11

12 **Abstract.** Observational studies have shown that the El Niño–Southern Oscillation (ENSO) exerts
13 an influence on the Quasi-Biennial Oscillation (QBO). The downward propagation of the QBO tends to
14 speed up and slow down during El Niño and La Niña, respectively. Recent results from general
15 circulation models have indicated that the ENSO modulation of the QBO requires a relatively high
16 horizontal resolution, and that it does not show up in the climate models with parameterized but
17 temporally constant gravity wave sources. Here, we demonstrate that the NASA GISS E2.2 models can
18 capture the observed ENSO modulation of the QBO period with a horizontal resolution of 2° latitude by
19 2.5° longitude but with its gravity wave sources being parameterized interactively. This is because El
20 Niño events lead to more vigorous gravity wave sources generating more absolute momentum fluxes
21 over the equatorial belt, as well as less filtering of these waves into the tropical lower stratosphere
22 through a weakening of the Walker circulation. Various components of the ENSO system such as the
23 SSTs, the convective activities, and the Walker circulation are intimately involved in the generation and
24 propagation of parameterized gravity waves, through which ENSO modulates the QBO period in GISS
25 E2.2 models.

26 **1. Introduction**

27 The QBO dominates the interannual variability in the tropical stratosphere (Baldwin et al., 2001)
28 while ENSO is the primary mode of interseasonal–interannual variability over the tropical Pacific Ocean
29 (Wang et al., 2016). It is well-known that both the QBO and the ENSO have far-reaching implications
30 for global weather and climate systems (Hamilton et al., 2015; Philander, 1990; Sarachik and Cane, 2010;
31 Domeisen et al., 2019).

32 The QBO and the ENSO defy linear relationships (Angell, 1986; Xu, 1992; Hu et al., 2012) as
33 highlighted by that fact that while the QBO and ENSO indices are negatively correlated before 1980s
34 and positively correlated after 1980s (Garfinkel and Hartmann, 2007; Domeisen et al., 2019; Rao et al.,
35 2020c) they are virtually uncorrelated over the longer periods from 1953 to recent times (Garfinkel and
36 Hartmann, 2007; Geller et al., 2016b, see their Figure 5 for details). However, Maruyama and Tsuneoka
37 (1988) spotted an intriguing connection between the anomalously short easterly phase of the QBO at 50
38 hPa in 1987 and the El Niño event that persisted through that year. Based on the results from a
39 mechanistic model, Geller et. al (1997) suggested that the equatorial sea surface temperatures (SST)
40 modulate the wave momentum fluxes into the stratosphere and thus the QBO. Remarkably, an
41 observational study conducted by Taguchi (2010) demonstrated that the downward propagation of the
42 QBO tends to speed up during El Niño and slow down during La Niña while the amplitude of the QBO
43 tends to be smaller during El Niño and larger during La Niña, respectively. Using radiosonde data from
44 10 near-equatorial stations distributed along the Equator, Yuan et al. (2014) found that the ENSO
45 modulation of the QBO period is more robust than that of the QBO amplitude, which is likely due to the
46 fact that the QBO periods are characterized by a high degree of zonal uniformity whereas the QBO
47 amplitudes exhibit the zonal asymmetries of about 10% (Hamilton et al., 2004, see their Fig. 15).

48 The QBO influences the distribution and transport of various chemical constituents (Zawodny and
49 McCormick, 1991; Trepte and Hitchman, 1992; Hasebe, 1994; Kawatani et al., 2014), the extratropical
50 circulation in the winter stratosphere (Holton and Tan, 1980; Labitzke, 1982; Rao et al., 2020a, 2020b,
51 2021), tropical moist convection (Collimore et al., 2003; Liess and Geller, 2012), the activities of tropical
52 cyclones (Gray et al., 1984; Ho et al., 2009), the ENSO (Gray et al., 1992; Huang et al., 2012; Hansen
53 et al. 2016), the Hadley circulation (Hitchman and Huesmann, 2009), the tropospheric subtropical jet
54 (Garfinkel and Hartmann, 2011a, 2011b; Kumar et al., 2022), the boreal summer monsoon (Giorgetta et
55 al., 1999; Yoden et. al 2023), and the Madden-Julian Oscillation (Yoo and Son, 2016). Thus, it is
56 imperative that weather and climate models have the capacity to simulate the ENSO modulation of the
57 QBO.

58 Various studies have investigated how the ENSO exerts its influence over the QBO in climate models.
59 Schirber (2015) conducted two sets of experiments to explore this issue using the general circulation
60 model European Centre/Hamburg 6 (ECHAM6) wherein a convection-based gravity wave (GW) scheme
61 was newly implemented. The first set of experiments was called QBOW where the initial QBO
62 configurations consisted of a westerly jet above the 10 hPa level and an easterly jet below that level.
63 Likewise, in the second set of experiments named as QBOE, the initial QBO conditions included an
64 easterly and westerly jet above and below the 10 hPa level, respectively. Schirber showed that for QBOW,
65 the ensemble mean period of the QBO from the El Niño runs is shorter than that from the La Niña runs
66 while for QBOE, the ensemble mean periods are comparable between the El Niño and the La Niña runs.
67 Schirber also noted that there is no systematic change in amplitude of the QBO jets between El Niño and
68 La Niña runs. Using version 3 of the EC-Earth Consortium’s climate model with a triangular spectral
69 truncation at total wavenumber 255 (T255, horizontal resolution of $\sim 0.54^\circ$), Christiansen et al. (2016)
70 reported that each of ten ensemble members simulated a faster QBO descent rate during El Niño than

71 during La Niña, and that their ensemble mean QBO phase speeds were comparable to those derived from
72 the reanalyses.

73 Employing two atmospheric general circulation models (AGCM) developed under the Model for
74 Interdisciplinary Research on Climate (MIROC) framework, Kawatani et al. (2019) investigated the
75 possible mechanism of the ENSO modulation of the QBO. They first compared a 100-year perpetual El
76 Niño run with a 100-year perpetual La Niña run from the MIROC-AGCM with T106 horizontal
77 resolution and 500-m vertical spacing in the stratosphere without any nonorographic GW
78 parameterizations. Then they repeated the two AMIP-style perpetual El Niño and La Niña experiments
79 but using the atmospheric part of the Model for Interdisciplinary Research on Climate, Earth System
80 Model (MIROC-ESM) with T42 horizontal resolution and 700-m vertical spacing in the stratosphere
81 where the effects of nonorographic GWs are parameterized and the GW sources are held constant in
82 time. They found that the MIROC-AGCM simulates shorter QBO periods during El Niño than during
83 La Niña because of the larger equatorial vertical wave fluxes of zonal momentum in the uppermost
84 troposphere and consequently the much larger resolved GW forcing in the stratosphere during warm
85 ENSO phase. However, they found almost no difference in the average QBO periods simulated by the
86 MIROC-ESM between El Niño and La Niña because the QBO was generated by the parameterized
87 nonorographic GW forcing in the model where the GW sources were held constant in time, thus did not
88 respond to the SST changes associated with the ENSO cycle (See their Figs. 16 and 18 for more details).

89 Using more than a dozen models from five modeling centers with their horizontal resolutions ranging
90 from T42 ($\sim 2.79^\circ$) to T1279 ($\sim 0.14^\circ$), Serva et al. (2020) found that a relatively high horizontal
91 resolution above T159 ($\sim 0.75^\circ$) was desirable to simulate the observed modulation of the QBO descent
92 rate under strong ENSO events, while the amplitude response is generally weak at any horizontal
93 resolution. They also pointed out that over-dependence on parameterizing the effects of GWs with

94 temporally invariant sources is detrimental to the realistic simulation of the coupling between the ocean
95 and the tropical stratosphere in current climate models.

96 As far as the ENSO modulation of the QBO period is concerned, both Kawatani et al. (2019) and
97 Serva et al. (2020) emphasized the importance of a relatively high horizontal resolution and the
98 inadequacy of non-interactive GW sources. However, the exploratory work of Schirber (2015) shows
99 that the ENSO modulation of the QBO period can, to some extent, be simulated in the GCM ECHAM6
100 with T63 and an associated Gaussian grid of $\sim 1.9^\circ$ horizontal resolution because rather than being held
101 constant in time, the properties of non-interactive GW sources in the tropics are determined by the
102 simulated convection which is modulated by ENSO phases.

103 Rind et al. (1988) pioneered the use of meteorologically interactive GW sources in the Goddard
104 Institute for Space Studies (GISS) climate models. These sources included flow over topography,
105 convection, wind shear, and, in Rind et al. (2007), wind deformation. By increasing the vertical
106 resolution and revising the formulations, various versions of the GISS models subsequently simulate a
107 spontaneous QBO (Rind et al., 2014, 2020; DallaSanta et al., 2021). The GISS E2.2 models are
108 comprehensive climate models optimized for the middle atmosphere (Rind et al., 2020; Orbe et al., 2020).
109 Their outputs have been submitted to the archive of the Coupled Model Intercomparison Project Phase
110 6 (CMIP6). Bushell et al. (2020) pointed out that most of current climate models are highly dependent
111 on parameterized nonorographic GW forcing to simulate a QBO. Unsurprisingly, DallaSanta et al. (2021)
112 found that the parameterized convective GWs play a dominant role in generating the spontaneous QBO
113 in the GISS E2.2 models.

114 High-resolution AGCMs can realistically simulate atmospheric structure without resorting to
115 parameterized GWs (e.g., Watanabe et al., 2008), but the associated computational cost is too high for
116 the Earth system modeling at the present time. Thus, most climate models still require GW

117 parameterization schemes. What is more, Fig. 4(c) in Serva et al. (2020) shows that two different GW
118 parameterization schemes employed by the same T255 model make a drastic difference in the ENSO
119 modulation of the QBO period. Specifically, one scheme makes a difference of about 10 months in the
120 ensemble mean QBO period between El Niño and La Niña episodes while the other hardly makes an
121 appreciable difference. In other words, improperly parameterized GW forcing could destructively
122 interfere with the ENSO modulation of the QBO period in high-resolution climate models. Therefore, it
123 is imperative that GWs forcing be parameterized properly in climate models with a variety of horizontal
124 resolutions.

125 In this paper, we will evaluate the ENSO modulation of the QBO simulated by the GISS E2.2 models
126 against the observed and explore how the ENSO modulates the QBO period in those models. Section 2
127 describes the observations and GISS E2.2 models used in this study and outlines our methods of analyses.
128 Section 3 revisits the ENSO modulation of the QBO from the observational point of view. Section 4
129 evaluates the ENSO modulation of QBO period in the historical runs simulated by four versions of the
130 GISS E2.2 models. Section 5 explores the physical mechanisms underlying the simulated modulation.
131 Conclusions and discussion are presented in section 6.

132

133 **2. Observations, model simulations, and methods**

134 **2.1 Observations**

135 To study the observed QBO, we use the monthly mean zonal winds provided by Free University of
136 Berlin (FUB). The FUB data were produced by combining the radiosonde observations at the following
137 three equatorial stations: Canton Island near 172°W, 3°S (closed in 1967), Gan/Maledive Islands near
138 73°E, 1°S (closed in 1975), and Singapore near 104°E, 1°N (Naujokat, 1986). We use 63 years (i.e., 756

139 months) of the FUB data ranging from 1953 to 2015 at the following seven pressure levels: 70, 50, 40,
140 30, 20, 15, and 10 hPa.

141 The observed ENSO index is derived from the National Oceanic and Atmospheric Administration
142 (NOAA) Extended Reconstructed SST (ERSST) V5 datasets (Huang et al., 2017) provided by National
143 Centers for Environmental Information (NCEI). ERSST produced on a $2^\circ \times 2^\circ$ grid is derived from the
144 International Comprehensive Ocean-Atmosphere Data Set (ICOADS). The latest version of ERSST,
145 version 5, uses new datasets from ICOADS Release 3.0 SST, combining information from Argo floats
146 above 5 m and Hadley Centre Ice-SST version 2 ice concentrations.

147 The monthly Outgoing Longwave Radiation (OLR) on a $2.5^\circ \times 2.5^\circ$ grid from NCEI is used as a
148 proxy for tropical convection since cloud top temperatures are negatively correlated with cloud height
149 in the tropics (Salby, 2012). The ERA5 (Hersbach et al., 2020) monthly mean zonal winds were
150 employed to depict the observed Walker circulation against which we evaluate those simulated by GISS
151 E2.2 models. The employed OLR and zonal winds range from 1979 to 2015.

152 **2.2 Description of the models and simulations**

153 GISS E2.2 is a climate model specially optimized for the middle atmosphere (Rind et al., 2020; Orbe
154 et al., 2020) and its output was submitted to the Coupled Model Intercomparison Project Phase 6 (CMIP6)
155 archive. The horizontal resolution of all GISS E2.2 models is 2° (latitude) \times 2.5° (longitude) for the
156 atmosphere and the model extends from the surface to 0.002 hPa (\sim 89 km) with 102 vertical layers (for
157 more details, see Table 1 in Rind et al., 2020). Note that an adequate vertical resolution is necessary for
158 climate models to internally generate a spontaneous QBO (Scaife et al., 2000; Richter et al. 2014; Rind
159 et al, 2014, 2020; Geller et al. 2016a; Butchart et al. 2018).

