Acylperoxy radicals (RO<sub>2</sub>) are key intermediates in atmospheric oxidation of organic compounds and different from the general alkyl RO2 radicals in reactivity. However, direct probing of the molecular identities and chemistry of acyl RO2 remains quite limited. Here, we report a combined experimental and kinetic modelling study of the composition and formation mechanisms of acyl RO<sub>2</sub>, as well as their contributions to the formation of highly oxygenated organic molecules (HOMs) during ozonolysis of α-pinene. We find that acyl RO<sub>2</sub> radicals account for 67%, 94%, and 32% of the highly oxygenated C<sub>7</sub>, C<sub>8</sub>, and C<sub>9</sub> RO<sub>2</sub>, respectively, but only a few percent of C<sub>10</sub> RO<sub>2</sub>. The formation pathway of acyl RO<sub>2</sub> species depends on their oxygenation level. The highly oxygenated acyl RO<sub>2</sub> (oxygen atom number ≥ 6) are mainly formed by the intramolecular aldehydic H-shift (i.e., autoxidation) of RO<sub>2</sub>, while the less oxygenated acyl RO<sub>2</sub> (oxygen atom number < 6) are basically derived from the C-C bond cleavage of alkoxy (RO) radicals containing an α-ketone group or the intramolecular H-shift of RO containing an aldehyde group. The acyl RO2-involved reactions explain 50-90% of C<sub>7</sub> and C<sub>8</sub> closed-shell HOMs and 14% of C<sub>10</sub> HOMs, respectively. For C<sub>9</sub> HOMs, this contribution can be up to 30%-60%. In addition, acyl RO<sub>2</sub> contribute to 50%-95% of C<sub>14</sub>-C<sub>18</sub> HOM dimer formation. Because of the generally fast reaction kinetics of acyl RO<sub>2</sub>, the acyl RO<sub>2</sub> + alkyl RO<sub>2</sub> reactions seem to outcompete the alkyl RO<sub>2</sub> + alkyl RO<sub>2</sub> pathways, thereby affecting the fate of alkyl RO2 and HOM formation. Our study sheds lights on the detailed formation pathways of the monoterpene-derived acyl RO2 and their contributions to HOM formation, which will help to understand the oxidation chemistry of monoterpenes and sources of low-volatility organic compounds capable of driving particle formation and growth in the atmosphere.

