ emission in winter than in summer, emission controls with a
225 focus from October to May should be considered in the design of future clean air actions in China,
226 since total $PM_{2.5}$ emission during this period accounts for approximate 75% annual amount. Spatial
227 distributions of the changes of $PM_{2.5}$ emission from year 2017 to 2020 compared to year 2016
228 show significant decreases occurred at Beijing-Tianjin-Hebei region (BTH), Yangtze River Delta
229 region (YRD), Pearl River Delta region (PRD) and Sichuan-Chongqing Region (SCR), especially
230 for years 2019-2020 (Figure 4). From year 2016 to 2020, BTH, YRD and SRC have larger
231 reductions of $PM_{2.5}$ emission than PRD, but SCR has larger reduction ratio compared to year 2016
232 than BTH and YRD (Figure 5). Therefore, BTH and YRD have more potentials for $PM_{2.5}$ emission
233 controls than PRD and SCR, which can give a guidance for future clean air actions. More
234 specifically, most provinces have $PM_{2.5}$ emission reduction from year 2016 to 2020, and the
235 reduction ratios generally increase from year 2017 to 2020 (Table 1), which confirms continuous
236 and effective emission controls from Clean Air Action to Blue Sky Defense War Plan in China.
237 The monthly DEPE also demonstrates the effectiveness of strict implementations of emission
238 reduction policies in China, such as the coal ban for residential heating since the 2017-2018 winter.
239 There was a sharp change of $PM_{2.5}$ emission, from increase in 2017 to decrease in 2018. As shown
240 by Figure 6, spatial distributions of the changes of $PM_{2.5}$ emissions in December compared to
241 November in 2017 show obvious increases in most China. However, the changes in 2018 show
242 significant decreases in areas of Beijing, Tianjin, Hebei, Shanxi, Henan and Anhui provinces due
243 to the implementation of the coal ban.

244 Despite the trend in $PM_{2.5}$ emissions from year 2016 to 2020, the DEPE of year 2016 has
245 similar monthly distributions to MEIC2016-2020 in general (Figure 3a). MEIC has a “Pan-shape”
246 monthly distribution with nearly time-invariant $PM_{2.5}$ emissions from April to October. This
247 seasonal dependence of emissions is mainly contributed by the variations of residential energy use,
248 which are empirically dependent on coarse monthly mean temperature intervals and thus cannot
249 reflect the realistic monthly variations (Streets et al., 2003; Li et al., 2017). The centralized heating
250 system in North China has a fixed date of turning-on and turning-off during each heating season.
251 Therefore, a sudden raise of emissions from October to November and a sudden drop of emissions
252 from March to April are shown. But the turning-on and turning-off date are variable in different

253 regions, which imposes a smoothing impact on the emissions. However, the DEPE yet shows a
254 “V-shape” monthly distribution, with the minimum occurring in August. The estimated $PM_{2.5}$
255 emission is 11.8% higher than MEIC2016 in April but 12.1% lower than MEIC2016 in August,
256 and these different monthly distributions can influence the consequent climate responses including
257 the radiative forcing and energy budget (Yang et al., 2020) and also impact the health issues (Liu
258 et al., 2018). Moreover, monthly fractions of the DEPE are consistent cross years (Figure 3c). The
259 absence of interannual variations of monthly $PM_{2.5}$ emission fraction provides basis for previous
260 studies that follow the same monthly changes of source emissions from different years (Zhang et
261 al., 2009; Zheng et al., 2020, 2021). Monthly allocations of $PM_{2.5}$ emission can be directly and
262 objectively obtained given an estimated total annual amount based on the estimated monthly
263 fractions of DEPE, which is valuable for emission inventory, air quality simulation, and potentially
264 applications for future scenarios due to more accurate month fractions of DEPE. Since the hourly
265 priors of $PM_{2.5}$ concentrations from the cycling assimilation for optimally estimating $PM_{2.5}$
266 emission fit to the observed $PM_{2.5}$ quantities (Figure 1), the monthly DEPE provides more realistic
267 monthly fluctuations than the empirical estimate.