160 With respect to atmospheric chemistry, the atmospheric component of the GISS E2.2 models was
161 configured in two ways for CMIP6. The first configuration is denoted as NonINTEractive (NINT) where

162 the fields of radiatively active components such as ozone and multiple aerosol species are specified from
163 previously calculated offline fields (Kelley et al. 2020; Miller et al., 2021). The second configuration
164 includes interactive gas-phase chemistry and a mass-based (One-Moment Aerosol, OMA) aerosol
165 module, where aerosols and ozone are driven by emissions and calculated prognostically (Bauer et al.,
166 2020; Nazarenko et al., 2022). The above-mentioned NINT and OMA configurations correspond to
167 physics-version=1 (“p1”) and physics-version=3 (“p3”), respectively, in the CMIP6 archive.

168 The basic dynamics and tropospheric physics structure of the GISS E2.2 models were based on the
169 GISS E2.1 model (Kelley et al., 2020). One version of the cloud parameterization schemes used in E2.2,
170 termed as “standard physics” (SP), has not been fully upgraded to the state-of-the-art module customized
171 for E2.1 which has only 40 vertical layers up to 0.1 hPa (Rind et al., 2020). Accordingly, E2.2–SP has a
172 younger sibling, E2.2–AP, whose cloud parameterization schemes, termed as “Altered Physics” (AP),
173 are more aligned with those in E2.1 and whose outputs were thus favored for the submission to the
174 CMIP6 archive. “Altered Physics” in E2.2–AP brings about a somewhat different response to SST as
175 compared with the “standard physics” in E2.2–SP.

176 The QBO in the GISS models are mainly driven by GWs (DallaSanta et al., 2021). The phase
177 velocities and momentum fluxes of GW sources are coupled to convective cloud-top-pressure altitudes,
178 convective mass fluxes, background wind fields, etc. (Rind et al., 1988, 2014, 2020). Specifically
179 speaking, intrinsic phase velocities $\pm 10 \text{ ms}^{-1}$ and $\pm 20 \text{ ms}^{-1}$ of GWs generated by convection are
180 Doppler-shifted by local background winds for shallow convection and for convection penetrating above
181 the altitudes of the 400-hPa pressure level, respectively. Convective gravity wave momentum flux
182 magnitude is determined by the density and Brunt-Vaisala frequency at the top of convective region and
183 the vertically integrated mass flux over the convective region. The mass flux in the model is strongly
184 related to the depth of penetration, and thus this parameterization is somewhat similar to that of the other

185 models that use convective sources (see Eq. 7 in Rind et al., 1988 and the further discussion in Rind et
186 al., 2014).

187 Using the same GW parameterization scheme, both E2.2–SP and E2.2–AP are included in this study
188 to gain insight into the mechanisms through which ENSO modulates the QBO period despite the fact
189 that the outputs of E2.2–SP were not submitted to the CMIP6 archive.

190 We will look into two atmosphere-only (AMIP) ensemble simulations where the evolution of SST
191 and sea ice fraction (SIF) is specified and two coupled ensembles where the respective model atmosphere
192 interacts with the ocean component termed as the GISS Ocean v1 (GO1) which extends from the surface
193 to the ocean floor with 40 vertical layers and has a horizontal resolution of 1° latitude by 1.25° longitude
194 (Schmidt, et al., 2014; Kelley et al., 2020). Table 1 lists the four model configurations and their respective
195 ensemble simulations investigated in this study.

196 The first two ensembles in Table 1 were generated by AMIP–OMA–SP and AMIP–OMA–AP models
197 where the SST and SIF from the HadISST1 dataset (Rayner et al., 2003) were prescribed for the
198 simulations between 1870 and 2014 while their climatological annual cycles over the 1876–1885 period
199 were specified for the earlier simulations between 1850 and 1869. Both AMIP–OMA–SP and AMIP–
200 OMA–AP prognostically calculate the concentrations of ozone, methane, chlorofluorocarbons, aerosols,
201 etc. The main differences between AMIP–OMA–SP and AMIP–OMA–AP reside in the package of cloud
202 parameterization schemes, which leads to their different responses to SST and thus may have important
203 implications for simulating the ENSO modulation of the QBO period. We discarded the simulations
204 ranging from 1850 to 1869 in this study because they are irrelevant to the ENSO modulation of the QBO
205 in the absence of interannual variations in the prescribed SST over that period. Note that the two extended
206 historical AMIP simulations from 1870 to 2014 listed in Table 1 were not submitted to the CMIP6
207 archive. However, AMIP–OMA–AP did generate a 5-member ensemble over the 1979–2014 period that

208 was submitted to the CMIP6 archive and tagged as E2-2-G.amip.r[1-5]i1p3f1. It is worth noting that the
209 climatological characteristics over the 1979–2014 period derived from the AMIP–OMA–AP ensemble
210 listed in Table 1 are comparable to those derived from E2-2-G.amip.r[1-5]i1p3f1 albeit the climate
211 trajectories of the individual ensemble members over the 1979–2014 period are expected to differ
212 between those two ensembles starting from January 1850 and January 1979, respectively, due to the
213 chaotic nature of climate systems.

214 The other two ensembles in Table 1 were generated by the Coupled–NINT–SP and Coupled–NINT–
215 AP where the respective atmospheric components are coupled with GO1. Both the Coupled–NINT–SP
216 and Coupled–NINT–AP simulations were performed with the prescribed atmospheric composition
217 generated from the AMIP-style OMA simulations using the historical forcings over the 1850–2014
218 period. As mentioned earlier with regard to the AMIP–OMA–SP and AMIP–OMA–AP runs, the
219 difference in cloud physics between the Coupled–NINT–SP and Coupled–NINT–AP models is exploited
220 to gain a deeper insight into the mechanisms through which the ENSO modulates the QBO periods. Both
221 Coupled–NINT–SP and Coupled–NINT–AP ensemble runs started from January 1850 and ended in
222 December 2014.

223 Since there are no interannual variations in the prescribed SST over the 1850–1869 period for both
224 the AMIP–OMA–SP and AMIP–OMA–AP runs, our analyses focus on the 1870–2014 period for those
225 two ensembles. For the sake of conciseness and consistency, we also discarded the outputs from two
226 coupled runs over the 1850–1869 period. In short, we only use the data over the 1870–2014 period from
227 the ensemble simulations listed in Table 1.

228 **2.3 Methods**

229 **2.3.1 Data processing**

230 We first fill the missing FUB zonal winds at the 10 hPa level for the first 3 years by linear
231 extrapolation in log-pressure height. Then, we remove the climatological mean zonal winds from the
232 observed to obtain the monthly anomalies of zonal winds. These anomalous monthly zonal winds will
233 be used for our observational study in this paper.

234 To obtain the ENSO index from the ERSSTv5 data ranging from 1953 to 2015, we use the same
235 method to calculate the Oceanic Niño Index (ONI) as the Climate Prediction Center (CPC) of NOAA.
236 Namely, the ONI is defined as a 3-month running mean of ERSSTv5 SST anomalies in the Niño 3.4
237 region ($5^{\circ}\text{S} - 5^{\circ}\text{N}$, $120^{\circ} - 170^{\circ}\text{W}$) based on centered 30-year base periods updated every 5 years
238 (https://origin.cpc.ncep.noaa.gov/products/analysis_monitoring/ensostuff/ONI_v5.php). This method
239 ensures a proper identification of El Niño and La Niña by taking the secular changes in SSTs into account.
240 The SST anomalies (SSTA) are defined as the deviations of the SST from its climatological annual cycle
241 over a selected base period. Specifically, the SSTA during 1951–1955 are based on the 1936–1965 base
242 period; the SSTA during 1956–1960 are based on the 1941–1970 base period; and so on. Thus, as the
243 CPC of NOAA we used the ERSSTv5 SST from January 1936 to January 2016 period to obtain the ONI
244 from January 1953 to December 2015.

245 Following the CPC of NOAA, we refer to El Niño or La Niña episodes as the periods when the ONIs
246 are greater than $+0.5^{\circ}\text{C}$ or less than -0.5°C for at least five consecutive months, respectively. Since the
247 temperature measurement is only accurate to the tenths place, all our calculated ONIs are rounded to the
248 nearest tenth. Based on the rounded ONIs, our identified El Niño and La Niña episodes are almost
249 identical to those listed at the above-mentioned website of NOAA CPC. Accordingly, we identified 21
250 El Niño and 15 La Niña events between 1953 and 2015.

251 Similarly, when we explore how GISS E2.2 models simulate the ENSO modulation of the QBO we
252 define the ONI as a 3-month running mean of prescribed SSTA from the AMIP–OMA–SP and AMIP–

253 OMA–AP runs, or simulated SSTA from the Coupled–NINT–SP and Coupled–NINT–AP runs in the
254 Niño 3.4 region (5°S– 5°N, 120°– 170°W) based on centered 30-year base periods updated every 5 years.
255 Here, the SSTA are also defined as the deviations of the SST from its climatological annual cycle over
256 a selected base period. Specifically, the SSTA during 1886–1890 are based on the 1871–1900 base
257 period; the SSTA during 1891–1895 are based on the 1876–1905 base period; the SSTA during 1991–
258 1995 are based on the 1976–2005 base period; the SSTA during 1996–2000 are based on the 1981–2010
259 base period. In addition, the SSTA during the earliest 1870–1885 and latest 2011–2014 spans are ad hoc
260 based on the 1870–1899 and 1985–2014 base periods, respectively. Thus, we used the specified or
261 simulated SSTs over the 1870–2014 period to obtain the ONI from February 1870 to November 2014.

262 For the sake of consistency, we also apply this same filtering procedure to all other fields simulated
263 by GISS E2.2 models such as OLR, zonal winds, resolved wave forcing, parameterized GW forcing,
264 absolute convective momentum flux, etc. Thus, the simulated zonal winds and other quantities were
265 subjected to a 3-month moving averaging. In addition, the secular trends of zonal winds and those other
266 quantities were also removed due to the adoption of the consecutive 5-year base periods. To further
267 simplify our analyses, all processed model outputs used in this study range from 1871 to 2013. In other
268 words, we also discarded the processed model outputs over the period between February 1870 to
269 December 1870 and that between January 2014 to November 2014.

270 Employing the above-mentioned criterion that was used to identify the observed ENSO events
271 between 1953 and 2015, we identified 34 El Niño and 30 La Niña events over the period from 1871 to
272 2013 from the specified HadISST1 dataset. We further found that the five members of the Coupled–
273 NINT–SP ensemble simulations generated 31, 31, 29, 35, and 36 El Niño events and produced 34, 34,
274 35, 37, and 35 La Niña events, respectively, over the period from 1871 to 2013. In parallel, we identified

275 37, 42, 40, 37, and 38 El Niño events and 38, 43, 37, 40, and 39 La Niña events from the SSTs simulated
276 by the five members of the Coupled–NINT–AP ensemble, respectively, over the same period.

277 **2.3.2 Statistical analysis**

278 Following Wallace et al. (1993), we decompose the zonal winds from both the observed and the
279 simulated between 10 and 70 hPa pressure levels into two leading pairs of empirical orthogonal functions
280 (EOFs) and principal components (PCs) because they typically account for more than 90% of the vertical
281 structure variance (Wallace et al., 1993; DallaSanta et al., 2021). For the sake of robustness, we excluded
282 the FUB data after 2015 because the first two EOFs explain no more than 60% of total variance during
283 the 2016 and 2019/20 QBO disruptions (Anstey et al., 2021). As a result, the QBO variability can be, to
284 a very good approximation, compactly depicted by the trajectory of $(PC_1(t), PC_2(t))$ in a linear space
285 spanned by the first two orthonormal EOFs.

286 As in previous studies (Wallace et al., 1993; Taguchi, 2010; Christiansen et al. 2016; Serva et al.
287 2020; DallaSanta et al., 2021), the instantaneous amplitude (am) and phase (ψ) of the QBO are defined
288 as

$$289 \quad am = \sqrt{PC_1^2 + PC_2^2} \quad (1)$$

$$290 \quad \psi = atan2(PC_2, PC_1) \quad (2)$$

291 Differentiating (2) with respect to time yields the instantaneous phase speed of the QBO:

$$292 \quad \psi' = (PC_1 \cdot PC_2' - PC_1' \cdot PC_2) / (PC_1^2 + PC_2^2) \quad (3)$$

293 Using Eqs. (1) – (3) and the monthly processed FUB data from 1953 to 2008, Taguchi (2010)
294 obtained 672 months of am and ψ' and partitioned each time series of $\{am\}$ and $\{\psi'\}$ into 16 categories.
295 The 16 categories correspond to the 16 combinations of four QBO phase quadrants at the 50-hPa level
296 and four seasons. Using a bootstrap (Chernick, 2007) method, Taguchi (2010) seminally illuminated the
297 annual synchronization of the QBO. Taguchi (2010) further used the bootstrap method to show that the

298 QBO signals during El Niño episodes exhibit weaker amplitude in six out of 16 categories and faster
299 phase propagation in eight out of 16 categories at a 90% or 95% confidence level (refer to Figure 6 in
300 Taguchi, 2010).

