16 **Abstract.** Soil water availability is an essential prerequisite for vegetation functioning. Vegetation takes up water from varying  
17 soil depths depending on the characteristics of their rooting system and soil moisture availability across depth. The depth of  
18 vegetation water uptake is largely unknown across large spatial scales as a consequence of sparse ground measurements. At  
19 the same time, emerging satellite-derived observations of vegetation functioning, surface soil moisture and terrestrial water  
20 storage, present an opportunity to assess the depth of vegetation water uptake globally. In this study, we characterise vegetation  
21 functioning through the Near-Infrared Reflectance of Vegetation (NIRv<sub>v</sub>) and compare its relation to (i) near-surface soil  
22 moisture from ESA-CCI and (ii) total water storage from GRACE at the monthly time scale during the growing season. The  
23 relationships are quantified through partial correlations to mitigate the influence of confounding factors such as energy and  
24 other water-related variables. We find that vegetation functioning is generally more strongly related to near-surface soil  
25 moisture, particularly in semi-arid regions and areas with low tree cover. In contrast, in regions with high tree cover and in  
26 arid regions, the correlation with terrestrial water storage is comparable to or even higher than with near-surface soil moisture,  
27 indicating that trees can and do make use of their deeper rooting systems to access deeper soil moisture, similar to vegetation  
28 in arid regions. At the same time we note that this comparison is hampered by different noise levels in these satellite data  
29 streams. In line with this, an attribution analysis that examines the relative importance of these soil water storages for vegetation  
30 reveals that they are controlled by (i) water availability influenced by the climate and (ii) vegetation type reflecting adaptation  
31 of ecosystems to local water resources. Next to variations in space, the vegetation water uptake depth also varies in time.  
32 During dry periods, the relative importance of terrestrial water storage increases, highlighting the relevance of deeper water

33 resources during rain-scarce periods. Overall, the synergistic exploitation of state-of-the-art satellite data products to  
34 disentangle the relevance of near-surface vs. terrestrial water storage for vegetation functioning can inform the representation  
35 of vegetation-water interactions in land surface models to support more accurate climate change projections.

## 36 **1. Introduction**

37 The regulation of water, energy, and biogeochemical cycling between land and atmosphere is primarily dependent on  
38 vegetation. In addition, global vegetation provides essential ecosystem services such as food production and uptake of some  
39 of the anthropogenic carbon dioxide emissions (Keenan and Williams, 2018). Vegetation growth depends on nutrient, water  
40 and energy availability. As a result, on a global scale, there are regions with energy or water limited vegetation functioning  
41 (Orth, 2021). In energy-limited regions, the functioning of vegetation is controlled by radiation and temperature, as they often  
42 lack sunny and warm conditions but have ample soil moisture. In contrast, soil moisture becomes critical for vegetation growth  
43 in water-limited regions. Plant photosynthesis involves opening the stomata for the uptake of CO<sub>2</sub>, while at the same time  
44 water is lost through transpiration. However, in water-limited conditions, plants can reduce the stomatal opening to avoid water  
45 loss, leading to a decrease in photosynthesis. Hence, variations in soil moisture are likely to affect vegetation functioning in  
46 water-limited conditions. Moreover, climate change has led to an expanded water limitation on vegetation (Denissen et al.,  
47 2022) and increased vegetation sensitivity to soil moisture (Li et al., 2022). For these reasons, it is essential to better understand  
48 the dependence of vegetation functioning on soil moisture to comprehend their coping mechanisms during drought to predict  
49 the future of global water, energy, and carbon cycles.

50  
51 Plants extract water from varying soil depths based on the positioning of their roots and the availability of soil moisture and  
52 nutrients. In general, the plant water uptake depth further differs spatially across different climate regimes and vegetation  
53 types, and temporally between seasons. Vegetation in arid regions is more susceptible to fluctuations in near-surface soil  
54 moisture compared to vegetation in humid regions (Xie et al., 2019). Grasses, which generally have shorter roots than trees  
55 and shrubs, are more reliant on near-surface moisture than deeper moisture (Schenk and Jackson, 2002). Further, root water  
56 uptake profiles vary within individual plant types according to above-ground biomass and age, with larger and older trees  
57 having deeper roots capable of extracting water from deeper soil layers (Schenk and Jackson, 2002; Tao et al., 2021).  
58 Additionally, within similar climate regimes, plant water uptake varies across topographic positions. Upland and lowland roots  
59 tend to be shallower, making vegetation more reliant on near-surface soil moisture, while roots go deeper in steep terrain  
60 between these landscapes to access both surface and deep moisture (Fan et al., 2017).

61  
62 Though spatial variations of plant water uptake depths across vegetation types and climate regimes, and temporal shift during  
63 dry-months, are widely studied at point scale, inadequate deep soil moisture records pose a major obstacle to study vegetation  
64 root water uptake at a global scale. Microwave remote sensing allows to infer near-surface soil moisture dynamics globally.

65 While microwaves penetrate only the top few centimeters and do not cover the entire soil moisture profile, they represent  
66 larger depths of moisture variation, providing valuable insights into [at least some of the](#) root zone soil moisture (Feldman et  
67 al., 2023). Land surface models provide an alternative source of global soil moisture data across depths, but they are subject  
68 to uncertainties arising from meteorological data, inaccurate knowledge of soil and vegetation characteristics, and the  
69 representation of complex processes such as photosynthesis, infiltration, and evaporation (Koster et al., 2009; Seneviratne et  
70 al., 2010). Hence, some studies have employed reanalysis-based soil moisture estimates, to investigate the relationship between  
71 vegetation and soil moisture at the global scale ([Li et al., 2021; Miguez-Macho and Fan, 2021](#))([Li et al., 2021; Miguez-Macho](#)  
72 [and Fan, 2021](#)); but those are likely to be impacted by model assumptions affecting soil moisture dynamics, particularly for  
73 deeper layers where less observational constraints are available. Thus, studying vegetation interactions with the entire water  
74 column, including near-surface and deep soil moisture, at a global scale using exclusively observation-based dataset is  
75 imperative to enhance the understanding of relevance of near-surface and deep soil moisture for vegetation functioning.