Monoterpenes (C<sub>10</sub>H<sub>16</sub>) comprise an important fraction of nonmethane hydrocarbons in the global atmosphere (Guenther et al. 2012, Sindelarova et al. 2014) and make a significant contribution to the secondary organic aerosol (SOA) budget (Pye et al. 2010, Iyer et al. 2021). The presence of double bond and large molecular size of monoterpenes favor their oxidation reactivity towards O<sub>3</sub>, hydroxyl (OH), and nitrate (NO<sub>3</sub>) radicals (Berndt 2022, Roger et al. 2004, Atkinson, Hasegawa and Aschmann 1990, Kurten et al. 2015, Kristensen et al. 2016, Bianchi et al. 2019), as well as the formation of low-volatility products and SOA (Molteni et al. 2019, Shen et al. 2022, Bianchi et al. 2019, Zhang et al. 2018, Fry et al. 2014, Fry et al. 2009). The organic peroxy radicals (RO<sub>2</sub>) in the gas-phase oxidation of monoterpenes can undergo autoxidation and form a class of highly oxygenated organic compounds (HOM) (Bianchi et al. 2019, Jokinen et al. 2014, Mentel et al. 2015, Berndt et al. 2016, Berndt 2022, Zhao, Thornton and Pye 2018, Bell et al. 2021), which are primarily low- or extremely low-volatility organic compounds (LVOCs and ELVOCs) (Bianchi et al. 2019, Ehn et al. 2014) and thus play a crucial role in SOA formation and growth. Significant advances have been made in recent years concerning the monoterpene RO2 autoxidation and its contribution to HOM formation (Zhao et al. 2018, Shen et al. 2022, Ehn et al. 2014, Berndt et al. 2016, Xu et al. 2019, Berndt 2022, Lin et al. 2021). It is recognized that a part of monoterpene RO<sub>2</sub> radicals derived from the traditional ozonolysis channel (i.e., isomerization of Criegee intermediates, CI) and OH addition channel can autoxidize at a rate larger than 1 s<sup>-1</sup> and could be an important contributor to HOM formation (Zhao et al. 2018, Xu et al. 2019, Berndt 2021). Recently, new reaction channels leading to the RO2 radicals that can undergo fast autoxidation have been proposed. A quantum chemical calculation study indicated that an excited CI arising from αpinene ozonolysis could undergo ring-breaking reactions and directly lead to a ring-opened RO<sub>2</sub> due to the excess energy, which can autoxidize at a rate of ~1 s<sup>-1</sup> and rapidly form highly oxidized RO<sub>2</sub> with up to 8 oxygen atoms (Iyer et al. 2021). In addition, the minor hydrogen abstraction channel by OH radicals has been proposed as a predominant pathway to HOM formation from OH oxidation of  $\alpha$ -pinene under atmospheric conditions (Shen et al. 2022). RO<sub>2</sub> species can be simply divided into alkyl RO<sub>2</sub> and acyl RO<sub>2</sub> (RC(O)OO) according to whether R is an acyl radical. There are significant differences in the reactivity of these two kinds of RO<sub>2</sub>. Firstly, the rate constant of acyl RO<sub>2</sub> with NO is in general slightly higher than that of alkyl RO<sub>2</sub> (Orlando and Tyndall 2012, Calvert et al. 2008, Atkinson et al. 2007). For example, the reaction rate constants of acyl RO<sub>2</sub>, CH<sub>3</sub>C(O)O<sub>2</sub>, and alkyl RO<sub>2</sub>, CH<sub>3</sub>CH<sub>2</sub>O<sub>2</sub>, with NO have been reported to be  $20 \times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> and  $9.2 \times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, respectively (Orlando and Tyndall 2012, Calvert et al. 2008, Atkinson et al. 2007). Besides, acyl RO<sub>2</sub> can react rapidly with NO<sub>2</sub> and form thermally unstable peroxyacyl nitrates (RC(O)OONO<sub>2</sub>), which have a lifetime of tens of minutes at room temperature and of days and even months in winter or in the upper atmosphere with lower temperatures (Orlando and Tyndall 2012, Atkinson et al. 2007). Although alkyl RO<sub>2</sub> radicals can also react with NO<sub>2</sub> and form the alkyl peroxynitrates (ROONO<sub>2</sub>), they are extremely unstable and will decompose into RO2 radicals and NO2 in less than 1s (Orlando and Tyndall 2012, Kirchner et al. 1997). Lastly, the rate constant of cross-reaction of acyl RO<sub>2</sub> ( $1.5\pm0.3\times10^{-11}$  cm<sup>3</sup> molecule  $^1$  s  $^{-1}$  ) is significantly higher than that of alkyl RO  $_2$  (2  $\times10^{-17}$  - 1  $\times10^{-11}\,\text{cm}^3$  molecule  $^1$  s  $^{-1}$  ) (Zhao et al. 2018, Tyndall et al. 2001, Atkinson et al. 2007, Villenave and Lesclaux 1996). As a result, these two kinds of RO<sub>2</sub> may play different roles in the autoxidation as well as HOM and dimer formation. The quantum calculations revealed that different functional groups in RO2 would lead to significantly different intramolecular H-shift rates (Otkjær et al. 2018). The C=O and C=C substituents lead to resonance stabilized carbon radicals and could enhance the H-shift rate constants by more than a factor of 400. The fast aldehydic H-shift rate contributes to a series of acyl radicals (RC(O)) with the radical site at the terminal carbonyl carbon, which further produce the acyl RO<sub>2</sub> with O2 addition. Many RO2 formed in the oxidation of monoterpenes have the aldehyde functionality, especially for α-pinene ozonolysis, in which all the primary and many later-generation RO<sub>2</sub> contain at least one aldehyde group (Berndt et al. 2018, Berndt 2022, Li et al. 2019, Noziere et al. 2015, Shen et al. 2022). As a result, acyl RO<sub>2</sub> may comprise a considerable fraction of total RO<sub>2</sub> species and contribute significantly to the formation of low-volatility products and SOA in the monoterpene oxidation system. A recent study by Zhao et al. (2022) found that the acyl RO<sub>2</sub>involved reactions contribute to 50%-80% of oxygenated  $C_{15}$ - $C_{20}$  dimers (O:C  $\geq$  0.4) and 70% of  $C_{15}$ - $C_{19}$  dimer esters in SOA from  $\alpha$ -pinene ozonolysis. However, currently the direct probing of the molecular identities and chemistry of monoterpene-derived acyl RO2 radicals is rather limited. The role of acyl RO<sub>2</sub> in HOM formation remains to be quantified. In this study, the molecular identities and formation mechanisms of acyl RO2 radicals, as well as their contributions to HOM formation in the  $\alpha$ -pinene ozonolysis are investigated. The experiments were conducted in a flow reactor with different concentrations of NO<sub>2</sub>, which acted as an efficient scavenger for the acyl RO<sub>2</sub>. The molecular composition and abundance of the gas-phase HOMs were measured by a chemical ionization-atmospheric pressure interface-time-of-flight mass spectrometer (CI-APi-TOF) using nitrate as the reagent ions. In addition, kinetic modelling using the Framework for 0-D Atmospheric Modeling (F0AM v4.1) employing Master Chemical Mechanisms (MCM v3.3.1) updated with the latest advances of the RO<sub>2</sub> chemistry was performed

to gain insights into the reaction kinetics and mechanisms of acyl RO<sub>2</sub> species. We find that acyl RO<sub>2</sub> account for a major fraction of highly oxygenated C<sub>7</sub> and C<sub>8</sub> RO<sub>2</sub> and play a significant role in the formation of HOM monomers and dimers with small molecular size. This study will help to understand the role of acyl RO<sub>2</sub> in the formation of low-volatility species from monoterpene oxidation and reduce the uncertainties in the future atmospheric modelling of the formation and impacts of aerosols.