301 It is worth pointing out that while Taguchi’s conclusion is physically meaningful, his statistical
302 analysis is not robust concerning the ENSO influence on the QBO. For instance, there are 18 sample
303 points in the (MAM, E) category where MAM stands for the months of boreal spring, i.e., March, April,
304 and May while E indicates the QBO winds at the 50-hPa level are easterly. As Taguchi (2010) mentioned
305 that the actual sample size should be six rather than 18 due to the data clustering. Among those 18 months
306 of data, there are six for El Niño conditions and one for La Niña condition. Also pointed out by Taguchi
307 (2010), actually sample sizes are two and one for El Niño and La Niña conditions, respectively, in the
308 (MAM, E) category. It is hard to imagine we can infer any meaningful result from one La Niña sample
309 point and two El Niño sample points out of the sample with its size being nine because Chernick (2007)
310 points out that samples of size less than 10 are usually too small to rely on sample estimates, even in
311 “nice” parametric cases, and that we should expect that such sample sizes are also too small for bootstrap
312 estimates to be of much use (see his page 174). With regard to the above-mentioned (MAM, E) category,
313 the following conclusion is evidently not robust: the QBO amplitude during El Niño episodes is weaker
314 than that during La Niña episodes at a 95% confidence level (refer to Figure 6(b) in Taguchi, 2010)
315 because one extreme La Niña and/or a couple of extreme El Niño sample points can influence the
316 outcome of the statistical test.

317 Since we have observed 21 El Niño and 15 La Niña events between 1953 and 2015, the sample sizes
318 of El Niño and La Niña appear large enough for us to conduct a classical parametric test. Namely, we
319 have two samples: one consists of 21 independent El Niño events and the other contains 15 independent
320 La Niña events. For each ENSO event, we define the amplitude [am] and phase speed [ψ'] of the QBO

321 as the monthly am in Eq. (1) and the monthly ψ' in Eq. (3) that are averaged over the number of months
 322 of that event. Thus, both the El Niño sample and the La Niña sample are described by two statistics [am]
 323 and [ψ'], namely the mean amplitude and mean phase speed of the QBO for an ENSO event. Note that
 324 in this paper, a quantity enclosed by a pair of square brackets denotes the average value of that quantity
 325 over the duration (i.e., the total number of months) of an ENSO event.

326 We employ Welch's t -test (Moser and Stevens, 1992) to infer whether there is a significant difference
 327 in [am] or [ψ'] between the El Niño and La Niña population means. For the sake of conciseness, we will
 328 refer to [am] and [ψ'] as A and Ψ' , respectively, in this subsection and section 3. In other words, we will
 329 no longer use the mnemonic notations [am] and [ψ'] in this subsection and section 3 wherein we will
 330 instead employ A and Ψ' , respectively, for brevity.

331 To examine whether the sample mean QBO amplitude is significantly different between El Niño and
 332 La Niña, we first construct the statistic:

$$333 \quad t = \frac{\bar{A}_1 - \bar{A}_2}{s_{\bar{A}_1 - \bar{A}_2}} \quad (4)$$

334 where \bar{A}_1 and \bar{A}_2 are the values of A s that are averaged over the number of the El Niño and La Niña
 335 events, respectively.

$$336 \quad s_{\bar{A}_1 - \bar{A}_2} = \sqrt{\frac{s_{A_1}^2}{N_1} + \frac{s_{A_2}^2}{N_2}} \quad (5)$$

337 where s_{A_1} and s_{A_2} are the corrected sample standard deviation of A for El Niño and La Niña,
 338 respectively while N_1 and N_2 are the sample sizes of El Niño and La Niña events. According to Moser
 339 and Stevens (1992), the degrees of freedom for the t -distribution is

$$340 \quad \mathbf{v} = \frac{(s_{A_1}^2/N_1 + s_{A_2}^2/N_2)^2}{\left(\frac{s_{A_1}^2}{N_1}\right)^2/(N_1-1) + \left(\frac{s_{A_2}^2}{N_2}\right)^2/(N_2-1)} \quad (6)$$

341 2.3.3 Analysis of the QBO forcings

342 The QBO owes its existence to wave-mean flow interaction (Lindzen and Holton, 1968; Holton and
 343 Lindzen, 1972; Plumb, 1977). The evolution of zonal mean zonal winds is governed by the transformed-
 344 Eulerian-mean (TEM) momentum equation formulated in pressure coordinates on a sphere (Andrews et
 345 al., 1983):

$$346 \quad \frac{\partial \bar{u}}{\partial t} = \bar{G} + \frac{1}{\rho_0 a \cos \varphi} \bar{\nabla} \cdot \bar{\mathbf{F}} - \left\{ \frac{\bar{v}^*}{a \cos \varphi} \left[\frac{\partial}{\partial \varphi} (\bar{u} \cos \varphi) - f \right] + \bar{\omega}^* \frac{\partial \bar{u}}{\partial p} \right\} + \bar{X}, \quad (7)$$

347 where the Eliassen-Palm flux $\bar{\mathbf{F}}$ is defined as

$$348 \quad \bar{\mathbf{F}} = \{F^{(\varphi)}, F^{(p)}\} = a \cos \varphi \{ -\overline{u'v'} + \psi \bar{u}_p, -\overline{u'\omega'} - \varepsilon [(a \cos \varphi)^{-1} (\bar{u} \cos \varphi)_\varphi - f] \}, \quad (8)$$

349 and its divergence as

$$350 \quad \bar{\nabla} \cdot \bar{\mathbf{F}} = \frac{1}{a \cos \varphi} \frac{\partial}{\partial \varphi} (F^{(\varphi)} \cos \varphi) + \frac{\partial F^{(p)}}{\partial p}. \quad (9)$$

351 In Eq. (7), t denotes time, p pressure, φ latitude, (u, v, ω) "velocity" in (longitude, latitude, pressure)
 352 coordinates, a the mean radius of Earth, ρ_0 pressure-dependent basic density, and f the Coriolis
 353 parameter. In Eq. (8), ε is defined as

$$354 \quad \varepsilon = \overline{v'\theta'}/\bar{\theta}_p = -\overline{v'T'}/\left(\frac{\kappa \bar{T}}{p} - \frac{\partial \bar{T}}{\partial p}\right), \quad (10)$$

355 where θ denotes potential temperature, T temperature, and κ the ratio of the gas constant to the specific
 356 heat at constant pressure. Note that in Eqs. (7) – (10) primes denote departures from the zonal means
 357 which are represented by overbars, and residual meridional and vertical velocities, i.e., \bar{v}^* and $\bar{\omega}^*$, are

358 defined as $(\bar{v} - \frac{\partial \psi}{\partial p})$ and $(\bar{\omega} + \frac{1}{a \cos \varphi} \frac{\partial (\varepsilon \cos \varphi)}{\partial \varphi})$, respectively.

359 On the right hand side (RHS) of Eq. (7), the first term, \overline{G} , is the forcing from the GWs parameterized
360 in E2.2 models; the second term, $\frac{1}{\rho_0 a \cos \varphi} \vec{\nabla} \cdot \vec{F}$, is the forcing driven by the waves resolved by GISS
361 E2.2 models; the third term, $-\left\{ \frac{\overline{v}^*}{a \cos \varphi} \left[\frac{\partial}{\partial \varphi} (\overline{u} \cos \varphi) - f \right] + \overline{\omega}^* \frac{\partial \overline{u}}{\partial p} \right\}$, is associated with the TEM
362 advection; and last term, \overline{X} , is the zonal component of friction or other nonconservative mechanical
363 forcing (Andrews et al., 1987). Since \overline{X} is small as far as the QBO is concerned, we will focus on
364 analyzing the first three terms of Eq. (7) and ignore the last term of that equation in this study.

365

366 **3. Revisiting the ENSO modulation of the QBO from observations**

367 In the era of big data, bootstrap methods are a powerful tool that is used to analyze uncertainties for
368 any machine learning model. However, the bootstrap methods cannot get something for nothing. It is
369 not reliable if sample size is too small. In this section, we will use the classical parametric method
370 outlined in subsection 2.3.2 to revisit the ENSO modulation of the QBO using the FUB data described
371 in subsection 2.1.

372 The solid and dashed black lines in Fig. 1 depicts the two leading EOFs derived from the monthly
373 anomalies of the FUB zonal winds between 1953 and 2015. The vertical structures of those two EOFs
374 are very similar to those depicted in Fig. 2a of Taguchi (2010) who used the FUB zonal winds from 1953
375 to 2008. Our calculated two leading EOFs account for 92.6% of the vertical structure variance (57.1%
376 by EOF1 and 35.5% by EOF2) which is slightly smaller than the value of 96.1% shown in Taguchi
377 (2010). Note that this discrepancy is not mainly due to the difference in the adopted time spans. When
378 we use the monthly anomalies of the FUB zonal winds between 1953 and 2008, the resultant two leading
379 EOFs account for 92.9% of the vertical structure variance (57.0% by EOF1 and 35.9% by EOF2). Coy
380 et al. (2020) pointed out that the descent of the QBO winds varies at intraseasonal, seasonal, and

381 interannual time scales (see their Figure 1 for more details). Thus, it is natural that two leading EOFs
382 explain more variance of the FUB zonal winds when those winds have been deseasonalized and
383 subjected to a 5-month running averaging.

384 As mentioned before, there are 21 El Niño and 15 La Niña episodes between 1953 and 2015, i.e.,
385 $N_1 = 21$ and $N_2 = 15$. Our calculations yield $\bar{A}_1 = 39.5 \text{ ms}^{-1}$, $\bar{A}_2 = 42.4 \text{ ms}^{-1}$, $\nu = 33$, and $t =$
386 -1.50 . Apparently, $\bar{A}_1 < \bar{A}_2$, which suggests that the QBO amplitude is smaller during El Niño than
387 during La Niña. Performing a two-tailed test, however, we find that the QBO amplitudes during El Niño
388 episodes are not statistically different from those during La Niña episodes at the 5% significance level.
389 This is consistent with the finding of the observational study by Yuan et al. (2014), namely, the ENSO
390 modulation of the QBO amplitude is less robust than that of the QBO period. This is also consistent with
391 the findings of the modeling studies conducted by Schirber (2015) and Serva (2020).

392 Note that when we use the FUB zonal winds and the ERSSTv5 data over the 1953–2008 period as
393 Taguchi (2010), our calculations yield $N_1 = 19$, $N_2 = 13$, $\bar{A}_1 = 39.1 \text{ ms}^{-1}$, $\bar{A}_2 = 43.1 \text{ ms}^{-1}$, $\nu = 29$,
394 and $t = -1.98$. A two-tailed test shows that the difference of the QBO amplitude between El Niño and
395 La Niña is not statistically significant at the 5% significance level either.

396 Apparently, no matter whether we use the FUB data over the 1953–2008 period or over the 1953–
397 2015 period, the influence of the ENSO on the QBO amplitude is not statistically significant at the 5%
398 significance level. Thus, we will not further explore whether GISS E2.2 models can simulate the ENSO
399 modulation of the QBO amplitude in this study.

400 To examine whether the sample mean QBO phase speed is significantly different between El Niño
401 and La Niña, we similarly use Eqs. (4) – (6) except that \bar{A}_1 and \bar{A}_2 are replaced by $\bar{\Psi}'_1$ and $\bar{\Psi}'_2$,
402 respectively. Based on the data from 1953 to 2015, we obtained $N_1 = 21$ and $N_2 = 15$, $\bar{\Psi}'_1 = 0.246$
403 radians/month, $\bar{\Psi}'_2 = 0.183$ radians/month, $\nu = 28$, and $t = 2.36$. Evidently, $\bar{\Psi}'_1 > \bar{\Psi}'_2$, indicating that

404 the phase speed of the QBO is greater during El Niño than during La Niña. Performing a two-tailed test,
405 we ascertain that the phase speed of QBO during El Niño episodes are statistically different from those
406 during La Niña episodes at the 5% significance level. Put in another way, the mean QBO period of 25.6
407 months (i.e., $2\pi/0.246$) during El Niño is statistically shorter than that of 34.3 months (i.e., $2\pi/0.183$)
408 during La Niña over the 1953–2015 period. Furthermore, when we use the FUB zonal winds and the
409 ERSSTv5 data over the 1953–2008 period as Taguchi (2010), our calculations yield $N_1 = 19$ and $N_2 =$
410 13 , $\overline{\Psi}_1' = 0.253$ radians/month, $\overline{\Psi}_2' = 0.180$ radians/month, $\nu = 25$, and $t = 2.87$. Apparently, we
411 reach a similar conclusion that the mean QBO period of 24.8 months (i.e., $2\pi/0.253$) during El Niño is
412 statistically shorter than that of 34.9 months (i.e., $2\pi/0.180$) during La Niña at the 5% significance level.