76  
77 The Gravity Recovery and Climate Experiment (GRACE) satellite mission, launched in 2002, provides total water storage  
78 (TWS) anomalies observations at the global scale. The TWS captures not only soil water but also snow and ice, canopy water,  
79 surface water and groundwater. Its depth of representation is therefore difficult to physically quantify, and that is why we  
80 [studies study](#) TWS anomalies. Nevertheless, they seem to be related to variations of overall water availability (near-surface +  
81 deep soil moisture) for vegetation (Yang et al., 2014). The inter-annual carbon dioxide growth rate in the atmosphere, for  
82 example, has been found to be well correlated with the total water storage anomalies on a global scale, indicating the relevance  
83 of total water column for vegetation functioning (Humphrey et al., 2018). In this study, we assume that TWS anomalies can  
84 be used to estimate the variation of overall water availability (near-surface + deep soil moisture) for vegetation under (i) snow-  
85 free conditions, and assuming that (ii) water storage variations in lakes or groundwater are negligible at the monthly time scale,  
86 (iii) and canopy water storage is much smaller than soil water storage and hence also negligible. ([Zheng and Jia, 2020; Stocker](#)  
87 [et al., 2023](#)). [While soil moisture fluctuations represent the largest variation of TWS \(Rodell and Famiglietti, 2001\), it is](#)  
88 [essential to note that certain regions exhibit notable short term fluctuations in lake and groundwater due to human management](#)  
89 [\(Strassberg et al., 2007; Cooley et al., 2021\).](#)

90  
91 This study focuses on understanding the relevance of near-surface [soil moisture](#) vs. total water storage for vegetation  
92 functioning on a global scale using observation-based datasets, thereby inferring vegetation's large-scale water uptake depth  
93 from observation-based datasets. For this purpose, we utilise TWS and near-surface soil moisture and correlate them with  
94 vegetation functioning, represented by Near-Infrared Reflectance of Vegetation (NIRv). In particular, we analyse (1) what is  
95 the relevance of near-surface soil moisture vs. the terrestrial water storage for vegetation functioning?, (2) how does the  
96 importance of near-surface soil moisture vs. terrestrial water storage change during dry months? and (3) how do climatic,  
97 vegetation, and topographic characteristics explain the variability in the relevance of near-surface vs. terrestrial water storage  
98 for vegetation functioning?

## 102 2.1 Data

### 103 2.1.1 Vegetation Functioning:

104 In our study, vegetation functioning is characterised by satellite measurements of Near-Infrared Reflectance of vegetation  
105 (NIRv) and Solar Induced Fluorescence (SIF) (**Table 1**). NIRv is the product of near-infrared reflectance and the normalised  
106 difference vegetation index (NDVI) and represents the vegetation structure and vegetation greenness (Badgley et al., 2017).  
107 The NIRv data is available at a high spatial resolution of 0.05°, and the original 16-day data was aggregated to the monthly  
108 NIRv data. SIF is directly related to the photosynthetic activity of plants because the excess energy from sunlight, that triggers  
109 the light reaction during photosynthesis, is dissipated by leaf as chlorophyll fluorescence (Mohammed et al., 2019). SIF data  
110 is derived from the Global Ozone Monitoring Experiment (GOME-2), because GOME-2 provides relatively reliable data over

111 a long period (2007-2018). The 0.5° spatial and 16-day temporal resolution SIF data is processed into monthly data as described  
112 by (Köhler et al., 2015).

113

114 The high spatial resolution of NIRv allows for a detailed study of the correlation of vegetation functioning with soil water  
115 availability. Therefore, we performed the main analyses using NIRv data. However, SIF is more sensitive to drought stress  
116 than NIRv (Qiu et al., 2022). Therefore, we perform additional analyses with SIF to show that the relationships hold for a  
117 different and more direct indicator of vegetation functioning.

### 118 2.1.2 Soil Water Storage

119 This study includes two different measures of soil water availability. The near-surface soil moisture (SSM) provides an  
120 estimate of water availability in the top layer of the soil, while the Terrestrial Water Storage (TWS) Anomaly provides an  
121 estimate of the overall water column of the soil. The SSM data is derived from the European Space Agency (ESA) Climate  
122 Change Initiative Program (CCI), which combines active and passive satellite microwave measurements to provide reliable  
123 estimates of SSM (Dorigo et al., 2017). The ESA CCI soil moisture data, at a daily temporal resolution, was aggregated to  
124 monthly temporal resolution. The TWS Anomaly data is derived from the GRACE mission, which measures changes in the  
125 Earth's gravity field (Landerer and Swenson, 2012). Here, we use the JPL-Mascons product of TWS Anomalies which is  
126 available at a 0.5° spatial and monthly temporal resolution (Watkins et al., 2015).

### 127 2.1.3 Meteorological Data

128 Employed climate variables include monthly air temperature ( $T_a$ ), 2m dew point temperature ( $T_d$ ), precipitation (P), and net  
129 radiation ( $R_n$ ) from the ERA5 reanalysis products at a 0.25° spatial resolution. The vapor pressure deficit (vpd) is calculated  
130 from  $T_a$  and  $T_d$ . Further, the aridity index is calculated from the ratio between the long-term mean  $R_n$  ( $\text{mm y}^{-1}$ ) ( $1 \text{ MJ/sq.m/day}$   
131  $= 0.408 \text{ mm/day}$ ) and P ( $\text{mm y}^{-1}$ ) for each grid cell (Budyko, 1974). We opted for this formulation as it offers a direct estimation  
132 of aridity and water (energy) constraints on vegetation. This eliminates the necessity to navigate through various formulations  
133 utilized for calculating potential evapotranspiration. However, we conducted additional validations of our results using the  
134 Global Aridity Index dataset (Zomer et al., 2022) based upon the FAO Penman-Monteith Reference Evapotranspiration  
135 equation. The use of the Global Aridity Index did not change the results of our study (Section 3.4). In addition, the mean and  
136 standard deviation of the climate variables are calculated and incorporated in the attribution analysis (Section 2.2.3).

### 137 2.1.4 Vegetation, soil, and topography data

138 To evaluate the resulting correlation of vegetation functioning and water storages with respect to vegetation characteristics,  
139 we employ the tree cover fraction data from the AVHRR vegetation continuous fields products (VCF5KYR,  
140 <https://lpdaac.usgs.gov/products/vcf5kyrv001/>) (Hansen, Matthew and Song, Xiao-Peng, 2018). For this purpose, the mean  
141 of tree cover fraction for the years between 2007 and 2016 is calculated.