268 **4. Diurnal variations of $PM_{2.5}$ emission**

269 The DEPE with high temporal-resolution given the time-invariant prior PR2010 can reveal
270 features that are unable to represent in the commonly used emission estimates. Although the prior
271 PR2010 has no diurnal variations, hourly posteriors of $PM_{2.5}$ emission provide the first objectively
272 estimated diurnal variations for different seasons for years 2016-2020. However, these estimated
273 diurnal variations include the contributions of the time-varying boundary layer. An observing
274 system simulation experiment (OSSE) is performed to investigate the effects of the boundary layer
275 [from 0000 UTC 29 December to 0006 UTC 1 February 2016](#). Details of this OSSE are presented
276 in Appendix. The results indicate that the magnitude of posterior $PM_{2.5}$ emission from the OSSE
277 is closer to the true emission than the prior. Since we have hourly assimilated observations to
278 simultaneously update the chemical concentrations and source emissions, the impacts of time-
279 varying boundary layer on the posterior $PM_{2.5}$ emissions are limited (Figures S1). A little larger
280 estimated $PM_{2.5}$ emission fractions occurred in the morning and smaller estimated $PM_{2.5}$ emission
281 fractions occurred in the afternoon, comparing to the time-invariant true emission. Nevertheless,
282 the influences of time-varying boundary layer are still important to $PM_{2.5}$ emission estimates. To

283 statistically present the diurnal variations, the fractions of hourly $PM_{2.5}$ emissions divided by the
284 daily amount are averaged over different years and regions after excluding the impacts of time-
285 varying boundary layer based on the short-term period simulation, although the influences of
286 boundary layer could strongly vary with seasons or years (Figures 7 and 8, and Table 2). The
287 diurnal variations of $PM_{2.5}$ emission are critical for understanding the mechanisms of $PM_{2.5}$
288 formation and evolution and are also essential for $PM_{2.5}$ simulation and forecast.

289 Five-year mean diurnal variations of the estimated $PM_{2.5}$ emission fraction for mainland
290 China show that despite the monthly variations of $PM_{2.5}$ emission, the diurnal-variation fractions
291 for November, December, January and February are similar, while those for June, July and August
292 are similar (Figure 7a). There are stronger diurnal variations of $PM_{2.5}$ emission in summer than in
293 winter, which are represented by larger $PM_{2.5}$ emission fractions during morning and less $PM_{2.5}$
294 emission fractions during evening. The diurnal variations of $PM_{2.5}$ emission from March to May
295 gradually transform from the patterns of winter to those of summer, and *vice versa* for the diurnal
296 variations of $PM_{2.5}$ emission from September to November. The monthly changes of diurnal
297 variations of $PM_{2.5}$ emission are consistent with the seasonal dependence, since monthly variations
298 of $PM_{2.5}$ emission are mainly related to the variations of residential consumptions (Li et al., 2017)
299 in which the space-heating has nearly no diurnal variations and then larger $PM_{2.5}$ emissions during
300 winter lead to reduced diurnal variations than summer. Similar to the monthly fractions of
301 estimated $PM_{2.5}$ emission for mainland China, diurnal variations of $PM_{2.5}$ emission fraction are
302 consistent cross years for a given month (Figure 8). Table 2 gives five-year mean diurnal variations
303 of the estimated $PM_{2.5}$ emission fraction for each month. Based on these high-resolution diurnal-
304 variation fractions, hourly estimates of $PM_{2.5}$ emission can be objectively obtained for a given
305 monthly estimated $PM_{2.5}$ emission.

306 Despite the high temporal resolution, the DEPE also has the ability to analyze diurnal
307 variations for specific cities. The monthly changes of diurnal variations of $PM_{2.5}$ emission
308 estimated for megacities with urban populations larger than 5 million and non-megacities with
309 urban populations smaller than 5 million (Notice of the State Council on Adjusting the Standards
310 for Categorizing City Sizes, 2014) are consistent with those estimated from mainland China
311 (Figure 7). Compared to the diurnal variations of $PM_{2.5}$ emission estimated for mainland China,
312 the megacities have stronger diurnal variations, while the non-megacities have weaker diurnal

313 variations. These detailed descriptions of $PM_{2.5}$ emission that are usually absent in common
314 emission estimates can be essential for $PM_{2.5}$ simulation, especially for providing timely and
315 realistic guidance for severe haze events.

316 There has been lack of local measurements for diurnal variations and widely adopted
317 diurnal variation profiles of $PM_{2.5}$ emission in China. Compared to the diurnal variations of $PM_{2.5}$
318 emission fractions estimated based on diurnal variation profiles from US and EU (Wang et al.,
319 2010; Du et al., 2020), the estimated $PM_{2.5}$ emission fractions are 1.25% larger during the evening,
320 which greatly changes the diurnal variations of DEPE. The noon and evening peaks estimated from
321 DEPE have smaller $PM_{2.5}$ emission fractions, with mean underestimations of $PM_{2.5}$ emission
322 fraction of 0.40% and 0.83% for noon peak and evening peak respectively (Figures 7a and 9). In
323 fact, the smaller evening peaks of Wang et al. (2010) occurred in November, December, January,
324 February and March, while they are almost indistinct from April to October, similar to that from
325 DEPE. The morning peak of Wang et al. (2010) is similar to that of DEPE for spring and fall, but
326 the former overestimates $PM_{2.5}$ emission fraction of 0.57% for winter while underestimates $PM_{2.5}$
327 emission fraction of 1.05% for summer. Due to the overestimated peaks, diurnal variations of
328 Wang et al.(2010) have sharper appearance rate for morning peak and disappearance rate for
329 evening peak. Compared to the diurnal variations based on diurnal variation profiles from ES and
330 EU (Wang et al., 2010), the diurnal variations of the DEPE are constrained by the atmospheric-
331 chemical model and observed $PM_{2.5}$ concentrations, which can objectively determine the diurnal
332 variations of $PM_{2.5}$ emission for specific regions and seasons.