413 Thus, no matter whether we use the FUB data over the 1953–2008 period or over the 1953–2015
414 period, the influence of the ENSO on the QBO phase speed is statistically significant at the 5%
415 significance level. In other words, our observational study robustly buttresses the following conclusion
416 of Taguchi (2010): the QBO descent is faster during El Niño than during La Niña. Henceforth, we will
417 focus only on the ENSO modulation of the QBO period in this study.

418 To facilitate comparison with other studies (e.g., Taguchi, 2010; Christiansen et al., 2016; Serva et
419 al. 2020), we also calculate the mean phase speed of the QBO by averaging monthly ψ' in Eq. (3) over
420 all the 210 months of the El Niño episodes and over all the 201 months of the La Niña episodes between
421 1953 and 2015. Subsequently, we obtain the mean QBO period of 25.6 months during El Niño and of
422 32.2 months during La Niña for the 1953–2015 period. Similarly, we obtain the mean phase speed of the
423 QBO by averaging monthly ψ' in Eq. (3) over all the 186 months of the El Niño episodes and over all
424 the 174 months of the La Niña episodes for the 1953–2008 period. The resultant values are 24.9 and 32.2
425 months, respectively, which are very close to 25 and 32 months inferred by Taguchi (2010). No matter

426 whether the selected FUB data span from 1953 to 2008 or range from 1953 to 2015, we robustly conclude
427 that the QBO descent rate is faster during El Niño than during La Niña.

428 Note that it is difficult to rigorously determine the degrees of freedom for a t -test when we choose the
429 monthly data as sample points which share some common characteristics, i.e., are not independent of
430 each other during an ENSO event (for more details, refer to Taguchi, 2010). In the remainder of this
431 paper, when we need to conduct a Welch's t -test we choose the QBO period averaged over each ENSO
432 episode as a sample point. Otherwise, the mean values during El Niño or La Niña are referred to the
433 quantities averaged over all the months of El Niño or La Niña category in alignment with previous works
434 conducted by Taguchi (2010), Christiansen et al. (2016), and Serva et al. (2020).

435 The QBO is mainly driven by tropical waves (Lindzen and Holton, 1968; Holton and Lindzen, 1972;
436 Plumb 1977) of which tropical convection is an important source (Holton, 1972; Salby and Garcia, 1987;
437 Bergman and Salby, 1994; Tsuda et al., 2009; Alexander et al., 2017). To investigate how tropical
438 convection is influenced by the ENSO, we first produce the monthly anomalies of OLR from NOAA
439 NCEI over the 1979–2015 period. Then we obtain the mean OLR anomalies (OLRA) for La Niña and
440 El Niño conditions by averaging the monthly OLRA over all the months that fall into La Niña and El
441 Niño categories, respectively. Fig. 2a show that mean OLRA exhibit a broad and positive pattern that
442 spans the central and eastern equatorial Pacific and a negative pattern in the maritime continent for the
443 La Niña conditions. In contrast, Fig. 2b show that they exhibit a broad and negative pattern that spans
444 the central and eastern equatorial Pacific and a positive pattern in the maritime continent for the El Niño
445 conditions. The large differences in the mean OLRA in Fig. 2c between El Niño and La Niña conditions
446 are closely related with the contrast in the SSTA patterns shown in Fig. 3. Namely, the distinctive
447 patterns of positive and negative SSTA extend over the central and eastern Pacific during the El Niño
448 and La Niña episodes, respectively, which not only gives rise to the corresponding positive and negative

449 rainfall anomalies (Philander, 1990) and the concomitant OLRA shown in Fig. 2, but also leads to
450 various teleconnections outside the tropics (Domeisen et al., 2019).

451 In order to test whether the difference patterns of OLRA and SSTA shown in Figs. 2c and 3c are
452 statistically robust we use [OLRA] and [SSTA] as our sample points to perform two-tailed tests. Figs.
453 S1 and S2 shown in the supplement demonstrate that the difference patterns are statistically significant
454 at the 5% significance level.

455 In the next section, we will evaluate how the ENSO modulates the QBO periods in the E2.2 models
456 and whether those models can realistically capture the contrast in the OLR (and convection) patterns that
457 generally underlies the difference in wave driving of the QBO between warm and cold ENSO conditions.

458

459 **4. ENSO modulation of the QBO period in GISS E2.2 models**

460 Now we investigate the ENSO modulation of the QBO period in the ensemble simulations listed in
461 Table 1.

462 We first calculate the monthly mean anomalies of zonal winds using the method outlined in
463 subsection 2.3.1. Then we average those monthly mean anomalous zonal winds over the latitudinal belt
464 from 5° S to 5° N to obtain the monthly QBO winds over the 1871 to 2013 period at the following seven
465 pressure levels: 70, 50, 40, 30, 20, 15, and 10 hPa.

466 As in section 3, we decompose the QBO winds from 10 to 70 hPa over the 1871–2013 period into
467 two leading pairs of empirical orthogonal functions (EOFs) and principal components (PCs). For each
468 of the 19 ensemble simulations listed in Table 1, the first two leading EOFs account for at least 92.9%
469 of the vertical structure variance which is comparable to the value derived from the observations
470 discussed in section 3. Since coupled models encounter more difficulties in simulating the ENSO
471 modulations of the QBO (Serva et al. 2020, see their Fig.4 for more details), we first look into the

472 ensemble simulations from the Coupled–NINT–AP model, which incorporates the most up-to-date cloud
473 parameterization schemes. The red and blue lines in Fig. 1 depicts the first two leading EOFs from each
474 of all five Coupled–NINT–AP runs. For each of those five runs, the first two leading EOFs account for
475 at least 93.8% of the vertical structure variance. The vertical structures of those two EOFs from each
476 Coupled–NINT–AP run are broadly similar to the solid and dashed black lines derived from observations
477 in Fig. 1. The respective vertical structures of the first two leading EOFs are almost identical among all
478 five Coupled–NINT–AP ensemble runs, which is expected because all runs share the same model and
479 differ from each other only in their initial conditions. It is worth noting that the vertical structures of the
480 first two leading EOFs simulated by Coupled–NINT–AP are somewhat different from those observed
481 below the 20 hPa level because none of CMIP models could simulate a QBO in the lower stratosphere
482 that is as strong as the observed (Richter et al., 2020). In addition, we find that the vertical structures of
483 the first two leading EOFs from other three ensemble simulations listed in Table 1 (figures not shown)
484 are comparable to those from the Coupled–NINT–AP runs.

485 For the ensemble simulations listed in Table 1, we define an El Niño or La Niña event according to
486 the criterion described in subsection 2.3.1. Similarly, Eq. (3) is used to calculate the instantaneous (i.e.,
487 monthly) phase speed of the simulated QBO. For each El Niño or La Niña event, the mean phase speed
488 of the simulated QBO from any individual run listed in Table 1 is obtained by averaging the
489 instantaneous phase speeds of the simulated QBO over the number of months of that event. Accordingly,
490 we have one sample consisting of independent El Niño events and the other consisting of independent
491 La Niña events. In addition, we employ a two-tailed Welch's t -test outlined in subsection 2.3.2 to
492 examine whether there is a significant difference in the phase speed of the simulated QBO between the
493 El Niño and La Niña population means.

494 Table 2 describes how the ENSO influence the QBO period in each member of all ensembles, where
 495 E[1-4] represent AMIP-OMA-SP, AMIP-OMA-AP, Coupled-NINT-SP, and Coupled-NINT-AP
 496 ensembles, respectively while r_1, r_2, \dots indicate its respective member of each ensemble. As we
 497 mentioned in subsection 2.3.1, for the member r_1 of E1, i.e., the first run of the AMIP-OMA-SP
 498 ensemble, there are 34 El Niño and 30 La Niña events between 1871 and 2013, i.e., $N_1 = 34$ and $N_2 =$
 499 30 in Eqs. (5) and (6). Then we obtained the phase speed of the QBO for each episode of those 34 El
 500 Niño and 30 La Niña events, from which we derived the mean phase speed of the QBO averaged over
 501 the 34 El Niño and 30 La Niña events, respectively. Accordingly, our mean phase speeds of the QBO
 502 simulated by r_1 of E1 averaged over the El Niño and La Niña events are obtained as 0.202 radians/month
 503 and 0.185 radians/month, respectively, and the standard deviations about those mean phase speeds as
 504 0.0345 radians/month and 0.0275 radians/month, respectively. Substituting those numbers into
 505 Eqs. (4) – (6) yields $\nu = 61$, and $t = 2.25$. Therefore, the phase speed of the QBO simulated by r_1 of
 506 E1 is statistically significantly greater during El Niño than during La Niña at the 5% significance level.
 507 Accordingly, we register the mean QBO period of 31.1 months (i.e., $2\pi/0.202$) during the El Niño
 508 episodes and 34.0 months (i.e., $2\pi/0.185$) during the La Niña episodes as the entries for r_1 of E1 in
 509 Table 2. Since the phase speeds of the QBO simulated by r_1 of E1 are statistically significantly different
 510 between the El Niño and La Niña categories at the 5% significance level, we can regard the QBO periods
 511 as being statistically significantly different between El Niño and La Niña episodes and register their
 512 difference, -2.9 months, in Table 2 with a pair of parentheses indicating this significance. Similarly, we
 513 calculated the QBO periods during ENSO extremes and their difference simulated by every member of
 514 all ensembles and registered them in Table 2 where the numbers in the parentheses indicate that the
 515 phase speed of the simulated QBO is statistically significantly greater during El Niño than during La
 516 Niña at the 5% significance level.

517 Table 2 shows that 18 of 19 runs from the four GISS E2.2 models listed in Table 1 can simulate the
518 ENSO modulation of the QBO period discussed in section 3. For each Coupled–NINT–AP ensemble
519 run, the phase speed of the simulated QBO is statistically significantly greater during El Niño than during
520 La Niña at the 5% significance level. For the AMIP–OMA–SP and AMIP–OMA–AP ensembles, most
521 members also generate a spontaneous QBO whose phase speed is statistically significantly greater during
522 El Niño than during La Niña at the 5% significance level. Intriguingly, in none of the Coupled–NINT–
523 SP ensemble runs is the phase speed of the simulated QBO statistically significantly different between
524 El Niño and La Niña episodes at the 5% significance level albeit the contrast in the QBO periods between
525 the two categories simulated by r1 of E3 (i.e., Coupled–NINT–SP) is equal to -6.2 months and greater
526 than that simulated by most members of Coupled–NINT–AP. We will look further into this issue in
527 section 6.

528 **5. Mechanisms of the ENSO modulation of the QBO period in GISS E2.2 models**

529 **5.1 ENSO modulation of the QBO forcings**

530 Section 4 shows that the ENSO modulation of the QBO period can be simulated by each of the AMIP–
531 OMA–SP, AMIP–OMA–AP, and Coupled–NINT–AP models. The difference in the phase speed of the
532 simulated QBO between ENSO extremes is statistically significant at the 5% significance level for most
533 of those model runs. For Coupled–NINT–SP, one of its historical runs exhibits an opposite response,
534 namely, the simulated QBO propagates downward slower during El Niño than during La Niña while
535 other four runs from the identical model configuration do bring about a faster phase speed of the QBO
536 during warm ENSO events. However, no matter whether the difference in the QBO period simulated by
537 Coupled–NINT–SP is positive or negative between ENSO extremes, it is not statistically significant at
538 the 5% significance level. In this section, we start with investigating how the first three terms in Eq. (7),

539 i.e., the parameterized GW forcing, the resolved wave forcing, and the TEM advection, respond to ENSO
540 extremes and how their evolutions are related with those of the simulated QBO winds.

541 As shown in sections 3 and 4, both the observed and simulated QBO can be very well represented by
542 the trajectory of $(PC_1(t), PC_2(t))$ in a linear space spanned by the first two orthonormal EOFs. In other
543 words, at any time t , the QBO wind profile, $U'_{profile}$ is very close to the following linear combination:
544 $PC_1(t) \cdot EOF_1 + PC_2(t) \cdot EOF_2$. Here, the QBO wind, U' , refers to the deseasonalized and smoothed
545 monthly mean zonal winds averaged over the zonal belt from 5° S to 5° N. We construct the composite
546 fields of the QBO winds, the GW forcing, the resolved wave forcing, and the TEM advection according
547 to the phase angle of the QBO wind profiles. For each month that falls into the El Niño or La Niña
548 category, we use Eq. (2) to calculate the phase angle of the QBO wind profile, each cycle of which over
549 the 1871–2013 period is divided into 24 bins with the bin size of 15°. Note that if two QBO wind profiles
550 belong in the same bin, they look similar because any one of them can be approximated by the other
551 multiplied by a scalar factor. Therefore, for each of the El Niño and La Niña categories, it is very natural
552 for us to generate the composite QBO winds for that category by averaging all wind profiles in each bin
553 and produce the concomitant composite fields of the GW forcing, the resolved wave forcing, and the
554 TEM advection in the corresponding bin.