Formatted: Font color: Text 1

Formatted: Font: Not Bold

142 Topographical variables such as elevation and slope are incorporated along with other meteorological variables to determine  
143 the relative contribution of different variables to the correlation between vegetation functioning and water storage. Topographic  
144 data at a 5 km resolution were downloaded from the EarthEnv. These data are calculated based on the 250 m GMTED dataset  
145 and compared against the 90 m SRTM 4.1 dev dataset. The data were resampled to a coarser resolution of 5 km using various  
146 aggregation techniques, details of which are in (Amatulli et al., 2018). Furthermore, for each grid cell, the fraction of sand and  
147 clay in soil (Reynolds et al., 2000)(Reynolds et al., 2000) along with the percentage of irrigated area (Siebert et al., 2015) were  
148 considered in attribution analysis.  
149

## 150 2.2 Methodology

### 151 2.2.1 Data pre-processing

152 A flowchart of the data pre-processing and analyses is presented in **Figure S1**. The time period of analysis is from 2007 to  
153 2018 constrained by the concurrent availability of all involved datasets. All the analyses were performed in monthly temporal  
154 resolution and at 0.05° spatial resolution (for NIRv) and 0.5° spatial resolution (for SIF). The SSM and TWS data were initially  
155 available at 0.25° and 0.5° resolution, but were disaggregated or aggregated to 0.05° or 0.5° degrees, depending on the spatial  
156 resolution of the analysis performed, based on the assumption that the soil water storage anomalies are representative over  
157 larger areas. Also, the meteorological data and vegetation, soil, and topographic data were resampled into the same resolution.  
158 After aggregating all the datasets to 0.05° resolution, the monthly anomalies were calculated by subtracting the long term mean  
159 monthly cycle and by removing linear trends. A SIF threshold was applied in each grid cell to filter out non-growing season  
160 data. For this purpose, we filtered out all the months from 2007-2018 when the mean-monthly SIF value was below the  
161 threshold of 0.2 mW/m<sup>2</sup>/sr/nm. We apply an additional temperature threshold ( $T_a > 5^\circ\text{C}$ ) to remove the months with frozen  
162 soil and snow cover, similar to (Li et al., 2021)(Li et al., 2021). Last, all months with missing soil water storage or vegetation  
163 functioning records were excluded.

### 164 2.2.2 Calculate the relevance of near-surface (SSM) soil moisture and terrestrial water storage (TWS) for vegetation 165 functioning

166 We calculated the Spearman correlation between vegetation functioning (NIRv) and soil water storages (SSM and TWS) for  
167 each grid cell during growing season months when observations for at least 40 months were available. To derive partial  
168 correlation estimates between NIRv and the water storages, we employed a bootstrapping approach (resampling with  
169 replacement from the original data) within each grid cell, with 1000 repetitions to compute bootstrap means and confidence  
170 intervals. The cutoff of 40 months was implemented to guarantee a substantial number of observations for growing-season  
171 months in each grid cell. This consideration assumes that the minimum number of growing-season months varies from 3 to 4  
172 months per year globally. In addition to soil moisture, also air temperature ( $T_a$ ) and net radiation ( $R_n$ ) affect the vegetation  
173 functioning. Moreover, SSM (soil moisture) and TWS (total water storage) demonstrate a notable correlation, as illustrated in

174 **Figure S2**, signifying the presence of mutual information. To exclusively examine the individual impacts of each water storage  
175 variable on vegetation functioning and disentangle mutual information from other water variables, we accounted for  
176 confounding effects. This entailed computing the partial correlation between NIRv and water storages (SSM or TWS), while  
177 controlling for Ta, Rn, and the other water storage variable (TWS or SSM). Since we focus on understanding the role of soil  
178 moisture on vegetation functioning, which is primarily critical in water-limited conditions, we removed the grids cells with  
179 negative partial correlations from our analysis. Such negative partial correlations may hint at vegetation's converse effect on  
180 soil moisture (when increasing vegetation activity depletes the soil moisture) and a negative correlation could occur in the grid  
181 cells where water limits vegetation productivity through oxygen limitation (Ohta et al., 2014). Also, note that predominant  
182 energy limitation of the vegetation prevents the evaluation of the relevance of soil moisture vs. terrestrial water storage as  
183 partial correlations will become insignificant when temperature or radiation are mainly controlling vegetation functioning.  
184

185 It is important to note that we chose not to apply a significance criterion in analyzing the partial correlation between NIRv and  
186 water storages. When controlling for both water storage (TWS or SSM) and energy variables (Ta and Rn) in the partial  
187 correlation (NIRv~SSM or TWS), a limited number of grid cells demonstrate significant correlation globally, given the high  
188 correlation between SSM and TWS (**Figure S2**). This poses challenges for drawing global inferences on vegetation water  
189 uptake. However, our overarching goal is to discern variations in the partial correlation of NIRv with water storages across  
190 differing climate-vegetation gradients and how it changes from the growing season to dry months, rather than confirming  
191 specific statistical thresholds. For this, we want to maintain a sufficient amount of grid cells necessary for making global  
192 inferences. However, to ensure that our results are not affected by the significance criterion, we conducted additional analyses  
193 considering only grid cells with a significant partial correlation (though a very small number compared to the total grid cells  
194 available for each AI-TC class globally), as described in **section 3.4**.

195  
196 The impact of all pre-processing steps on the number of grid cells included in this study is illustrated in **Figure S3**. Generally,  
197 our filtering procedures enable us to concentrate primarily on water-limited regions, as they effectively remove a substantial  
198 number of grid cells from the wet regions globally.

199  
200 To analyse how the importance of SSM and TWS changes during dry months, we specifically selected the months characterized  
201 by the lowest 10% SSM for each grid cell, representing the driest conditions within the growing-season months. The partial  
202 correlations between NIRv and water storages,  $r(\text{NIRv} \sim \text{SSM})$  and  $r(\text{NIRv} \sim \text{TWS})$  were calculated separately for dry months.  
203 To focus on vegetation response to similar extent of dryness spatially, only grid cells with greater than 100 monthly  
204 observations were considered for the dry months analysis. In addition, only the grid cells which had positive partial correlation  
205 in growing season months were included for the dry months analysis.  
206

Formatted: Font: Bold

Formatted: Font: Bold

Formatted: Font: Bold

207 After computing the partial correlations, we grouped the grid cells by aridity and tree cover classes, which allowed us to  
208 analyse the evolution of correlations and the difference between the partial correlation across aridity-tree cover classes.  
209 Afterwards, we again employed a full bootstrapping methodology with 1000 repetitions to compute the bootstrap means and  
210 confidence interval ~~using a full bootstrapping methodology (resampling with replacement from the original data)~~ for each  
211 aridity-tree cover class with sufficient number of observations for both growing season and dry months. -

212  
213 Moreover, to test the robustness of the results, we did additional partial correlation analyses, for which we correlated the SIF  
214 (instead of NIRv) with SSM and TWS. The analyses with SIF were performed at a spatial resolution of 0.5°, at which SIF data  
215 was available.