## 2.1 Flow Reactor Experiments.

The α-pinene ozonolysis experiments were carried out under room temperature (298 K) and dry conditions (relative humidity < 5%) in a custom-built flow reactor, which has been described in detail previously (Yao et al. 2019). The α-pinene vapor was generated by evaporating its pure liquid (99%, Sigma-Aldrich) into a flow of zero air (10.65 L min<sup>-1</sup>) added to the reactor using an automated syringe pump (TYD01-01-CE, Baoding Leifu Fluid Technology Co., Ltd.). The initial concentrations of α-pinene ranged from 500 ppb to 3 ppm in different experiments. Ozone was generated by passing a flow of ultra-high-purity (UHP) O<sub>2</sub> (150 mL min<sup>-1</sup>, Shanghai Maytor Special Gas Co., Ltd.) through a quartz tube housing a pen-ray mercury lamp (UV-S2, UVP Inc.) and its concentration (45 ppb and 180 ppb under low and high O<sub>3</sub> conditions, respectively) was measured by an ozone analyzer (Model 49i, Thermo Fisher Scientific, USA). The NO<sub>2</sub>, acting as an acyl RO<sub>2</sub> scavenger, was derived from its standard cylinder gas (15.6 ppm, Shanghai Weichuang Standard Gas Co., Ltd.) and its initial concentration ranged from 0 to 30 ppb. To validate the formation mechanisms of acyl RO<sub>2</sub>, selected experiments with the addition of NO or cyclohexane were also conducted. NO was derived by its standard cylinder gas (9.8 ppm, Shanghai Weichuang Standard Gas Co., Ltd.) and its initial concentration also ranged from 0 to 30 ppb. The gas-phase cyclohexane (~ 500 ppm), acting as an OH scavenger, was generated by bubbling a gentle flow of UHP N<sub>2</sub> through liquid cyclohexane (LC-MS grade, CNW). The total air flow in the flow reactor was 10.8 L min<sup>-1</sup> and the residence time was 25 seconds. The relatively low O<sub>3</sub> concentration and short reaction time in the flow reactor avoid significant production of NO<sub>3</sub> radicals from NO<sub>2</sub> and O<sub>3</sub> and make the NO<sub>3</sub> oxidation contribute only 0.3%-1.2% of the total α-pinene oxidation in our experiments. Therefore, the NO<sub>3</sub> chemistry could be neglected in this study. A summary of the experimental conditions is given in Tables S1 and S2 in the Supplement. The gas-phase RO<sub>2</sub> radicals and closed-shell products were measured by a nitrate-based CI-API-TOF mass spectrometer (abbreviated as nitrate-CIMS; Aerodyne Research, Inc.), and a long timeof-flight mass spectrometer with a mass resolution of ~10000 Th/Th was used here. The mass calibration error is below 1.8 ppm. The sheath flow, including a 2 mL min<sup>-1</sup> UHP N<sub>2</sub> flow containing nitric acid (HNO<sub>3</sub>) and 22.4 L min<sup>-1</sup> zero air was guided through a PhotoIonizer X-ray (Model L9491, Hamamatsu, Japan) to generate nitrate reagent ions. The total sample flow rate was 9 L min<sup>-1</sup> during the experiments. The instrument was calibrated with a sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) calibration factor and a mass dependent transmission efficiency. The mass spectra within the m/z range of 50 to 700 were analyzed using the tofTools package developed by Junninen et al. (2010) based on Matlab. After getting the signals of the gas phase oxygenated organic molecules (OOMs), their concentration can be calculated as follows (Jokinen et al. 2012, Bianchi et al. 2019):

142 
$$\frac{l_{OOM}}{l_{NO_{-}} + l_{HNO_{3}NO_{-}} + l_{HNO_{3}HNO_{3}NO_{-}}} \times \frac{1}{T_{t}}$$
 (1)

C is the calibration factor of  $H_2SO_4$ , with a value of  $4.06 \times 10^9$  molecule cm<sup>-3</sup> in this study;  $I_X$  is the detected signal of X in the unit of counts per second (cps) and most OOMs were detected as adducts with  $NO_3$ ;  $T_i$  is the mass-dependent transmission efficiency of the instrument determined using the following equation by adding propanoic acid, pentanonic acid and heptanonic acid vapors to deplete  $NO_3^-$  (Figure S1):

148 
$$T_i = 0.56 + 7.2 \times 10^4 / ((m/z - 498.84)^2 + 3.46 \times 10^4)$$
 (2)