555 Fig. 4 depicts the composite fields of the QBO winds (black contours) and parameterized (left panels)
556 and resolved (right panels) wave forcing averaged over all realizations of the Coupled–NINT–AP
557 ensemble. All composite fields in this section have been subjected to the averaging over the latitudinal
558 belt from 5°S to 5°N. The ensemble average is achieved on the basis that the respective vertical
559 structures of the first two leading EOFs are almost identical among all five Coupled–NINT–AP ensemble
560 runs as demonstrated in Fig. 1. Both Figs. 4a and 4b show a characteristic feature of the QBO. Namely,
561 the maximum eastward and westward wave forcing from parameterized GWs are located below and

562 propagate downward with the westerly and easterly QBO jets. Fig. 4c reveals the stronger parameterized
563 GW forcing in both eastward and westward shear zones of the QBO winds during El Niño than during
564 La Niña, which gives rise to the faster phase speed of the QBO during warm ENSO episodes than during
565 its cold counterparts. Figs. 4d and 4e show that the relationship between resolved wave forcing and the
566 QBO winds are somewhat more complex. When zonal wind anomalies are close to zero, the coherent
567 and modest resolved westward wave forcing helps the easterly shear zone of the QBO winds to propagate
568 downwards from the 10 hPa level to the 70 hPa level during both the cold and warm ENSO episodes
569 while the coherent and modest resolved eastward wave forcing helps the westerly shear zone of the QBO
570 winds to propagate downwards only from the 20 hPa level to the 70 hPa level during both the cold and
571 warm ENSO episodes. At altitudes above the 20 hPa level, easterly jet cores are modestly weakened by
572 the resolved eastward wave forcing during the two extreme ENSO phases. In particular, Fig. 4f indicates
573 that at altitudes above the 30 hPa level the response of the resolved wave forcing to the ENSO acts to
574 slow down the downward propagation of the QBO during El Niño than during La Niña. However, the
575 parameterized GW forcing shown in Fig. 4 clearly dominates over the resolved wave forcing, which is
576 consistent with the finding of DallaSanta et al. (2021) that the parameterized convective GWs play a
577 dominant role in generating the spontaneous QBO in the GISS E2.2 models.

578 Figs. 5a–5c depict the composite fields of the QBO winds (black contours) and TEM advection
579 averaged over all realizations of the Coupled–NINT–AP ensemble. Comparing Figs. 5a–5c with Fig. 4
580 reveals that the TEM advection composite is also larger than composite resolved wave forcing in the
581 Coupled–NINT–AP model. Thus, the QBO simulated by this model is intimately related to the
582 parameterized GW forcing and the TEM advection. It is well-known that while wave forcing is largely
583 balanced out by the TEM advection in the extratropical stratosphere (Haynes, et al., 1991) tropical wave
584 forcing not only drives internal variabilities of zonal winds but also cancel out the TEM advection in the

585 stratosphere (Scott and Haynes, 1998). Figs. 5a–5b also show that the maximum positive and negative
586 advective tendencies are located above rather than below and propagate downward with the westerly and
587 easterly QBO jets, thus acting to slow down the downward propagation of the QBO, which is mainly
588 caused by the persistent tropical upwelling and a general feature of the QBO (Giorgetta et al. 2006; Rind
589 et al., 2014). Fig. 5c indicates that there exist stronger positive and negative advective tendencies above
590 the westerly and easterly QBO jets during El Niño than during La Niña. In other words, the TEM
591 advection alone leads to a slower phase speed of the QBO during El Niño than during La Niña. This is
592 not surprising because El Niño gives rise to a stronger tropical upwelling in the lower stratosphere (Calvo
593 et al., 2010; Simpson et al., 2011; Domeisen et al., 2019).

594 Figs. 5d–5f show the composite QBO winds (black contours) and the composite sum of parameterized
595 GW forcing, resolved wave forcing, and TEM advection averaged over all realizations of the Coupled–
596 NINT–AP ensemble. In other words, the upper, middle, and lower panels depict the sum of the fields
597 shown in all the corresponding panels of Fig. 4 and Figs. 5a–5c. The pattern of the composite sum is
598 generally determined by the pattern of parameterized GW forcing even though the latter is more coherent
599 than the former. Thus, we conclude that the shorter QBO period during El Niño simulated by Coupled–
600 NINT–AP is mainly caused by stronger parameterized GW forcing during warm ENSO episodes. We
601 also find that stronger parameterized GW forcing during warm ENSO events are simulated by AMIP–
602 OMA–SP and AMIP–OMA–AP models (figures not shown), which helps us understand why most
603 members from each of those three ensembles generate a spontaneous QBO whose phase speed is
604 statistically significantly greater during El Niño than during La Niña at the 5% significance level.

605 Now we explore how ENSO influences parameterized GW forcing, resolved wave forcing, and TEM
606 advection simulated by the Coupled–NINT–SP model, i.e., the remaining model listed in Tables 1 and
607 2. Contrasting between Fig. 6a and Fig. 4c reveals that the ensemble mean composite response to the

608 ENSO of parameterized GW forcing simulated by Coupled–NINT–SP is substantially weaker than that
609 simulated by Coupled–NINT–AP. Although the Coupled–NINT–SP simulations still bring about
610 enhanced westward parameterized GW forcing in the easterly shear zones of the simulated QBO winds
611 during El Niño in contrast to La Niña, the magnitude of the reinforcement is only about two thirds of
612 that simulated by Coupled–NINT–AP. In particular, in Fig. 6a there is no coherent pattern of enhanced
613 eastward parameterized GW forcing in the westerly shear zones of the QBO winds simulated by
614 Coupled–NINT–SP, which is in glaring contrast to the coherent pattern of positive enhancement shown
615 in Fig. 4c generated from the Coupled–NINT–AP ensemble. Figs. 6b and 6c show that both resolved
616 wave forcing and TEM advection respond to the ENSO weakly and uniformly in the Coupled–NINT–
617 SP ensemble simulations. Combining all three composite fields together, Fig. 6d demonstrates that the
618 ensemble mean of the Coupled–NINT–SP simulations still simulates a coherent but much weaker
619 response to the ENSO of resultant forcing at altitudes above the 40 hPa level, which helps us to explain
620 why only some of the Coupled–NINT–SP ensemble runs can simulate a faster QBO descent rate during
621 El Niño than during La Niña and the ENSO does not make a difference in the phase speed of the QBO
622 that is statistically significant at the 5% significance level in any of those Coupled–NINT–SP runs.

623 **5.2 ENSO modulation of the generation and propagation of parameterized gravity waves**

624 A natural question that arises is how the parameterized GW forcing relates to the SSTA of ENSO
625 extremes specified in or simulated by the GISS E2.2 models listed in Table 1. Figs. 7a and 7b show the
626 ensemble averages of the composite SSTA averaged over all La Niña and El Niño months respectively
627 over the 1871–2013 period simulated by Coupled–NINT–AP. Comparing Figs. 7a and 7b with Figs. 3a
628 and 3b reveals that the amplitude of the ENSO simulated by Coupled–NINT–AP is larger than the
629 observed. Figs. 7c and 7d show the differences between the simulated SSTA arising from the ENSO
630 events shown in Figs. 7a and 7b and the observed SSTA shown in Figs. 3a and 3b, indicating that the

631 largest discrepancies occur over the western and eastern equatorial Pacific. Figs. 7a and 7b also
632 demonstrate that the model has a capability to simulate the ENSO amplitude asymmetry (Cane and
633 Zebiak, 1987; Yu and Mechoso, 2001), namely, the amplitudes of the ENSO are relatively larger during
634 warm episodes than during cold episodes. As in Fig. 3 of Zhao and Sun (2022), Fig. 7e depicts the sum
635 of the composite SSTA shown in Figs. 7a and 7b that they used to characterize the ENSO amplitude
636 asymmetry while Fig. 7f shows their difference. Their Fig. 3 reveals that most CMIP6 models cannot
637 simulate the pattern of a positive residual in the sum of the composites of ENSO extremes in the tropical
638 eastern Pacific. Further comparison between Fig. 3 in Zhao and Sun (2022) and Fig. 7e indicates that the
639 ENSO amplitude asymmetry simulated by Coupled-NINT-AP is only about 50% of that simulated by
640 the GISS-E2-1-H model discussed in their study whose ENSO amplitude asymmetry is comparable to
641 the observed.

642 Since this study is chiefly concerned with the ENSO modulation of the QBO period, we focus on the
643 ensemble mean difference between the composite SSTA of ENSO extremes, which can be interpreted
644 as the trough-to-crest amplitude of the ENSO cycle. Comparing Fig. 8a with Fig. 3c indicates that the
645 trough-to-crest ENSO amplitude derived from the HadISST1 dataset over the 1871–2013 period is
646 somewhat smaller than that derived from the ERSSTv5 dataset over the 1953–2015 period, which is
647 consistent with the finding by Grothe et al. (2019) that the increase in the ENSO variability is statistically
648 significant (>95% confidence) from the preindustrial to recent era, no matter whether the latter is defined
649 by the previous 30, 50, 75, or 100 years before 2016. Fig. 7f and Fig. 8 also reveal that the ENSO
650 amplitude simulated by Coupled-NINT-AP is substantially greater than that simulated by Coupled-
651 NINT-SP, which was previously revealed in Rind et al. (2020). The tendency to generate stronger ENSO
652 oscillations means that the Coupled-NINT-AP runs will also more readily exceed the $\pm 0.5^\circ\text{C}$ criteria
653 for El Niño and La Niña events, and the Coupled-NINT-AP runs do simulate more ENSO events over

654 the 1871–2013 period than the Coupled–NINT–SP runs as indicated in subsection 2.3.1. Fig. 8 further
655 shows that the ENSO amplitude simulated by Coupled–NINT–SP is noticeably greater than those
656 specified in the AMIP–OMA–SP and AMIP–OMA–AP models (which, being derived from observations,
657 are identical) even though it is substantially weaker than that simulated by Coupled–NINT–AP.

658 We also ascertain that the Hadley circulation simulated by each of the four models listed in Table 1
659 strengthens and weakens during warm and cold ENSO episodes respectively (figure not shown), which
660 is consistent with the finding by Oort and Yienger (1996).

661 Schirber (2015) discovered that the parameterized GW mean momentum source is about 15% larger
662 in the El Niño ensemble than in the La Niña ensemble because the El Niño leads to enhanced
663 precipitation and convective heating. Similarly, we calculate the absolute value of convective
664 momentum fluxes (ACMF) at the source altitude and composite the ACMF anomalies averaged over the
665 latitudinal belt between 5°S and 5°N from El Niño and La Niña categories respectively over the 1871–
666 2013 period. Fig. 9 shows the composite difference in the equatorial mean ACMF anomalies between El
667 Niño and La Niña over the 1871–2013 period, indicating that the absolute momentum fluxes at the source
668 levels over the equatorial belt is larger during El Niño episodes than during La Niña episodes for each
669 of 19 runs listed in Table 1. This finding is consistent with that of Geller et al. (2016b), Alexander et al.
670 (2017), and Kang et al. (2018), namely, both convective GW momentum fluxes and convective GW
671 wave forcing are generally stronger during El Niño than during La Niña in the equatorial region. The
672 ensemble mean difference in the absolute momentum fluxes at the source levels averaged over that
673 equatorial belt between El Niño and La Niña is obtained as 0.07, 0.15, 0.10, and 0.12 mPa for AMIP–
674 OMA–SP, AMIP–OMA–AP, Coupled–NINT–SP, and Coupled–NINT–AP, respectively. Note that
675 these composite differences in ACMF between El Niño and La Niña translate into ACMF being about
676 10–20% larger in the El Niño ensembles than in the La Niña ensembles, thus agree with the Schirber

677 (2015). Since the QBO period is inversely dependent upon the momentum flux (Plumb, 1977), the
678 differences in equatorial absolute momentum fluxes at the source altitude contribute to shortening and
679 lengthening of the simulated QBO period during warm and cold ENSO phases, respectively.

680 Fig. 3 shows that the locations of warmest SSTs shift from the maritime continent during La Niña
681 episodes to the central and eastern equatorial Pacific during El Niño episodes. Since strong convective
682 activities over tropical oceans are generally located above the regions where the SSTs exceed 26°– 28° C
683 (Graham and Barnett, 1987; Zhang, 1993), strong convective activities also shift eastward from cold to
684 warm ENSO phases, as illustrated in Fig. 2. Using satellite data, the climatological study by Sullivan et
685 al. (2019) demonstrated that the occurrence of organized deep convection during El Niño events
686 increases threefold in the central and eastern Pacific and decreases twofold outside of these regions in
687 contrast to that during La Niña events. It is well-established that the Walker circulation strengthens
688 during La Niña and weakens during El Niño (Bjerknes, 1969).