### 216 217 **2.2.3 Attribution Analysis**

218 We used a random forest model to understand the spatial variability in the relevance of SSM versus TWS for NIRv. Random  
219 forest is a nonparametric based regression algorithm which does not require any statistical assumptions on the predictor and  
220 target variables which makes it particularly useful for detecting the nonlinear relationship (Breiman, 2001). Given potential  
221 nonlinear impacts of various factors (climate, soil types, vegetation) on the relationship between moisture storages and  
222 vegetation functioning, this study employed the random forest method to assess the relative contributions of these variables.

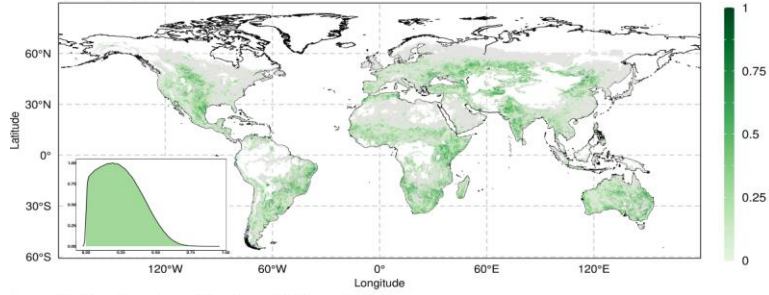

223  
224 In our study, 15 predictors were included in the random forest model based on their potential physical relevance to the target  
225 variable, which is the difference in correlation between SSM and TWS with NIRv in growing season months. These predictors  
226 included mean and standard deviation of climate variables ( $T_a$ ,  $R_n$ , P and vpd), aridity index, topographical variables (elevation  
227 and slope), vegetation variable (tree cover), soil-related variables (fraction of clay and sand), and percentage of irrigated areas  
228 for each grid cell. We calculated the mean and standard deviation of the climate variables only during the growing-season  
229 months, as determined for the subsequent partial correlation analysis~~---~~. Furthermore, only the grid cells exhibiting positive  
230 partial correlation between NIRv and SSM as well as NIRv and TWS during growing season-months were included in the  
231 random forest analysis. For training a random forest model, we used the “xgboost” package in R (Chen and Guestrin, 2016).

232  
233 We further incorporate SHAP (SHapley Additive exPlanations) values for interpreting the predictions of the random forest  
234 model (Lundberg et al., 2020). The SHAP value for a feature is the average difference in prediction of the model when that  
235 feature is included compared to when it is excluded, over all possible combinations of features. By calculating SHAP values  
236 for each feature in the model, we identified which features were most important in explaining the spatial variability in the  
237 relevance of SSM versus TWS. For calculating the SHAP values, we employed “SHAPforxgboost” package in R.

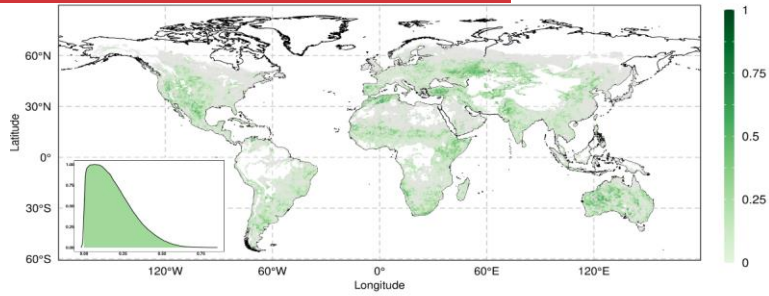

238 **3. Results and Discussion**

239 **3.1 Coupling of vegetation functioning with surface soil moisture and total water storage in the growing season**