333 5. Impact of COVID-19 on $PM_{2.5}$ emissions

334 The abrupt changes of $PM_{2.5}$ emissions during the initial stage of COVID-19 in China
335 provide a natural case study to validate the ability of the dynamic-based data assimilation method
336 to obtain high temporal-resolution $PM_{2.5}$ emission estimates. The abrupt outbreak of the COVID-
337 19 pandemic has produced dramatically socioeconomic impacts in China. To prevent the virus
338 spread, a lockdown was first implemented on 23 January 2020 in Wuhan, Hubei province, and
339 subsequently the national lockdown has been enforced in China (Liu et al., 2020; Huang et al.,
340 2020; Zhu et al., 2021). Consequently, the total $PM_{2.5}$ emission of February 2020 for China shows
341 an obvious decrease compared to those of previous years (Figure 3). The high temporal-resolution
342 DEPE reveals the detailed changes of $PM_{2.5}$ emission with time (Figure 10). The $PM_{2.5}$ emission

343 started to decrease right around the COVID outbreak, and had been smaller than those of year
344 2019 till early March. The emissions at the following months of 2020 are similar to those of 2019,
345 due to the epidemic prevention and control policies enforced by the China government. During
346 February 2020, the DEPE shows significant reductions at the north China plain and northeast of
347 China where prominent PM_{2.5} emission occurred, while spotted PM_{2.5} emission differences with
348 small magnitudes showed at the other regions (Figures 11a-b). Along with recovery from the
349 COVID-19, the estimated PM_{2.5} emission rebounded in March (Figures 3a, 10, 11c-d), which is
350 contributed to the national work resumption. Thus, the DEPE is able to timely reflect the dynamic
351 response of PM_{2.5} emission to the COVID-19. Although similar emission reductions and emission
352 trends are obtained from the bottom-up technique (Zheng et al., 2021), the reduction amount and
353 ratio from the botomm-up technique are larger than those estimated from DEPE (Figure 10 and
354 Table 1). This is possibly due to significant reductions of PM_{2.5} emission from the residential sector
355 as in the bottom-up technique (Zheng et al., 2021), however, PM_{2.5} emissions from the residential
356 sector might not significantly changed around the COVID outbreak.

357 To avoid fluctuations due to diurnal variations and monthly changes of PM_{2.5} emission, 7-
358 day averaged PM_{2.5} emission differences between year 2020 and 2019 are used to analyze the
359 dynamic impact of COVID-19 on PM_{2.5} emission (Figure 12). Before the lockdown, there were
360 slight PM_{2.5} emission differences over several provinces (Figures 12a-b). During the first week of
361 lockdown, PM_{2.5} emission reduction larger than 5×10^{-2} ($\mu\text{g} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$) that is about 60%-70%
362 emission reduction, occurred at Hubei, Hunan, Guangdong, Anhui and Zhejiang provinces (Figure
363 12c). The PM_{2.5} emission reduction extended to BTH and Shandong province during the second
364 week of lockdown (Figure 12d), and continuously spread to the three northeast provinces of China
365 during the third week of lockdown (Figure 12e). During the third week of lockdown, the increased
366 PM_{2.5} emissions for BTH and SCR are possibly caused by the long national vocation of spring
367 holiday of year 2019 (Ji et al., 2018). The inhomogeneous spatial variations of PM_{2.5} emissions
368 possibly relate with different traditions and policy enforcements for different provinces. The PM_{2.5}
369 emission reduction had been maintained over the central and northern China till early March when
370 the lockdown was lift (Figures 12f-i). Though it is hard to see continuous and consistent signal of
371 lockdown for the whole China, the timely DEPE can provide up-to-date guidance for quantifying
372 socioeconomic impacts from rare events with large emission changes such as the COVID-19.