689 Next, we construct the equatorial zonal winds as the zonal winds averaged from 5°S to 5°N. Then we
690 define the equatorial winds during La Niña and El Niño as the equatorial winds averaged over all months
691 that fall into the La Niña and El Niño categories, respectively. Fig. 10 illuminates that the Walker
692 circulation derived from ERA5 reanalysis during El Niño is substantially weaker than its counterpart
693 during La Niña over the equatorial Pacific and the eastern equatorial Indian ocean. Particularly in the
694 upper equatorial troposphere, the westerlies above the central and eastern Pacific during El Niño
695 episodes are decreased by more than 50% as compared with those during La Niña ones while the
696 easterlies above the equatorial Indian ocean and the maritime continent during El Niño conditions are
697 weakened by more than 30% as compared with those during La Niña ones. Kawatani et al. (2019) argue
698 that the weaker upper tropospheric winds during El Niño episodes enable a greater amount of GW
699 momentum fluxes to be transferred from the troposphere into stratosphere because less GWs are filtered

700 out. This argument assumes critical-level absorption of otherwise weakly damped, vertically propagating
701 GWs, which was adopted by Lindzen and Holton (1968). The weaker Walker circulation leads to a
702 shorter QBO period during El Niño while the stronger Walker circulation results in a longer QBO period
703 during La Niña.

704 Fig. 11 depicts the ensemble mean composite difference in the equatorial zonal wind anomalies
705 between warm and cold ENSO extremes simulated by the E2.2 models listed in Table 1. The patterns of
706 the simulated wind anomalies shown in Fig. 11 are very similar to that derived from the ERA5 reanalysis
707 shown in Fig. 10c. Namely, the weakened Walker circulation simulated by the E2.2 models during El
708 Niño episodes results in weaker upper tropospheric westerlies over the central and eastern equatorial
709 Pacific and weaker upper tropospheric easterlies over the maritime continent and equatorial Indian ocean
710 while the intensified Walker circulation simulated by the E2.2 models during La Niña episodes leads to
711 stronger upper tropospheric westerlies over the central and eastern equatorial Pacific and stronger upper
712 tropospheric easterlies over the maritime continent and equatorial Indian ocean. The difference in the
713 wind filtering of upward propagating GWs causes a greater transfer of GW momentum fluxes into the
714 tropical stratosphere during El Niño episodes than during La Niña episodes, leading to a shorter QBO
715 period during El Niño events than during La Niña events. Fig. 11 reveals that the maximum contrast in
716 the upper tropospheric zonal winds between warm and cold ENSO extremes simulated by two AMIP
717 models, i.e., AMIP-OMA-SP and AMIP-OMA-AP, reaches -13.1 ms^{-1} and -12.1 ms^{-1} , respectively,
718 over the central and eastern equatorial Pacific, and attains 6.6 ms^{-1} and 6.4 ms^{-1} , respectively, over
719 the maritime continent and equatorial Indian ocean. Those maximum contrasts are somewhat smaller
720 than what is derived from the ERA5 reanalysis shown in Fig. 10, namely -15.0 ms^{-1} over the central
721 and eastern equatorial Pacific and 7.8 ms^{-1} over the maritime continent and equatorial Indian ocean.
722 However, the maximum contrast in the upper-tropospheric zonal winds over the central and eastern

723 equatorial Pacific between warm and cold ENSO extremes simulated by two coupled ocean-atmosphere
724 models, i.e., Coupled-NINT-SP and Coupled-NINT-AP, only reaches -7.5 ms^{-1} and -8.2 ms^{-1} ,
725 respectively, thus is substantially smaller than that derived from the ERA5 reanalysis. Meanwhile, the
726 maximum contrast in the upper-tropospheric zonal winds over the maritime continent and equatorial
727 Indian ocean between warm and cold ENSO extremes simulated by those two coupled models, reaches
728 7.0 ms^{-1} and 10.3 ms^{-1} , respectively, which is slightly smaller than and somewhat larger than the
729 observed values, respectively.

730 The comparison of the observed and simulated changes in the Walker circulation between warm and
731 cold ENSO extremes shown in Figs. 10 and 11 can both account for a shorter QBO period simulated by
732 all GISS E2.2 models and explain why the two AMIP models can better capture the ENSO modulation
733 of the QBO period than the Coupled-NINT-SP model as indicated in Table 2. However, it can neither
734 explain why the Coupled-NINT-AP model can capture the ENSO modulation of the QBO period as two
735 AMIP models nor illuminate why the coupled model with the altered physics (i.e., Coupled-NINT-AP)
736 performs better than the coupled model with the standard physics (i.e., Coupled-NINT-SP). Further
737 comparing the simulated SST changes between warm and cold ENSO extremes shown in Figs. 7 and 8
738 hints that the unduly amplified ENSO in the coupled AP runs holds the key to those unsettled issues that
739 is detailed as follows.

740 Using a large ensemble of multiple climate models, Serva et al. (2020) discovered that the AMIP
741 historical runs generally better capture the ENSO modulation of the QBO period than the coupled ocean-
742 atmosphere historical simulations. In particular, among a few coupled ocean-atmosphere models that do,
743 to various extents, capture the ENSO modulation of the QBO period, the common feature is that each of
744 them can largely simulate the observed OLR anomaly pattern shown in Fig. 2c albeit the magnitudes of
745 those simulated OLRA from their historical runs are roughly 50% stronger than the observed (for more

746 details, refer to their Fig. 8 in Serva et al., 2020). For the sake of comparison, we construct the ensemble
747 mean composite difference in the OLRA between warm and cold ENSO extremes in the same way we
748 constructed the ensemble mean composite difference in the zonal wind anomalies depicted in Fig. 11.

749 Figs. 12a and 12b show that the patterns of the OLRA simulated by AMIP–OMA–SP and AMIP–
750 OMA–AP largely resemble the observed one shown in Fig. 2c. Although the pattern simulated by
751 AMIP–OMA–AP matches better with the observed, the convective activities during El Niño episodes
752 simulated by AMIP–OMA–SP and AMIP–OMA–AP are apparently inadequate over the region where
753 the upper tropospheric westerlies weaken most conspicuously during warm ENSO extremes shown in
754 Figs. 11a and 11b, respectively. Thus, although the contrast in the wind filtering of GWs between El
755 Niño and La Niña episodes simulated by the two AMIP E2.2 models are comparable to the observed,
756 the difference in the GW momentum flux transferred into the equatorial stratosphere between warm and
757 cold ENSO extremes may well be smaller than the observed with the correct SSTs. This partly explains
758 why the contrast between the observed mean QBO period during El Niño episodes (i.e., 25.6 months)
759 and the observed mean QBO period during La Niña episodes (i.e., 34.3 months) is higher than that
760 simulated by the two AMIP models shown in Table 2 (i.e., E1 and E2 in Table 2). As exhibited by the
761 coupled model capable of simulating the ENSO modulation of the QBO period, Fig. 12d shows that the
762 contrast in the OLRA between warm and cold ENSO extremes simulated by Coupled–NINT–AP is
763 apparently sharper than the observed one shown in Fig. 2c. In particular, the tropical convection in the
764 central and eastern Pacific during El Niño episodes simulated by Coupled–NINT–AP is both more
765 extensive and more intensive than that simulated by the two AMIP models shown in Figs. 12a and 12b,
766 which is consistent with the fact that the composite contrast in the SSTA simulated by Coupled–NINT–
767 AP shown in Fig. 7d is substantially sharper than that prescribed in the two AMIP models shown in Fig.
768 8a. Thus, even though the wind filtering of GWs during El Niño episodes simulated by Coupled–NINT–

769 AP shown in Figs 12d is significantly smaller than that simulated by AMIP–OMA–SP and AMIP–
770 OMA–AP shown in Figs 12a and 12b, respectively, the combined effect of the lower contrast in the wind
771 filtering and the higher contrast in the amount of GW momentum fluxes generated by convective
772 activities between warm and cold ENSO extremes over the central and eastern tropical Pacific results in
773 a comparable ENSO modulation of the QBO period simulated by Coupled–NINT–AP to that simulated
774 by the two AMIP models as illustrated in Table 2.

775 Finally, comparing Fig. 12c with Fig. 2c and other three panels in Fig. 12 reveals that convective
776 activities during the warm ENSO phase simulated by the Coupled–NINT–SP model are substantially
777 weaker than both the observed and those simulated by other three models list in Table 1. Combining the
778 small composite OLR difference shown in Fig. 12c and the small difference in the wind filtering shown
779 in Fig. 8c between warm and cold ENSO extremes over the central and eastern equatorial Pacific results
780 in a low contrast in GW forcing between warm and cold ENSO phases shown in Fig. 6a, which, short of
781 the compensating effect of the excessively amplified ENSO in Coupled–NINT–AP ensemble runs,
782 should lead to a relatively weaker ENSO modulation of the QBO period simulated by the Coupled–
783 NINT–SP model as illustrated in Table 2. However, this is not the whole story; and we will return to this
784 subject in the discussion section¹.

785

786 **6. Discussion and Conclusions**

¹ In order to test whether the difference patterns shown in section 5 are statistically robust we also use the statistics averaged over an ENSO event as our sample points to perform two-tailed tests. Figs. S3–S9 shown in the supplement demonstrate that those difference patterns are statistically significant at the 5% significance level to a large extent.

787 Both Kawatani et al. (2019) and Serva et al. (2020) pointed out that a relatively high horizontal
788 resolution is necessary to simulate the ENSO modulation of the QBO period. Employing an Earth system
789 model with T42 ($\sim 2.79^\circ$) horizontal resolution, Kawatani et al. (2019) further demonstrated that the
790 ENSO modulation of the QBO could not be simulated with their fixed GW sources. Serva et al. (2020)
791 also pointed out that the reliance on stationary parameterizations of GWs is partly responsible for failing
792 to simulate the observed modulation of the QBO by the ENSO in current climate models.

793 Rind et al. (1988) implemented various interactive GW sources in the GISS climate models. With the
794 momentum flux of the parameterized convective waves dependent on the convective mass flux,
795 buoyancy frequency and density at the top of the convective region, wind velocity averaged over the
796 convective layers, etc. and with a horizontal resolution of 2° latitude by 2.5° longitude, all the four
797 versions of GISS E2.2 models in this study can simulate the ENSO modulation of the QBO period to
798 various degrees. For each of 19 runs conducted in this study, the absolute momentum fluxes at the source
799 levels over the equatorial belt is larger during El Niño episodes than during La Niña episodes, leading
800 to a shorter and longer QBO period, respectively.

801 Realistic simulation of the ENSO modulation of the QBO periods entails the realistic simulation of
802 both the ENSO and the QBO. With the realistic SSTs specified, both the composite difference in the
803 Walker circulation and the composite OLR difference between warm and cold ENSO extremes simulated
804 by the two AMIP E2.2 models are close to the observed. Since the AMIP model with the “altered physics”
805 performs better than that with the “standard physics” as far as the simulated OLR is concerned, the
806 ensemble mean difference in the QBO period between La Niña and El Niño episodes (i.e., ~ 4.5 months)
807 simulated by AMIP–OMA–AP is larger than that simulated by AMIP–OMA–SP (i.e., ~ 3.9 months),
808 which indicates that convective parameterization scheme is important not only for simulating the
809 resolved waves as pointed out by Horinouchi et al. (2003) and Lott et al. (2014), but also for

810 parameterizing GWs. However, the convective activities simulated by both AMIP E2.2 models are still
811 inadequate over the central and eastern equatorial Pacific as compared to the observed, which may partly
812 account for why the ensemble mean differences in the QBO period between La Niña and El Niño
813 episodes simulated by both AMIP models are smaller than the observed difference (i.e., ~8.7 months).

814 Although the simulated Walker circulation associated with the ENSO cycle is comparable among the
815 two coupled ocean-atmosphere models in this study, the E2.2 model with the “standard physics”
816 performs well in its simulated SSTs which is very close to the observed while the ENSO amplitudes
817 simulated by the other model with the “altered physics” are substantially greater than the observed. Yet
818 the model with the “standard physics” not only fails to properly simulate the shift of the strongest
819 convection from the maritime continent during La Niña to the central and eastern equatorial Pacific
820 during El Niño, but also grossly fail to simulate the sufficient amplitude of the OLR concomitant with
821 the ENSO cycle. The weaker response of the Walker circulation and convective activities to the ENSO
822 cycle together with the dislocated centers of convection concomitant to cold and warm ENSO extremes
823 leads to the smallest ensemble mean difference in the QBO period between La Niña and El Niño episodes
824 (i.e., ~2.7 months) simulated by the Coupled–NINT–SP model. The weaker variation of the Walker
825 circulation and the excessive change in convection compensate to give an impression of realistically
826 simulating the ENSO modulation of the QBO period by the other model with the “altered physics”, i.e.,
827 Coupled–NINT–AP, with its ensemble mean differences in the QBO period between La Niña and El
828 Niño episodes being ~4.8 months. However, it is worth pointing out that we don’t regard that model as
829 the best among the four models listed in Table 1 because the relatively satisfactory results are achieved
830 in a compensatory, thus unrealistic, way. Serva et al. (2020) conducted both the atmosphere-only and
831 coupled historical simulations and found that the trough-to-crest amplitudes of the OLR associated with
832 the ENSO cycle are two times larger than the observed for a few models that relatively well capture the

833 ENSO modulation of the QBO period, which together with our results suggests that the parameterized
834 convection is a linchpin of realistically simulating the ENSO, the QBO, and the ENSO modulation of
835 the QBO.