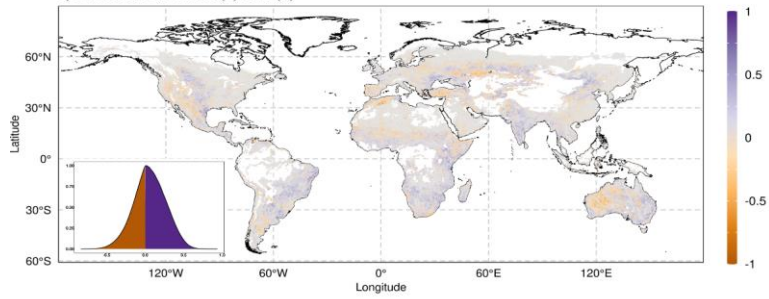

**a) Coupling strength between NIRv and SSM**

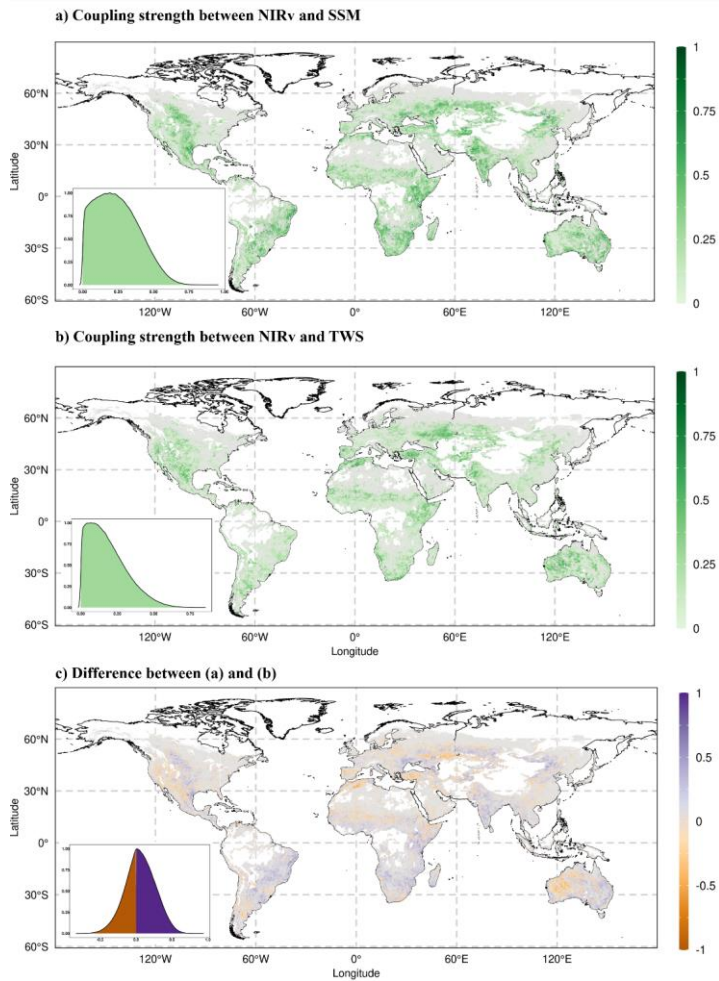

**b) Coupling strength between NIRv and TWS**

**c) Difference between (a) and (b)**

241

242

244

245

246

247

248

Figure 1: Coupling strength between vegetation functioning (NIRv) and (a) near-surface soil moisture (SSM), and (b) total water storage (TWS) during the growing season months. The color bar denotes the mean partial correlation for each grid cells, computed from the partial correlations across individual bootstrapping samples. Monthly anomalies of all variables are used to calculate the partial correlation. (c) Difference between (a) and (b). The purple colour in (c) indicates the greater partial correlation of NIRv with SSM compared to the partial correlation of NIRv with TWS while orange colour indicates the opposite. Grid cells with positive relationships for both correlations (a) and (b) are shown in (c) with blueish and orange colours. Light grey colour indicates negative partial correlations between NIRv and water storage. The absence of color within the land boundary signifies inadequate

249 **observational data for precise computation of the partial correlation. Each inset in the respective maps illustrates the probability**  
250 **distribution function (pdf) of the correlations.**

251 The partial correlation of NIRv with near-surface soil moisture varies globally during growing-season months (**Figure 1a**).  
252 NIRv demonstrates stronger correlation with near-surface soil moisture within semi-arid climates, Central North America,  
253 South America, regions in South Africa and Australia. The correlation is stronger in Southern Europe and the Mediterranean  
254 region compared to central and Northern Europe. The correlation gradient from the hot and dry Mediterranean region to wet  
255 and cold Northern Europe corresponds to the gradient of water-limited ecosystems to energy-limited ecosystems obtained in  
256 other studies (Denissen et al., 2022; Teuling et al., 2009).

257  
258 The global correlation of NIRv with TWS follows a similar pattern as with SSM (**Figure 1b**) in growing-season months. The  
259 correlation of NIRv with TWS is higher in drier central northern America and Australia compared to other regions. The  
260 similarities in the correlation of NIRv with SSM and TWS are expected because the monthly anomalies of SSM and TWS are  
261 highly correlated during growing season months in most of our study area (**Figure S2**).

262  
263 The difference between the partial correlation of NIRv with SSM and TWS (**Figure 1c**) indicates that the NIRv correlates  
264 stronger with TWS in Western America, Southern Europe, and arid regions of Australia compared to other regions globally  
265 during growing-season months. In South America and Southern Africa, however, the NIRv shows a stronger correlation with  
266 SSM. AlthoughTo ensure that the observed patterns of difference of partial correlation between SSM and TWS are not the  
267 artifacts arising from the computation of differences based on mean partial correlation, we compared the 95% confidence  
268 intervals obtained through bootstrapping. Our results indicate that, for the majority of the considered grid cells, the entire  
269 confidence intervals of the correlation (NIRv ~ TWS) fall outside the bounds of the correlation (NIRv ~ SSM) which indicates  
270 that the correlations differences are significant, thus enhancing the robustness and confidence in our findings (Figure S4).  
271 Furthermore, even if we control for the effect of soil water storage (SSM or TWS) when computing partial correlation to  
272 discern the relative importance for vegetation, it should be noted that the varying noise levels inherent in these datasets might  
273 impact our results.

Figure 2: Summarising the coupling strengths of vegetation functioning (NIRv) with (a) near-surface soil moisture (SSM) and (b) terrestrial water storage (TWS) in the growing season-months across climate (aridity index) and vegetation regimes (fraction of tree cover). (c) shows the difference between (a) and (b). Numbers within the boxes denote the number of grid cells for each aridity-tree cover class. Aridity-tree cover classes containing less than 1000 grid cells are shown in grey. The color bar denotes the mean partial correlation for each class, computed from bootstrapping. The asterisk in figure (c) signifies that the 95% confidence interval (lower and upper) shares the consistent sign (+/-) in the difference of partial correlation. Only grid cells with positive partial correlation are considered.

Next, we analyse the partial correlation between NIRv and soil water storages across different aridity and tree cover fraction classes during growing season months. For this, we group the grid cells into different aridity and tree cover fraction classes and then do bootstrapping to compute mean partial correlation and the 95 percent confidence intervals for each class with more than 1000 grid cells. We find that the partial correlation of NIRv with SSM (Figure 2a) increases with increasing aridity for aridity index (0-4). This can be attributed to the intensification of water stress on vegetation under increasingly arid conditions, resulting in a stronger correlation between NIRv and SSM. However, for a further increase in aridity (4-8), the strength of the correlation of NIRv with SSM declines. This is due to a low soil moisture availability and low temporal variability under extremely arid conditions (Figure S4S5). The pattern of increasing correlation along aridity index is also observed in the partial correlation between NIRv and TWS: (Figure 2b).

Furthermore, the correlation of NIRv with SSM decreases for higher tree cover fractions (Figure 2a). However, such a gradient along tree cover fraction is less pronounced in the partial correlation of the NIRv with TWS (Figure 2b). This overall depicts that the coupling of vegetation functioning with SSM is generally higher for non-forested areas compared to forested areas while this gradient is less pronounced in the case of TWS.

Though the difference in inherent noise levels associated with SSM and TWS impacts partial correlation analysis, we can compare the evolution of the gradient along tree cover or aridity index and assert how the relevance of SSM and TWS changes with varying tree cover or aridity index, assuming that the noise levels are similar across varying AI-TC classes. Taking this into account, we find that NIRv correlates more strongly with near-surface soil moisture compared to terrestrial water storage in semi-arid regions with low tree cover (Figure 2c), suggesting that the vegetation preferentially takes up water from SSM

Formatted: Line spacing: single

Formatted: Font: Bold

305 whenever available to meet its transpiration demand. This might be due to lower energy expenditure on root water uptake,  
306 abundant nutrients and reduced chance of root water logging in the near-surface soil moisture (Feldman et al., 2023; Schenk  
307 and Jackson, 2002; Tao et al., 2021). Conversely, the correlation between the NIRv and TWS in arid areas (AI 4-8) and regions  
308 with a high fraction of tree cover is equivalent to or greater than that of SSM, suggesting that trees can utilise their extensive  
309 root systems to access deeper soil moisture, as also observed in arid vegetation. This is consistent with previous studies  
310 reporting that the vegetation dependence on sub-surface soil moisture is higher in arid and seasonal-arid climates (Miguez-  
311 Macho and Fan, 2021). However, in certain regions with higher tree cover in humid areas, specifically with AI 0.5-1, such  
312 conclusions cannot be confidently drawn statistically. The reason is that the confidence intervals for the difference in partial  
313 correlation of NIRv with SSM and TWS fluctuate between positive (indicating greater relevance of SSM) and negative  
314 (indicating greater relevance of TWS) values (**Figure 2c**).