To clarify whether there is SOA formation in the experiments, a scanning mobility particle sizer (SMPS, TSI), which consists of an electrostatic classifier (model 3080), a long or nano differential mobility analyzer (model 3081 and 3085 for different particle sizes), and a condensation particle counter (model 3087), was used to monitor the formation of SOA particles. Except in Exp 31 where the reacted α-pinene reached 36.8 ppb and there was low SOA formation with particle mass concentrations of 5.0×10<sup>-4</sup>-5.7×10<sup>-3</sup> μg m<sup>-3</sup> and number concentrations of 63-395 cm<sup>-3</sup>, no particle formation was observed by SMPS. Therefore, the RO<sub>2</sub> radicals and closed-shell products would be primarily distributed in the gas—phase, with their fates negligibly influenced by the low SOA formation under these experimental conditions.

## 2.2 Kinetic Model Simulations.

Model simulations of RO<sub>2</sub> and HOM formation in selected experiments were performed to constrain the reaction kinetics and mechanisms of acyl RO<sub>2</sub> using F0AM v4.1 (Wolfe et al. 2016), which employs MCM v3.3.1 (Jenkin, Young and Rickard 2015) updated with the chemistry of RO<sub>2</sub> autoxidation and cross-reactions forming HOM monomers and dimers. Newly added species and reactions to MCM v3.3.1 followed the work by Zhao et al. (2018) and Wang et al. (2021). Considering that the default MCM v3.3.1 does not include highly oxygenated acyl RO<sub>2</sub>, we added

the possible formation pathways of the potential acyl RO<sub>2</sub> measured in this study to the model based on the mechanisms proposed by Zhao et al. (2022).

The formation and reaction branching ratios of the two α-pinene-derived CIs are updated in the model according to the recent studies (Table S3) (Wang et al. 2021, Berndt 2022, Iyer et al. 2021, Claffin et al. 2018). The formation of a ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> species (C10H15O4RBRO2 in Table S3) from α-pinene ozonolysis proposed by a recent study (Iyer et al. 2021), as well as its subsequent autoxidation and bimolecular reactions, is included in the model. The autoxidation rate constant of the ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> is 1 s<sup>-1</sup>, and a lower limit of its molar yield (30%) was used according to the recent studies (Wang et al. 2021, Meder et al. 2023) and our results (see details in Section 3.3). We also added the hydrogen abstraction channel of  $\alpha$ -pinene oxidation by OH radicals according to a recent study (Shen et al. 2022). The branching ratio of this channel was set to 9%, with the rest 91% being the traditional OH addition pathways. The detailed reaction pathways and rate constants of RO<sub>2</sub> species in this channel followed the work by Shen et al. (2022), except for RO<sub>2</sub> cross-reactions, the rates of which were not reported in that study. As the primary RO<sub>2</sub> radicals (C<sub>10</sub>H<sub>15</sub>O<sub>2</sub>-RO<sub>2</sub>) formed via the hydrogen abstraction by OH radical are least-oxidized with only 2 oxygen atoms, their cross-reaction rate could be relatively low (Atkinson et al. 2007, Orlando and Tyndall 2012). In the model, this rate constant was set to  $1 \times 10^{-13}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>. For other alkyl RO<sub>2</sub> radicals (including HOM-RO<sub>2</sub>), their cross-reaction rate constant is assumed to be  $1 \times 10^{-}$ <sup>12</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> according to Zhao et al. (2018). The dimer formation rates for these alkyl RO<sub>2</sub> are same as their cross-reaction rates.

In flow reactor experiments, the equilibrium formation of ROONO2 would lead to the consumption of alkyl RO2 radicals. To account for the influence of this process on the RO2 budget and HOM formation, we included the reaction of RO2 + NO2 = ROONO2 in the model, with forward and reverse reaction rate constants of  $7.5 \times 10^{-12}$  cm³ molecule-1 s-1 and 5 s-1, respectively (Orlando and Tyndall 2012). To simply the parameterization, the forward and reverse reaction rate constants of newly added highly oxygenated acyl RO2 with NO2 are the same as default values in MCM v3.3.1. Besides, the cross-reaction rate constants of acyl RO2 (including acyl RO2 + acyl RO2 and acyl RO2 + alkyl RO2) forming monomers or dimers were both set to  $1 \times 10^{-11}$  cm³ molecule-1 s-1 (Orlando and Tyndall 2012). Considering that there are large uncertainties in the dimer formation rate of RO2, a sensitivity analysis was conducted to evaluate its influence on acyl RO2-involved HOM formation by varying the rate constant from  $1 \times 10^{-13}$  cm³ molecule-1 s-1 to  $1 \times 10^{-12}$  cm³ molecule-1 s-1 for alkyl RO2 and  $1 \times 10^{-12}$  cm³ molecule-1 s-1 to  $1 \times 10^{-11}$  cm³ molecule-1 s-1 for acyl RO2. The results show that changes in dimer formation rate constants within the above ranges have no significant influence

on the contribution of acyl  $RO_2$  to HOM formation (Figure  $\frac{S2S1}{}$ ).