836 Intriguingly, the simulated difference in the QBO period between La Niña and El Niño is 6.2 months
837 from the first realization simulated by Coupled–NINT–SP. However, it is not statistically significant at
838 the 5% significance level. Meanwhile, the differences in the QBO period between La Niña and El Niño
839 from most of the realizations simulated by Coupled–NINT–AP are apparently less than 6.2 months but
840 are all statistically significant. To gain a deeper insight, we calculate the frequency power spectra of
841 standardized ONIs derived from the observed and simulated SSTs. Fig. 13a depicts the power spectral
842 densities (PSD) of standardized ONI between 1953 and 2015 derived from the NOAA ERSSTv5 SST
843 while Fig. 13b delineates the PSD of standardized ONI between 1871 and 2013 derived from the
844 HadISST1 dataset as used in the AMIP runs. Figs. 13a and 13b show that although the ENSO accounts
845 for the lion’s share of SST variabilities, there is a good amount of SST variabilities on the decadal and
846 multidecadal time scales. Fig. 13d illustrates the PSD of standardized ONI between 1871 and 2013
847 simulated by the second realization of Coupled–NINT–AP, which demonstrates that the ENSO
848 overwhelmingly dominates over any other noises in SST variabilities simulated by those E2.2 models
849 with the “altered physics”. Furthermore, Fig. 13c shows the PSD of standardized ONI between 1871 and
850 2013 simulated by the first realization of Coupled–NINT–SP. Apparently, the SST variabilities
851 simulated by the E2.2 model with the “standard physics” are comparable to the observed, thus more
852 realistic. The smaller ratio of the ENSO signal to the noise simulated by the first realization of Coupled–
853 NINT–SP and the much larger ratio simulated by the second realizations of the E2.2 models with “alter
854 physics” explain why the difference of 6.2 months in the QBO period between La Niña and El Niño

855 from the former is not statistically significant while the differences of 2.6 and 4.8 months from the latter
856 are statistically significant as shown in Table 2.

857 The rich spectrum of internal variabilities simulated by Coupled–NINT–SP, to a large degree, reflects
858 the observed ones shown in Figs. 13a and 13b. Those large internal variabilities likely underlie why one
859 of the historical runs simulated by Coupled–NINT–SP gives rise to a slower mean QBO phase speed
860 during El Niño than during La Niña while other four runs from Coupled–NINT–SP do simulate a faster
861 phase speed of the QBO during warm ENSO events. Kawatani et al. (2019) conducted two 100-yr
862 experiments: one for a perpetual El Niño condition and the other for a perpetual La Niña condition. Their
863 Fig. 3 shows that although the long-term mean QBO period from the El Niño run is shorter than that
864 from the La Niña run, this is not the case for each individual year. This is because various internal
865 variabilities exert their influence over the QBO period.

866 None of the E2.2 configurations robustly simulate an ENSO modulation of QBO amplitude,
867 consistent with the weaker signal present in observations (Yuan et al., 2014). It is not surprising because
868 our observational analyses show that the ENSO modulation of the QBO amplitude is not statistically
869 significant at the 95% confidence level. In order to realistically simulate the ENSO modulation of the
870 QBO, various aspects of climate models such as the SSTs, the Walker circulation, the parameterizations
871 of convection and GWs need to be further improved, which is fortunately ongoing under the auspices of
872 the SPARC Quasi-Biennial Oscillation initiative (Butchart et al., 2018).

873

874 **Data availability**

875 The monthly mean zonal winds from Free University of Berlin are obtained from [https://www.geo.fu-](https://www.geo.fu-berlin.de/en/met/ag/strat/produkte/qbo/index.html)
876 [berlin.de/en/met/ag/strat/produkte/qbo/index.html](https://www.geo.fu-berlin.de/en/met/ag/strat/produkte/qbo/index.html). The NOAA ERSSTv5 SST is acquired from
877 <https://www.ncei.noaa.gov/products/extended-reconstructed-sst>. The NCEI OLR is downloaded from

878 <https://www.ncei.noaa.gov/products/climate-data-records/outgoing-longwave-radiation-monthly>. The
879 ERA5 monthly mean zonal winds are obtained from the ECMWF C3S at Climate Data Store:
880 <https://cds.climate.copernicus.eu/>. The Coupled–NINT–AP outputs are available from the Earth System
881 Grid Federation. The data used in this paper from the other three E2.2 models are accessible at
882 <https://zenodo.org/record/8360291>.

Table 1 The model configurations and respective ensemble simulations

Model configuration	Simulation	CMIP6 archive tag	Period	Ensemble size	Ensemble name
AMIP-OMA-SP	Historical AMIP	N/A	1850–2014	5	E1
AMIP-OMA-AP	Historical AMIP	N/A*	1850–2014	4	E2
Coupled-NINT-SP	CMIP6 Historical	N/A	1850–2014	5	E3
Coupled-NINT-AP	CMIP6 Historical	E2-2-G.historical.r[1-5]i1p1f1	1850–2014	5	E4

*E2-2-G.amip.r[1-5]i1p3f1 in the CMIP6 archive are the outputs of the same model but range from 1979 to 2014.

1224

Table 2 The ENSO influence on the QBO period

Member		r1			r2			r3			r4			r5		
ENSO Phase		EL	LA	EL-LA	EL	LA	EL-LA	EL	LA	EL-LA	EL	LA	EL-LA	EL	LA	EL-LA
Period (month)	E1	31.1	34.0	(-2.9)	34.9	35.9	-1.0	29.4	32.9	-3.5	29.7	36.7	(-7.0)	30.5	35.7	(-5.2)
	E2	33.1	36.5	(-3.4)	31.5	35.6	(-4.1)	32.1	35.4	-3.2	29.4	36.8	(-7.4)	n/a	n/a	n/a
	E3	27.5	33.7	-6.2	28.0	30.5	-2.5	30.5	29.8	0.7	30.0	31.5	-1.5	28.2	32.0	-3.8
	E4	31.2	35.0	(-3.8)	29.8	32.4	(-2.6)	29.7	35.4	(-5.7)	28.0	34.7	(-6.7)	28.0	33.4	(-5.4)

E[1-4] denote the ensemble simulations AMIP-OMA-SP, AMIP-OMA-AP, Coupled-NINT-SP, and Coupled-NINT-AP, respectively. r[1-5] indicate the ensemble members of those simulations. EL and LA are short for El Niño than during La Niña, respectively. The numbers in parentheses denote being statistically significantly different from zero at the 5% significance level.

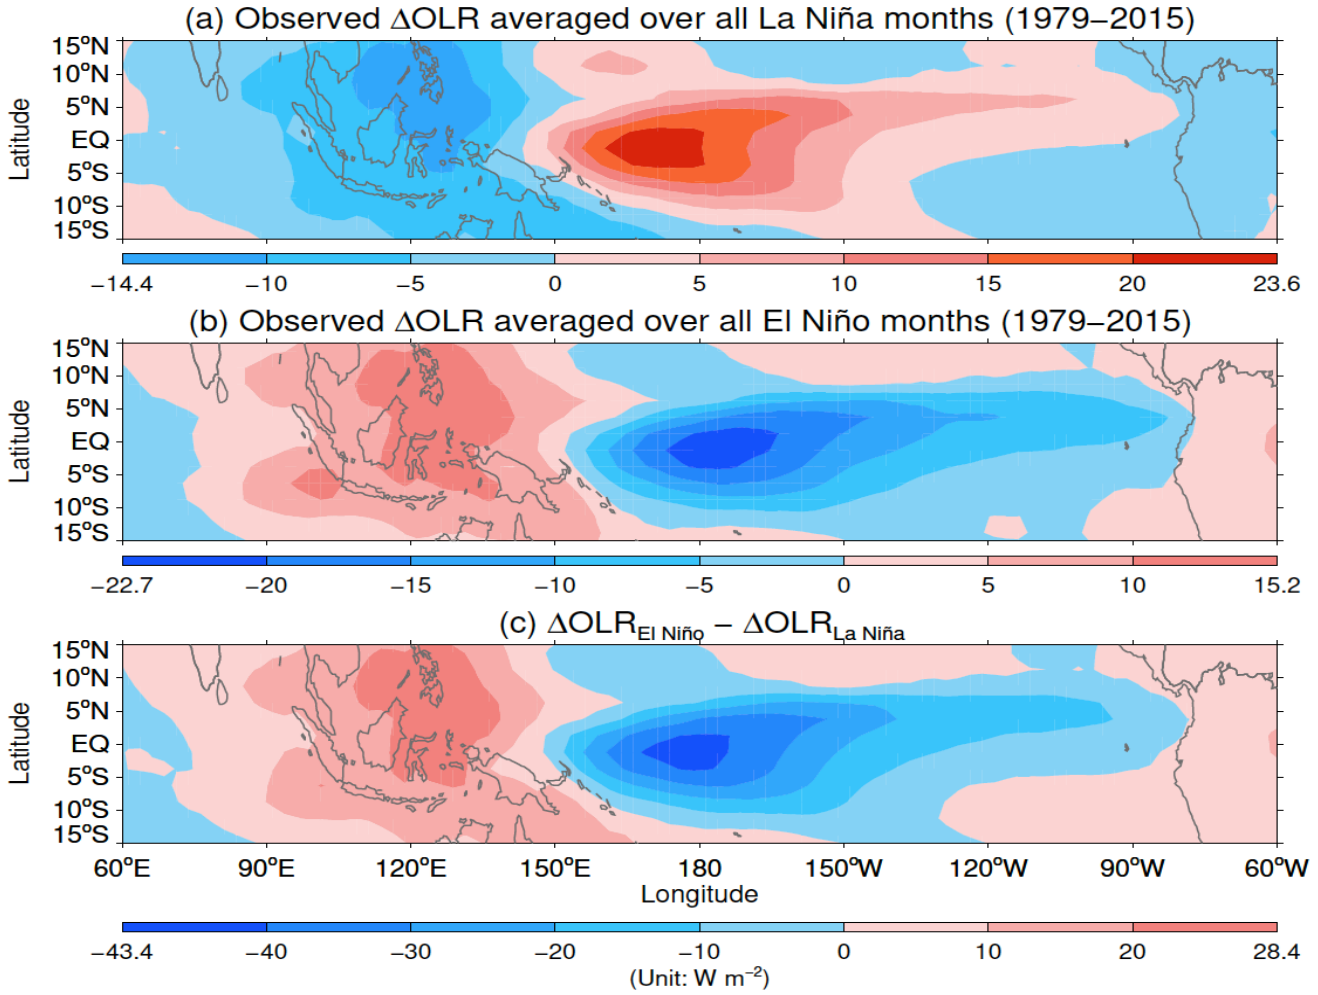

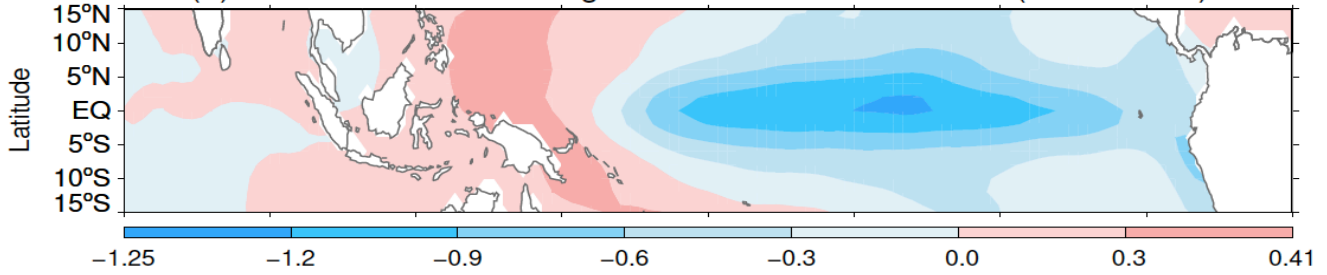

Fig. 2. Mean OLR deviations from climatology for (a) La Niña and (b) El Niño conditions over the tropical Indian and Pacific oceans. (c) Differences of mean OLR between El Niño and La Niña conditions. The mean composite OLR and their differences are derived from the datasets provided by NOAA NCEI.