315  
316 Note that while our analysis focuses on regions with water-controlled vegetation as denoted by positive correlations between  
317 NIRv and the considered soil water storages, some of these grid cells are located in comparatively wet climate regimes with  
318 aridity index values between 0 and 1 (**Figure 2**). This highlights the relevance of non-climatic factors such as soil and  
319 vegetation types or topography in determining vegetation-water relationships in addition to the climate regime. Next to this,  
320 in **Figure 2c** it seems that the relevance of terrestrial water storage is comparatively higher in wet climate (aridity 0.5-1) than  
321 in transitional climate regimes (aridity 1-2) as shown with the smaller correlation differences. This, however, is probably not  
322 the case and might simply be a reflection of reduced variability in surface soil moisture (**Figure S4S5**).

### 324 **3.2 Coupling of vegetation functioning with surface soil moisture and total water storage in dry months**

325 The correlation between NIRv and soil water storage increases during dry months (**Figure 3a,b**) compared to growing season  
326 months (**Figure 2a,b**). This increase is consistent for both SSM and TWS and across all tree cover fractions and aridity classes.  
327 This is because the water limitation on vegetation increases in dry months and so does the vegetation's sensitivity to the  
328 moisture. During the dry months, the correlation with near-surface soil moisture tends to rise, but the correlation with terrestrial  
329 water storage increases even more significantly (**Figure 3c**). This indicates the relevance of deeper water resources during  
330 periods of scarce rainfall. The partial correlation maps (**Figure S5S6**) also reveal that NIRv's correlation with TWS increases  
331 more than its correlation with SSM for most grid cells.

Figure 3: Summarising the coupling strengths of vegetation functioning (NIRv) with (a) near-surface soil moisture (SSM) and (b) terrestrial water storage (TWS) in the 10% driest months in each grid-cell across climate (aridity index) and vegetation regimes (fraction of tree cover). (c) shows the difference between (a) and (b). Numbers within the boxes denote the number of grid cells for each aridity-tree cover class. Aridity-tree cover classes containing less than 1000 grid cells are shown in grey. The color bar denotes the mean partial correlation for each class, computed from bootstrapping. The asterisk in figure (c) signifies that the 95% confidence interval (lower and upper) shares the consistent sign (+/-) in the difference of partial correlation. Only grid cells with positive partial correlation are considered.

341

During dry months, the number of analysed grid cells (Figure 3) is lower compared to all growing season months (Figure 2).

342

We performed a reanalysis of the correlation patterns within aridity-tree cover classes by selecting only those grid cells that

343

displayed positive partial correlation between NIRv and soil water storages during both the dry months and the growing season

344

months. The results demonstrate that the previously observed patterns remain valid, thereby eliminating the impact of the

345

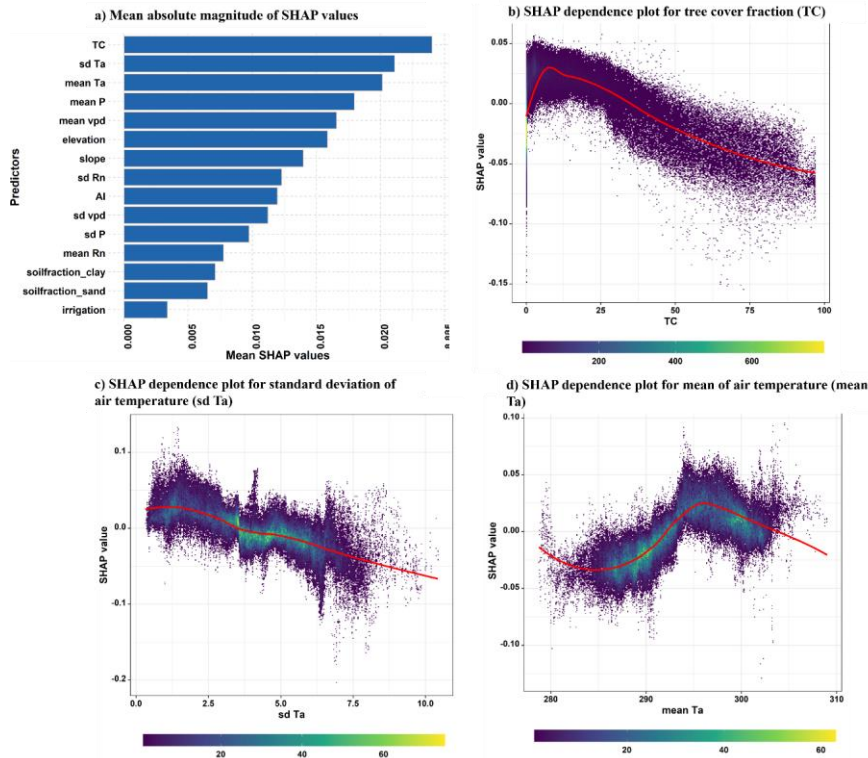

differing numbers of grid cells analysed- (Figure S6-S7).

### 3.3 Climate, vegetation, and topographic controls on the relevance of surface soil moisture vs. total water storage on vegetation

349

350

351

352

353

354

Figure 4: (a) Global feature importance based on the mean absolute magnitude of the SHAP values, the greater the predictor's relevance. (b-d) Evaluation of SHAP values (=contributions to the correlation difference illustrated in Figure 1c) against predictor values for the 3 most relevant predictors tree cover fraction (TC), variability of temperature (sd  $T_a$ ) and mean temperature (mean  $T_a$ ) during the growing season months. The colour indicates the density of data points. For plotting (b), (c) and (d), only 10 percent random samples of the whole dataset are utilised.