The wall losses of OH, HO<sub>2</sub>, and RO<sub>2</sub> radicals, as well as closed-shell HOM monomers and dimers in the flow reactor were considered using the KPS method proposed by Knopf et al. (2015) in the model (Table S4), with an assumption of irreversible uptake of these species on the reactor wall. It is found that the wall loss of OH, HO<sub>2</sub>, and RO<sub>2</sub> radicals accounts for 0.08-0.14%, 4.7-9.1%, and 7.3-25.5% of their total production, respectively, with lower values under higher reacted  $\alpha$ -pinene concentration conditions. Therefore, the wall loss process would not significantly influence  $\alpha$ -pinene oxidation and RO<sub>2</sub> chemistry. The wall losses of closed-shell HOM monomers and dimers account for 18.4-34.7% and 14.2-33.1% of their total production, respectively. It should be noted that the wall losses of typical RO<sub>2</sub> and HOMs have negligible impact on their responses to the addition of NO<sub>2</sub> (Figure \$3\$2). In addition, with the consideration of the wall loss effects, the effect and contribution of acyl RO<sub>2</sub> to the HOM formation only changed a little (0.02-0.5%). Therefore, the wall losses of RO<sub>2</sub> and HOMs in the flow reactor would not affect the interpretation of the results in this study.

## 3. Results and Discussion

# 3.1 Molecular composition of acyl RO<sub>2</sub> from α-pinene ozonolysis

The overall formation characteristics of gas-phase  $RO_2$ , closed-shell monomers, and dimers with the addition of  $NO_2$  (30 ppb) is shown in Figure 1 (Exps 8 and 14, Table S1). Since nitrate-CIMS is only highly sensitive to the highly oxygenated species, we only discuss the production of HOMs with oxygen atoms above 6 here. As for  $RO_2$  and closed-shell monomers (Figure 1a), the concentrations-signals of  $C_7$  and  $C_8$  species decrease by more than 50% with the addition of  $NO_2$ , while for  $C_9$  and  $C_{10}$  species, their decreases are relatively small (within 40%). In addition, we note that there is an unexpected increase in some  $C_9$  and  $C_{10}$   $RO_2$ , and the possible reason will be discussed in detail in Section 3.3.

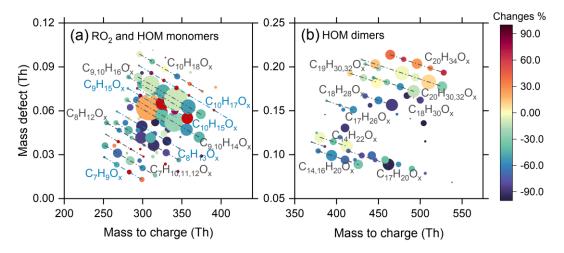

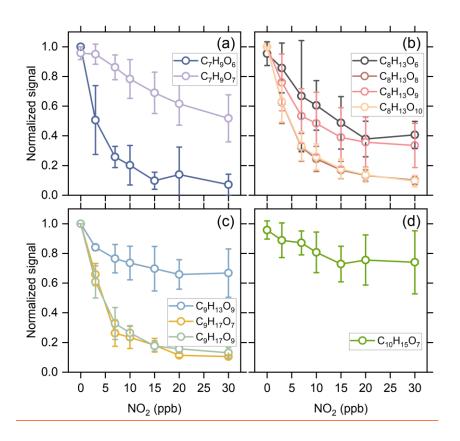

Figure 1 Mass defect plots of (a)  $RO_2$ , HOM monomers, and (b) HOM dimers formed from ozonolysis of  $\alpha$ -pinene in the presence of  $NO_2$  measured using nitrate-CIMS (Exps 8, 14). The circles are colored by the relative changes in concentration signal of  $RO_2$ , monomers and dimers due to the addition of  $NO_2$  (30 ppb). The area of circles is linearly scaled with the cube root of the concentration signal of HOMs formed in the absence of  $NO_2$ . The blue lines represent  $RO_2$  radicals.