373 ~~Although there were significant reductions of PM_{2.5} emissions over the central and northern~~
374 ~~China in February 2020, a severe air pollution event occurred over the north China in early~~
375 ~~February 2020. Previous studies have shown that the factors influencing the severe air pollution~~
376 ~~event include the still intensive emissions from industrial, power and residential, unfavorable~~
377 ~~meteorological condition, anomalously high humidity that promoted aerosol heterogeneous~~
378 ~~chemistry, and secondary aerosol formation associated with increased atmosphere oxidants (Le et~~
379 ~~al. 2020; Sulaymon et al. 2021; Li et al., 2021).~~

380 **6. Discussion**

381 High temporal-resolution and dynamics-based estimations of PM_{2.5} emission can be
382 objectively and optimally obtained by assimilating past and future observed surface PM_{2.5}
383 concentrations through flow-dependent error statistics. This advanced assimilation strategy can be
384 applied for emission estimates of other chemical species when corresponding observations are
385 available, and extend to observation types besides the surface concentrations, like the aerosol
386 optical depth (Liu et al., 2011; Choi et al., 2020). Moreover, current estimates of PM_{2.5} emission
387 are lack of explicitly representations of primary and secondary PM_{2.5}, which could be resolved by
388 joint estimation of the source emission, primary and secondary PM_{2.5} given the concentration
389 observations. Another deficiency of this top-down technique is that it cannot directly determine
390 dynamics-based PM_{2.5} emissions for different sectors and contributions from different policies,
391 although the bottom-up technique has the potential to untangle the different contributions from
392 different policies and quantify the different impacts on different sectors. However, this top-down
393 technique can be integrated into the bottom-up technique to retain advantages of both methods.
394 One future work is to integrate the top-down technique with the bottom-up one, by which the
395 emission estimates for different sectors and polices could be quantified. The annual emission
396 estimate from the bottom-up technique can be further downscaled to hourly estimates by first
397 distributing the annual amount to each month through the monthly allocations estimated from the
398 top-down technique, and then assuming evenly daily distribution, finally applying the fractions of
399 diurnal variation estimated from the top-down technique. The information collected by the bottom-
400 up technique is retained, while the common drawback of coarse temporal resolution for the bottom-
401 up technique is remedied. The integrated bottom-up and top-down technique can improve
402 spatiotemporal representations of source emissions cross time scales and sectors, which is

403 beneficial for emission inventory, air quality forecast, regulation policy and emission trading
404 scheme.

625 **Captions:**

626 **Figure 1.** Times series of hourly PM_{2.5} concentration biases ($\mu\text{g}\cdot\text{m}^{-3}$). The ensemble mean priors
627 compared to the observed quantities for December of years 2016–2020 (gray and black), and the
628 mean biases of years 2016–2020 (blue).

629 **Figure 2.** Model domain and observation sites for cycling assimilation. Red and blue dots denote
630 the assimilated and unassimilated observational sites, respectively.

631 **Figure 3.** (a) Dynamics-based monthly PM_{2.5} emission estimates ($\text{Tg}\cdot\text{day}^{-1}$) summed over
632 mainland China of each year from 2016 to 2020 (colored) and the estimated PM_{2.5} emission from
633 MEIC (gray); (b) Ratio of PM_{2.5} emission changes between two adjacent years from year 2016 to
634 2020 normalized by the PM_{2.5} emission of year 2016; (c) Monthly fractions of dynamics-based
635 PM_{2.5} emission estimates for years 2016–2020 (light blue), the five-year mean fractions of
636 dynamics-based monthly PM_{2.5} emission estimates with bars denoting one standard deviation of
637 the five-year variations (dark blue), and the monthly fractions of estimated PM_{2.5} emission from
638 MEIC (gray).

639 **Figure 4.** (a) Spatial distribution of dynamics-based PM_{2.5} emission estimates ($\mu\text{g}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) for
640 year 2016, and compared to that of year 2016, spatial distributions of dynamics-based PM_{2.5}
641 emission changes of year (b) 2017, (c) 2018, (d) 2019 and (e) 2020.

642 **Figure 5.** (a) The differences of dynamics-based PM_{2.5} emission estimates between years 2017-
643 2020 and 2016, and (b) the differences normalized by that of year 2016.

644 **Figure 6.** Spatial distributions of dynamics-based PM_{2.5} emission changes in December compared to November
645 in [\(a\) December 2017 compared to November 2017 and \(b\) December 2018 compared to November 2018,](#)
646 [\(c\) 2017 and \(d\) 2018.](#)

647 **Figure 7.** Five-year mean diurnal variations of dynamics-based PM_{2.5} emission fraction averaged
648 over (a) mainland China, (b) megacities with urban population ≥ 5 million, and (c) non-megacities
649 with urban population < 5 million.