355

356

357

358

359

We use a random forest model to understand the spatial variability in the relevance of SSM versus TWS for NIRv. The model was trained with 15 climatic, vegetation, and topographic predictors against the target variable which is the difference of the partial correlations of NIRv with SSM and TWS during growing season-months ( $R^2 = 0.59$ , see **methods section 2.2.3**). The mean absolute SHAP value plot shows that the tree cover and the climate variables (mean and standard deviation of  $T_a$ ) are most important variables for explaining the spatial variability in the relative importance of SSM vs. TWS for vegetation

360 functioning (**Figure 4a**). This overall highlights that the relative importance of SSM vs. TWS for the vegetation is broadly  
361 controlled by vegetation type, reflecting the local adaptation of ecosystem and climate, influencing water availability (Stocker  
362 et al., 2023).

363 Tree cover fraction is an important factor in determining the relevance of SSM and TWS for vegetation functioning (**Figure**  
364 **4e4b**). Regions with a high tree cover are more dependent on TWS, as trees generally have deeper root systems that allow  
365 them to adjust water uptake between different depths (Tao et al., 2021). Grasslands on the other hand have shallow roots that  
366 are more susceptible to surface soil moisture variations (Yang et al., 2014).

367  
368 Similarly, the relative importance of SSM and TWS varies non-linearly with the mean growing season temperature (**Figure**  
369 **4b4d**). TWS tends to be more crucial for vegetation functioning in areas with low (approximately below 20°C) or high (above  
370 27°C) growing season temperatures, while SSM has greater importance in regions with moderate growing season air  
371 temperatures. One possible explanation for this trend is that high temperatures induce a strong atmospheric water demand that  
372 dries near-surface soil layers, which leads vegetation to increase water extraction from deep soils. This observation is further  
373 underscored by the analogous pattern observed in the SHAP dependence plot for vpd, which accentuates atmospheric water  
374 demand (**Figure S8S8b**). In contrast, SSM is more available during growing season months in regions characterised by  
375 moderate temperatures. We hypothesize that the regions that experience relatively cold growing season temperatures exhibit  
376 stronger temperature and weather variability that may contribute to longer dry periods and, thus, emphasises the importance  
377 of deeper soil moisture for vegetation functioning. However, it should be noted that our findings regarding the relevance of  
378 TWS at high temperatures must be interpreted with caution due to the exclusion of most tropical forest regions from our  
379 analysis (**Figure S7S9**). As a result, most warm regions are dry, and there are only a few hot and wet regions included in our  
380 training data.

381  
382  
383 Not only the mean of the growing season temperature, but also its variability is crucial for explaining the significance of SSM  
384 and TWS for vegetation functioning (**Figure 4d4c**). A higher temporal variability in temperature increases the importance of  
385 TWS for vegetation. This is because atmospheric water demand scales with temperature. Hence, higher variability in  
386 temperature implies more peaks in related atmospheric water demand which is a stronger incentive for plants to access deeper  
387 water storages which are more often available to meet the vegetation's transpiration demand.

388  
389 **Figure S8** illustrates the effect of the other six important predictors on the model output. Apart from climatological parameters  
390 (mean P, mean vpd, variability in  $R_n$ , and aridity index), elevation and slope explain part of the variability in the relevance of  
391 SSM vs. TWS for NIRv. Although the reasons for increasing relevance of TWS for vegetation functioning at higher elevation  
392 remain unclear, it may be due to elevation's strong correlation with other climatic variables such as  $T_a$  and P.

393

394 Several local studies identified other relevant factors that determine root water uptake depth such as forest stand age and tree  
395 height, competition, root hydraulic architecture, and tree species (Zhu et al., 2022; Quijano et al., 2012; Stahl et al., 2013,  
396 Gessler et al., 2021; Liu et al., 2021). For example, young trees more easily increase their root activity in the shallow or deep  
397 soil dependent on soil moisture than mature trees (Zhu et al., 2022; Drake et al., 2011). These variables were not included in  
398 our attribution analysis, because they are not available at global scale.

### 399 3.4 Robustness Tests

400 In the aforementioned analysis, we included grid cells exhibiting both positive partial correlations, whether significant or non-  
401 significant. Upon further examination, we specifically assessed the evolution of partial correlation between NIRv and water  
402 storages, considering only grid cells with significant partial correlation ( $p < 0.00505$ ). The observed patterns along the aridity-  
403 tree cover gradient remained similar during growing season months. This suggests the robustness of our results to the choice  
404 of the statistical significance criterion, albeit with a substantial reduction in the number of globally available grid cells when  
405 considering only significant partial correlation (Figure S9S10).

406

407 Furthermore, to ensure that our results are robust to variations in the threshold for Solar-Induced Fluorescence (SIF) used to  
408 define growing season months, we conducted additional analyses with a different SIF threshold. Instead of filtering out all  
409 months from 2007-2018 when the mean-monthly SIF value was below the threshold of 0.2 mW/m<sup>2</sup>/sr/nm, we utilized a  
410 threshold of 0.5 mW/m<sup>2</sup>/sr/nm. Elevating the SIF threshold implies the exclusion of additional months characterized by lower  
411 vegetation activity for the partial correlation analysis. However, it is essential to note that this threshold does not seem to affect  
412 the number of globally available grid cells during growing season months and hence patterns along AI-TC classes are similar.  
413 Instead, it specifically influences the selection of dry months and hence the number of grid cells available for the analysis  
414 during dry months. Nevertheless, even with the elevated SIF threshold for defining growing season months, the observed  
415 patterns along aridity-tree cover (AI-TC) classes remain largely consistent with the results obtained in our main analyses  
416 (Figure S10S11).

417

418 Although NIRv can largely reflect vegetation functioning (Badgley et al., 2017), we repeat our analysis with SIF, which is an  
419 alternative and independent indicator for vegetation functioning and shows a near-linear relationship with gross primary  
420 productivity at the ecosystem level (Guanter et al., 2012)(Guanter et al., 2012). However, SIF is only available at a coarse  
421 resolution of 0.5 degree. The partial correlations,  $r(\text{SIF} \sim \text{SSM})$  and  $r(\text{SIF} \sim \text{TWS})$  largely agree with the pattern of  $r(\text{NIRv} \sim \text{SSM})$   
422 and  $r(\text{NIRv} \sim \text{TWS})$  across varying aridity index and tree cover classes (Figure S11-S12). This suggests that our overall  
423 conclusion on the relevance of SSM or TWS for vegetation functioning is robust across different indicators of vegetation  
424 productivity.