NO<sub>2</sub> could react rapidly with acyl RO<sub>2</sub> radicals to form RC(O)OONO<sub>2</sub>, which has a higher thermal-stability compared to ROONO<sub>2</sub> and can serve as a sink for acyl RO<sub>2</sub> on our experimental timescales. Therefore, a significant decrease in  $C_7$  and  $C_8$  RO<sub>2</sub> and HOMs upon the addition of NO<sub>2</sub> indicates that a major fraction of  $C_7$  and  $C_8$  RO<sub>2</sub> are acyl RO<sub>2</sub>. In contrast, the slight decrease in  $C_9$  and  $C_{10}$  HOM monomers shows that the contribution of acyl RO<sub>2</sub> to  $C_9$  and  $C_{10}$  RO<sub>2</sub> is relatively small. However, some of the  $C_{10}$  monomers showed a slight increase with the addition of NO<sub>2</sub>, especially for  $C_{10}H_{18}O_x$ -HOMs. The addition of NO<sub>2</sub> plays a twofold role in dimer formation from  $\alpha$ -pinene ozonolysis (Figure 1b). There is a significant inhibiting effect on  $C_{14}$ - $C_{18}$  dimers, which is due to the large contribution of acyl RO<sub>2</sub> to the total  $C_7$  and  $C_8$  RO<sub>2</sub> that generate such dimers. However,  $C_{19}$  and  $C_{20}$  dimers only show a slight decrease with the addition of NO<sub>2</sub>, and some of them are even enhanced. In particular, the enhancement in  $C_{20}H_{34}O_x$  is most significant, reaching 30%.

Kinetic model simulations show that the concentration of alkyl RO<sub>2</sub> decreases by 1-20% with the addition of 30 ppb NO<sub>2</sub> under different reacted α-pinene conditions (Exps 1-28). Considering that the acyl RO<sub>2</sub> could be rapidly consumed by NO<sub>2</sub>, if the concentration-signal reduction of a RO<sub>2</sub> species significantly exceeds 20% with 30 ppb NO<sub>2</sub> addition, we presume it has significant contribution from acyl RO<sub>2</sub>. As a result, a total of 10 acyl RO<sub>2</sub> were identified according to the changes of RO<sub>2</sub> concentration-signal as a function of initial NO<sub>2</sub> concentration, which include C<sub>7</sub>H<sub>9</sub>O<sub>6</sub>, C<sub>7</sub>H<sub>9</sub>O<sub>7</sub>, C<sub>8</sub>H<sub>13</sub>O<sub>6</sub>, C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>, C<sub>8</sub>H<sub>13</sub>O<sub>9</sub>, C<sub>8</sub>H<sub>13</sub>O<sub>10</sub>, C<sub>9</sub>H<sub>13</sub>O<sub>9</sub>, C<sub>9</sub>H<sub>17</sub>O<sub>7</sub>, C<sub>9</sub>H<sub>17</sub>O<sub>9</sub>, and C<sub>10</sub>H<sub>15</sub>O<sub>7</sub>. Figure 2 shows the averaged normalized acyl RO<sub>2</sub> concentrations signals measured as a

function of the added NO<sub>2</sub> concentration under different experimental conditions (Exps 1-28). Similarly, since nitrate-CIMS is only highly sensitive to products with high oxygen content, we only observed acyl RO<sub>2</sub> with oxygen atoms above 6. Consistent with the significant decrease in C<sub>7</sub> and C<sub>8</sub> species with the addition of NO<sub>2</sub> in Figure 1a, C<sub>7</sub> and C<sub>8</sub> acyl RO<sub>2</sub> decrease by more than 50% with the increase of NO<sub>2</sub> concentration (Figures 2a, b). For C<sub>9</sub> acyl RO<sub>2</sub>, the C<sub>9</sub>H<sub>17</sub>O<sub>7</sub>-RO<sub>2</sub> and C<sub>9</sub>H<sub>17</sub>O<sub>9</sub>-RO<sub>2</sub> also decrease dramatically with increasing NO<sub>2</sub>, and the decrease in C<sub>9</sub>H<sub>13</sub>O<sub>9</sub>-RO<sub>2</sub> is relatively smaller (Figure 2c). In addition, C<sub>10</sub>H<sub>15</sub>O<sub>7</sub>-RO<sub>2</sub> also shows a small decrease (Figure 2d), with a reduction of only 30% at 30 ppb NO<sub>2</sub>. The relativerelatively small reduction in the abundance of some of these RO<sub>2</sub> radicals indicates the presence of alkyl RO<sub>2</sub> radicals with the same chemical formulas. Along with the marked reduction in acyl RO<sub>2</sub> signals, the production of highly oxygenated RC(O)OONO<sub>2</sub> species such as C<sub>9</sub>H<sub>13</sub>O<sub>9</sub>NO<sub>2</sub>, C<sub>9</sub>H<sub>17</sub>O<sub>7</sub>NO<sub>2</sub>, and C<sub>10</sub>H<sub>15</sub>O<sub>7</sub>NO<sub>2</sub> with the addition of NO<sub>2</sub> were observed (see the spectra in Figure S3). However, we note that although some RC(O)OONO<sub>2</sub> such as C<sub>8</sub>H<sub>13</sub>O<sub>6</sub>NO<sub>2</sub> and C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>NO<sub>2</sub> are expected to be formed with NO<sub>2</sub> addition, they could not be unambiguously detected by nitrate-CIMS due to the overlapping of their peaks with strong alkyl RO<sub>2</sub> peaks (C<sub>9</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> and C<sub>9</sub>H<sub>15</sub>O<sub>10</sub>-RO<sub>2</sub>) in this study.