650 **Figure 8.** Diurnal variations of dynamics-based PM_{2.5} emission fractions for years 2016-2020
651 (light blue) and five-year mean fractions with bars denoting one standard deviation of the five-
652 year variations (dark blue) are averaged over mainland China for (a) January, (b) April, (c) July,
653 and (d) October.

654 **Figure 9.** Diurnal variations of PM_{2.5} emission fraction for each month based on diurnal variation
655 profiles from ES and EU (Wang et al. 2010).

656 **Figure 10.** Hourly (light red and blue) and daily (dark red and blue) dynamics-based PM_{2.5}
657 emission estimates ($\text{kg}\cdot\text{h}^{-1}$) summed over mainland China from January to March of years 2019
658 and 2020.

659 **Figure 11.** Spatial distributions of dynamics-based PM_{2.5} emission estimates ($\mu\text{g}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) on [\(ba\)](#)
660 February and [\(dc\)](#) March of year 2019, and spatial distributions of dynamics-based PM_{2.5} emission
661 reduction of year 2020 compared to year 2019 for [\(eb\)](#) February and [\(ed\)](#) March.

662 **Figure 12.** Mean spatial distributions of PM_{2.5} emission differences ($\mu\text{g}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) between year
663 2020 and 2019 for 9 weeks starting at 9 January 2020. Negative (positive) values indicate that
664 PM_{2.5} emission of year 2020 is smaller (larger) than that of year 2019. The numbers in (a) denote
665 provinces as: 1 Heilongjiang, 2 Neimenggu, 3 Xinjiang, 4 Jilin, 5 Liaoning, 6 Gansu, 7 Hebei, 8
666 Beijing, 9 Shanxi, 10 Tianjin, 11 Shanxi, 12 Ningxia, 13 Qinghai, 14 Shandong, 15 Xizang, 16
667 Henan, 17 Jiangsu, 18 Anhui, 19 Sichuan, 20 Hubei, 21 Chongqing, 22 Shanghai, 23 Zhejiang, 24
668 Hunan, 25 Jiangxi, 26 Yunnan, 27 Guizhou, 28 Fujian, 29 Guangxi, 30 Guangdong, 31 Taiwan,
669 32 Hongkong, 33 Macao, 34 Hainan.

780 **Appendix: Effects of meteorology**

781 An observing system simulation experiment (OSSE) is performed to investigate the effects of time-
782 varying boundary layer. A nature run is first conducted from 0000 UTC 25 December 2015 to
783 0000 UTC 2 February 2016, forced by the time invariant source emissions PR2010 (the true
784 emission). Synthetic observations of the six conventional air pollutant concentrations (i.e., PM_{10} ,
785 $PM_{2.5}$, SO_2 , NO_2 , O_3 , and CO) are generated from the natural run. Hourly synthetic observations
786 are created from 0000 UTC 29 December 2015 to 0006 UTC 1 February 2016, by interpolating
787 the gridded true surface concentrations to the chemical observation locations with additive random
788 errors of $N(0, R)$. R is the observation error variance, which is calculated by the formula in Elbern
789 et al. (2007). Outputs from the first four days of the natural run are excluded to avoid the transient
790 effect. Then the prior emissions are generated by $F^{pr} = (1.8 + \delta(x, y, z, t))F^{tr}$, where F^{tr} is the true
791 emission, δ is a random number sampled from the normal distribution $N(0, 1)$ (Peng et al. 2015).
792 Ensemble data assimilation experiments are conducted from 0000 UTC 29 December to 0006 UTC
793 1 February 2016. Outputs from the first two days of the OSSE are excluded due to the spin-up.

794 The magnitude of posterior $PM_{2.5}$ emission is closer to the true emission than the prior. Figure S1
795 presents the monthly mean diurnal variations of $PM_{2.5}$ emission fraction from the OSSE. It shows
796 that a little larger estimated $PM_{2.5}$ emission fractions occurred in the morning and smaller
797 estimated $PM_{2.5}$ emission fractions occurred in the afternoon, comparing to the time invariant true
798 emission. But the diurnal variations of $PM_{2.5}$ emission fractions caused by the boundary layer are
799 not as strong as that caused by the emission itself (Figure 7). The reason may be that we have
800 hourly assimilated observations to simultaneously update the chemical concentrations and source
801 emissions. Therefore, the impacts of time varying boundary layer on the posterior $PM_{2.5}$ emissions
802 are limited.

804 **Figure S1. Diurnal variations of PM_{2.5} emission fraction for the Observing System Simulation**
805 **Experiment.**