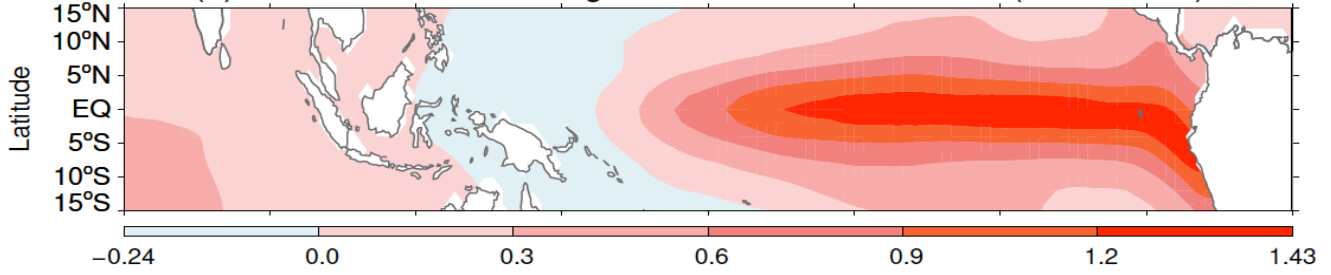

1261

(a) Observed Δ SST averaged over all La Niña months (1979–2015)

1265

(b) Observed Δ SST averaged over all El Niño months (1979–2015)

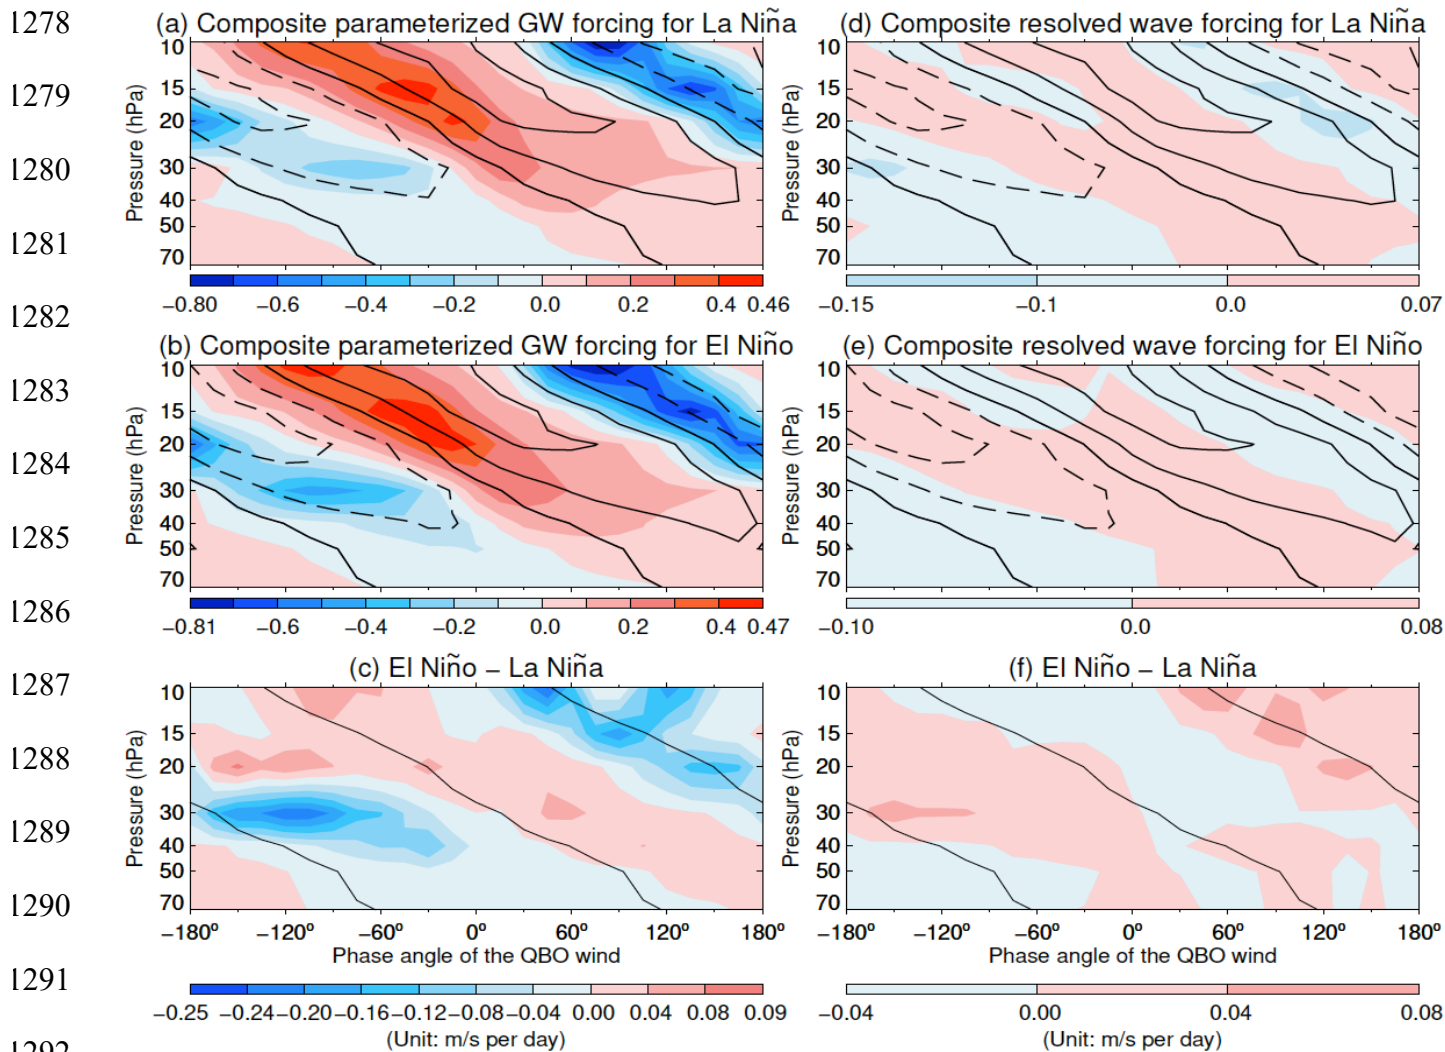

1269

(c) Δ SST_{El Niño} - Δ SST_{La Niña}

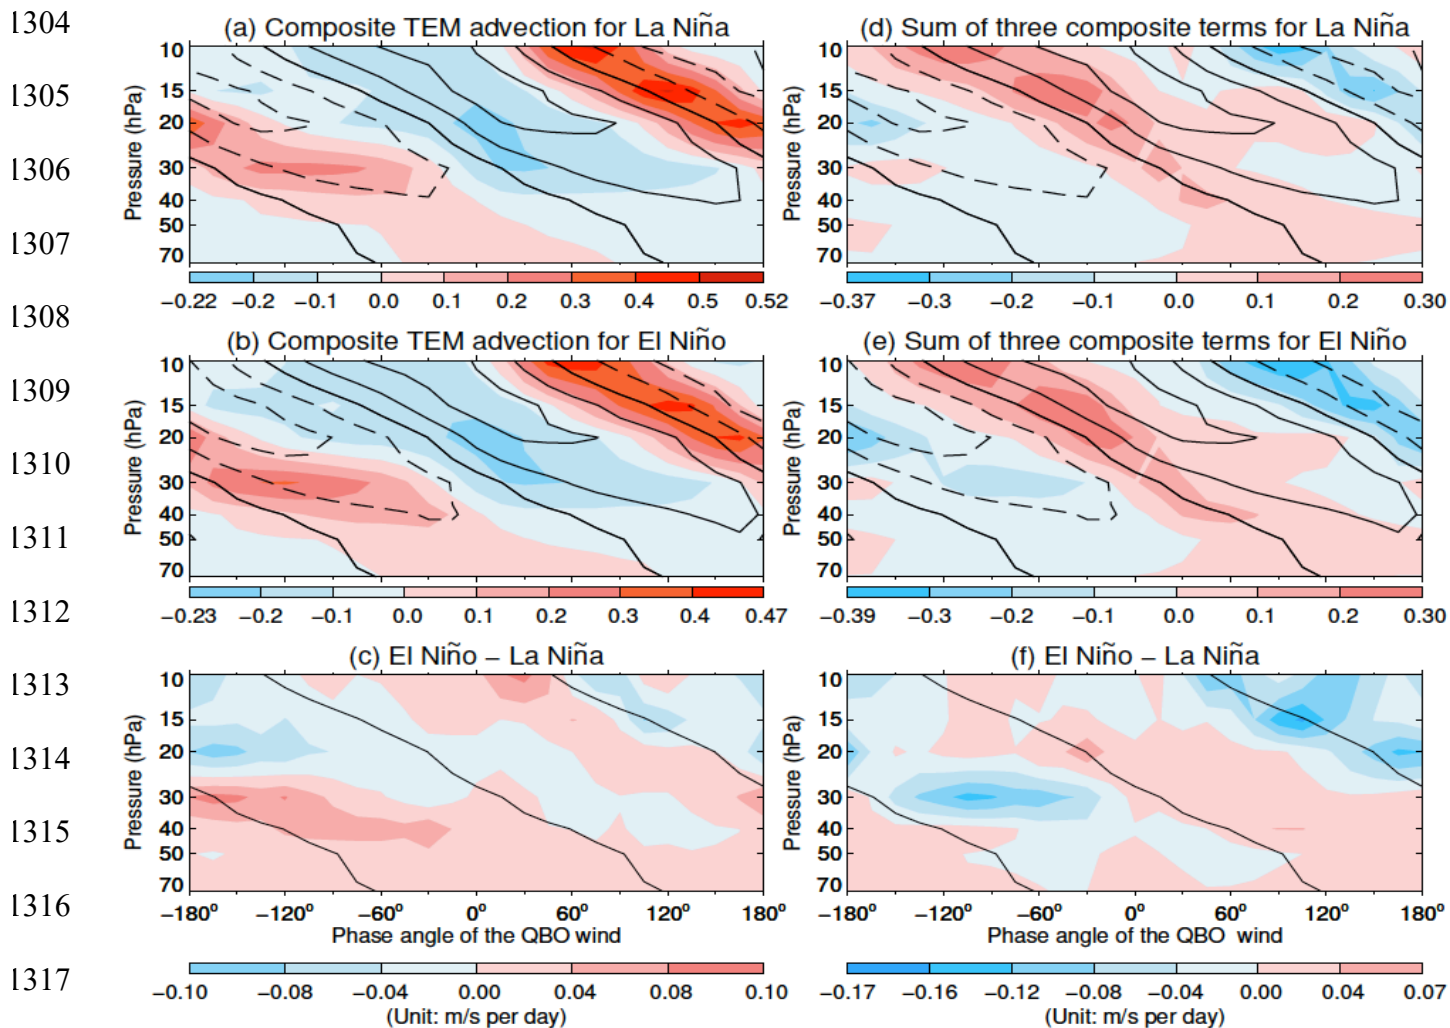

1274

1275 **Fig. 3.** Mean SST deviations from climatology for (a) La Niña and (b) El Niño conditions over the tropical
1276 Indian and Pacific oceans. (c) Differences of mean SSTA between El Niño and La Niña conditions. The
1277 mean composite SSTA and their differences are derived from the NOAA ERSSTv5 SST.

1292 **Fig. 4.** Ensemble average of the composite QBO winds simulated by the Coupled–NINT–AP model
 1293 during La Niña (upper panels) and El Niño (middle panels) is depicted by black contour lines where the
 1294 contour interval is 10 m s^{-1} with dashed lines denoting negatives and solid lines denoting positives and
 1295 zero. The location of strong shear zones of the QBO winds during ENSO extremes is delineated by the
 1296 zero wind contour lines in lower panels. For color filled contours, left panels depict the ensemble average
 1297 of the composite parameterized GW forcing simulated by the Coupled–NINT–AP model averaged from
 1298 5°S to 5°N during La Niña (a) and El Niño (b) and its composite difference between El Niño and La Niña
 1299 (c); right panels depict the ensemble average of the composite resolved wave forcing simulated by the
 1300 Coupled–NINT–AP model during La Niña (d) and El Niño (e) and its composite difference between El
 1301 Niño and La Niña (f).
 1302
 1303

1318 **Fig. 5.** The black contour lines are the same as those in Fig. 4. For color filled contours, left panels depict
 1319 the ensemble average of the composite TEM advection simulated by the Coupled-NINT-AP model
 1320 averaged from 5°S to 5°N during La Niña (a) and El Niño (b) and the composite difference between El
 1321 Niño and La Niña (c); right panels depict the ensemble mean totaling of the composite fields of GW
 1322 forcing, resolved wave forcing, and TEM advection simulated by the Coupled-NINT-AP model during
 1323 La Niña (d) and El Niño (e) and the composite difference between El Niño and La Niña (f).