Figure 3 shows the contribution of acyl and alkyl RO<sub>2</sub> to the highly oxidized C<sub>7</sub>-C<sub>10</sub> RO<sub>2</sub>. Acyl RO<sub>2</sub> contribute 67.266.9%, 94.3% and 31.931.7% to the total C<sub>7</sub>, C<sub>8</sub>, and C<sub>9</sub> RO<sub>2</sub> concentrations signals, respectively. By contrast, the only C<sub>10</sub> acyl RO<sub>2</sub> measured in this study is C<sub>10</sub>H<sub>15</sub>O<sub>7</sub>, which contributes to only 0.50.4% of the total  $C_{10}$  RO<sub>2</sub>. It should be note that there might be other  $C_{10}$  acyl RO<sub>2</sub> that were not observed due to the interferences from the alkyl RO<sub>2</sub> with the same chemical formulas, which respond differently to the addition of NO2 than acyl RO2 do (see details in the following discussion). Considering that some RO<sub>2</sub> formulas such as C<sub>10</sub>H<sub>15</sub>O<sub>7</sub> may have contributions from both acyl RO2 and alkyl RO2, we assumed the decrease of RO2 concentration signal with the addition of NO<sub>2</sub> as the concentration signal of acyl RO<sub>2</sub>. Besides, it is obvious that the normalized concentration signal basically decreases to the lowest value when the initial NO<sub>2</sub> concentration reaches 10 ppb (Figure 2), indicating that most of the acyl RO<sub>2</sub> are depleted at this NO<sub>2</sub> concentration. In addition, the decreasing extents of some acyl RO<sub>2</sub> are different for different reacted α-pinene concentrations, with lower decreasing extent for higher reacted α-pinene concentrations (Figure \$4\$54). This difference might be due to the promoted cross-reactions of acyl RO<sub>2</sub> as well as their precursor RO<sub>2</sub> at higher α-pinene concentrations, which are competitive with the reactions leading to acyl  $RO_2$  formation as well as the acyl  $RO_2 + NO_2$  reactions.

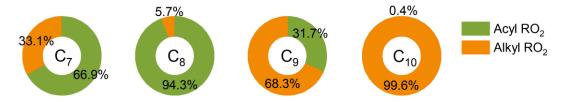

Figure 3 Contributions of acyl and alkyl RO<sub>2</sub> to the highly oxygenated C<sub>7</sub>-C<sub>10</sub> RO<sub>2</sub> measured by nitrate-CIMS.

In addition to the changes of acyl RO<sub>2</sub> concentrationsignal, we also show the changes of normalized alkyl RO<sub>2</sub> concentration—signal with the increasing initial NO<sub>2</sub> concentration in Figure \$5\$\frac{\$5}{265}\$. Although ROONO<sub>2</sub> formed by the reaction of alkyl RO<sub>2</sub> with NO<sub>2</sub> is thermally unstable and would decompose quickly to release RO<sub>2</sub>, it would still reach a formation/decomposition equilibrium in the system, thus consuming a small amount of alkyl RO<sub>2</sub>. However, it can be seen from Figure \$5\$\frac{\$565}{265}\$ that during 25 s of reaction in the flow reactor, a large part of alkyl RO<sub>2</sub> has an increasing trend with the increase of NO<sub>2</sub> concentration. We speculate that a portion of ROONO<sub>2</sub> could decompose back to RO<sub>2</sub> and NO<sub>2</sub> in the nitrate-CI inlet where the sample gases were diluted instantly and the equilibrium of ROONO<sub>2</sub> was disturbed, resulting in the release of a large amount of RO<sub>2</sub>.

To verify our speculation, the decomposition of ROONO<sub>2</sub> in the CI inlet was simulated based on the dilution ratio (1:3.5) and residence time (200 ms) in the inlet. As shown in Figure \$6\$\frac{576}{2}\$, more than 40% of ROONO<sub>2</sub> decompose back to RO<sub>2</sub> and NO<sub>2</sub> in the CI inlet, which would inevitably lead to an increase in RO<sub>2</sub> concentration. As the C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>NO<sub>2</sub> has a significant contribution from the relative stable RC(O)OONO<sub>2</sub> arising from the ring-opened acyl C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> reported by Iyer et al. (2021), its decomposition is relatively small (~21%). It should be noted that the RO<sub>2</sub> measured here is only a part of total RO<sub>2</sub> and that a large amount of RO<sub>2</sub> has already reacted to form closed-shell products as well as ROONO<sub>2</sub> in the flow reactor. Taking Exp 14 as an example (30 ppb NO<sub>2</sub>), the simulated concentrations of RO<sub>2</sub> and ROONO<sub>2</sub> are 1.3 ppb and 1.9 ppb, which approximately accounts for 27.1% and 39.6% of the total production of RO<sub>2</sub>, respectively. Therefore, the decomposition of ROONO<sub>2</sub> could indeed result in an increase in the RO<sub>2</sub> concentration signal. It should also be pointed out that because of the very short residence time in the CI inlet, such an increase in the RO<sub>2</sub> concentration would not significantly impact HOM formation.