425

426 Additionally, we tested if our results are robust when the aridity index is calculated based on the FAO Penman-Monteith  
427 Reference Evapotranspiration equation, for which we applied aridity classification based on UNEP 1997 guidelines-. Our  
428 results confirm the findings of **Section 3.1 and Figure 2** that as aridity increases, the correlation of NIRv with **Soil Surface**  
429 **Moisture** near-surface soil moisture (SSM) and **Total Water Storage** total water storage (TWS) intensifies. Moreover, in hyper  
430 arid regions (AI < 0.03) the correlation with TWS surpasses that with SSM (**Figure S12S13**). They also confirm that regions  
431 with higher tree Cover (TC) fraction correlates more strongly with TWS compared to SSM. Thus, the choice of aridity index  
432 formulation does not alter our main conclusions.

433  
434

435 When analyzing partial correlations between Total Water Storage (TWS) and vegetation metrics (NIRv or SIF) at finer  
436 resolutions (0.05 degrees for NIRv or 0.5 degrees for SIF), it is crucial to acknowledge the potential emergence of significant  
437 spatial autocorrelation. This is attributed to the fact that the actual spatial resolution of the satellite signal underlying the TWS  
438 data is 2-3 degrees.

#### 439 4. Summary and Conclusions

440 In this study we compare the relevance of near-surface soil moisture and of terrestrial water storage for vegetation functioning  
441 across the globe. We find that in semi-arid regions and regions with low tree cover, vegetation preferentially utilises the water  
442 from shallow soil, which is related to continuous availability of near-surface water availability and lack of deep rooting systems  
443 respectively. The stronger correlation of NIRv with SSM than TWS is supported by site-level studies that find a higher root  
444 water uptake of surface soil moisture (Brinkmann et al., 2019, Gessler et al., 2021, Deseano Diaz et al., 2023; Kulmatiski and  
445 Beard, 2013), also when deeper water is available. Some local studies however find a higher root water uptake from deeper  
446 layers (Zhu et al., 2022).

447  
448 By contrast, in mostly forested regions and in relatively dry climate regimes, the correlation with terrestrial water storage is  
449 comparable or higher than with near-surface soil moisture, indicating that trees and vegetation in arid regions use their deep  
450 root systems to access deeper soil moisture. Point-scale studies also found a different water uptake depth for trees and grasses  
451 ~~in~~ for example in savanna ecosystems (Kulmatiski et al., 2010), and a different water uptake depth for tree species (Kahmen  
452 et al., 2022). Liu et al. (2021) showed for example that for a karst forest in Southwest China, evergreen species rely mostly on  
453 water sources from the 0-30 cm layer, while deciduous species extracted most water from the 30-70 cm layer.

454  
455 We also find that vegetation's preferential water uptake depth changes over time. During particularly dry months, the relative  
456 importance of terrestrial water storage is higher, highlighting the importance of deep water resources during periods of low  
457 soil water availability. This is in line with previous studies showing changes in vegetation's water uptake depth during drought

Formatted: Font: 8 pt

Formatted: Font: Bold

Formatted: Font: Bold

458 periods at small spatial scales where accessing water in deeper soil layers helps plants to alleviate water stress and maintain  
459 transpiration (Migliavacca et al., 2009; Tao et al., 2021).

460

461 Our global results are supported by site-scale studies that find that, during drought, the deeper roots play a more active role in  
462 water extraction (Stahl et al., 2013, Volkmann et al., 2016; Tao et al., 2021). In some studies however, the increase of deep  
463 water uptake is only relative: the absolute uptake of deep water does not increase, but the uptake of shallow water decreases  
464 (Brinkmann et al., 2019, Gessler et al., 2021, Rasmussen et al., 2020; Kühnhammer et al., 2023). This means that the uptake  
465 of deeper soil layers cannot compensate for the loss of water uptake from the dry topsoil. Contrary to trees, grasses do not shift  
466 their uptake depth (Deseano Diaz et al., 2023), or even extract water from the most shallow soils (Prechsl et al., 2015,  
467 Kulmatiski and Beard, 2013).

468

469 Furthermore, we show that the spatial variability of the importance of near-surface soil moisture vs. terrestrial water storage  
470 for vegetation functioning is influenced by fraction of tree cover and mean and standard deviation of air temperature. This  
471 emphasises the role of climate in determining shallow vs. deep soil water resources, and the role of vegetation in adapting to  
472 different soil water availability patterns.

473

474 Vegetation functioning and soil water storages are generally coupled in both directions, i.e. while soil moisture availability  
475 affects vegetation functioning (positive coupling), this in turn also affects soil moisture through transpiration (negative  
476 coupling). As our study focuses on water-controlled vegetation we only consider positive couplings and filter out grid cells  
477 with negative correlations. Future research may consider the relevance of soil moisture across depths for the ~~positive~~negative  
478 coupling regions.

479

480 Overall, our analysis illustrates that satellite-based data can be used for belowground analysis at large spatial scales thanks to  
481 the fact that satellite retrievals can assess soil water storage dynamics across depths and because vegetation in water-controlled  
482 areas can be used as an indicator of soil water dynamics. Such novel ways to improve our understanding of belowground water  
483 dynamics is necessary and valuable as respective in-situ observations are scarce and of limited representativeness for larger  
484 areas, particularly given the typical spatial heterogeneity of soils and vegetation. Our results can further inform a better  
485 representation of belowground processes in global models in order to support more accurate projections of future changes in  
486 climate, water resources, and ecosystem services.

#### 487 **Data availability**

488 The monthly SIF data is available from <https://www.gfz-potsdam.de/sektion/fernerkundungund->

489 geoinformatik/projekte/global-monitoring-of-vegetation-fluorescence-globfluo/daten.The NIRv was calculated from the red  
490 and near-infrared reflectance obtained from the MOD13C1 v006 product (<https://lpdaac.usgs.gov/products/mod13c1v061/>).  
491 The ESA-CCI soil moisture can be accessed through <https://esa-soilmoisture-cci.org/> and Terrestrial Water Storage Anomaly  
492 data can be accessed through [https://podaac.jpl.nasa.gov/dataset/TELLUS\\_GRACGRFO\\_MASCON\\_CRI\\_GRID\\_RL06\\_V2](https://podaac.jpl.nasa.gov/dataset/TELLUS_GRACGRFO_MASCON_CRI_GRID_RL06_V2).  
493 The ERA5 climate variables are available from <https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5> . Tree  
494 cover fraction data is available from the AVHRR vegetation continuous fields products  
495 <https://lpdaac.usgs.gov/products/vcf5kyrv001/>, land cover data is available from <https://www.esa-landcover-cci.org/>, and  
496 topographic data is available via <https://www.earthenv.org/topography>. Similarly, the irrigation fraction data could be accessed  
497 from <https://mygeohub.org/publications/8> .