To confirm the reliability of our results, we examined the changes in the concentrations signals of  $RO_2$  and closed-shell products as a function of reacted  $\alpha$ -pinene in the absence of  $NO_2$  (Section S1 and Figure \$75878), and the results are consistent with previous studies (Zhao et al. 2018). In addition, we repeated Exps 15-21 on another nitrate-CIMS and a similar increase in alkyl  $RO_2$  signals with the addition of  $NO_2$  was observed on that instrument (Figure \$85989).

# 3.2 Formation mechanisms of acyl RO<sub>2</sub> during α-pinene ozonolysis

It has been recently suggested that there are three main pathways that directly lead to the formation of monoterpene-derived acyl RO<sub>2</sub> (Zhao et al. 2022). (Shen et al. 2022): (i) the autoxidation of RO<sub>2</sub> containing aldehyde groups (Reaction R1), (ii) the cleavage of C-C bond of RO containing an α-ketone group (Reaction R2), and (iii) the intramolecular H-shift of RO containing an aldehyde group (Reaction R3). In addition, the secondary OH oxidation of aldehyde products can also produce acyl RO<sub>2</sub> radicals. However, in the present study, the secondary OH oxidation is expected to be insignificant due to an excess of α-pinene compared to O<sub>3</sub>. Indeed, kinetic model simulations incorporating the secondary OH chemistry show that the contribution of secondary OH oxidation to acyl RO<sub>2</sub> formation is negligible even under high O<sub>3</sub> conditions (see details in Section S2 and Figure S910).

Here, we further investigated the formation mechanisms of acyl RO<sub>2</sub>. Figure 4 shows the reaction schemes leading to the formation of example acyl RO<sub>2</sub> radicals. The detailed formation mechanisms of acyl RO<sub>2</sub> measured in this study are shown in Figure \$9\$104. The formation of acyl RO<sub>2</sub>, especially those having the small molecular size ( $C_7$ - $C_9$ ), requires the production and subsequent decomposition (or ring-opening process) of RO radicals. Take  $C_8H_{13}O_6$ -RO<sub>2</sub> as an example (Figure 4), two steps of RO formation and decomposition following the primary  $C_{10}H_{15}O_4$ -RO<sub>2</sub> lead to the ring-opened  $C_8H_{13}O_4$ -RO<sub>2</sub> that can undergo rapid aldehydic H-shift to form the acyl RO<sub>2</sub>. While for  $C_8H_{13}O_9$ -RO<sub>2</sub>, it directly comes from the aldehydic H-shift of  $C_8H_{13}O_7$ -RO followed by the O<sub>2</sub> addition (Figure \$9\$1101).

To verify the formation mechanisms of acyl RO<sub>2</sub>, we added NO in some experiments (Exps 33-56)

to see how acyl RO<sub>2</sub> respond to the increasing NO concentration. As shown in Figure 5, the changes of C<sub>7</sub> and C<sub>8</sub> acyl RO<sub>2</sub> show opposite trend with the increasing NO and NO<sub>2</sub> concentration, except for C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>-RO<sub>2</sub>. NO can react with RO<sub>2</sub> to form RO radicals and promote the formation of RO<sub>2</sub> that requires the involvement of RO radicals in their formation. In addition to C<sub>8</sub>H<sub>13</sub>O<sub>6</sub>-RO<sub>2</sub> discussed above, the formation of C<sub>7</sub>H<sub>9</sub>O<sub>7</sub>-RO<sub>2</sub> and C<sub>8</sub>H<sub>13</sub>O<sub>9</sub>-RO<sub>2</sub> needs 2 and 4 steps of the RO formation following C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> (Figure \$9\$\frac{\$9\$\$S1\frac{104}}{104}\$), respectively. Therefore, the increase of RO concentration due to the addition of NO would promote the production of these acyl RO<sub>2</sub>. These results prove that the RO radicals indeed play an important role in the acyl RO2 formation. While for C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>-RO<sub>2</sub>, its concentration signal decreases substantially with the addition of NO up to 3 ppb, similar to the trend observed with the addition of NO<sub>2</sub>. After reaching the minimum at 7 ppb NO, the concentration signal of C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>-RO<sub>2</sub> tends to increase with the further increase of NO concentration. Given that C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>-RO<sub>2</sub> is likely to directly come from the autoxidation of C<sub>8</sub>H<sub>13</sub>O<sub>6</sub> acyl RO<sub>2</sub> (see Figure \$9\$1101), the rapid consumption of C<sub>8</sub>H<sub>13</sub>O<sub>6</sub>-RO<sub>2</sub> by NO and NO<sub>2</sub> (formed by O<sub>3</sub> oxidation of NO) may outcompete its autoxidation process, thus leading to a decrease in C<sub>8</sub>H<sub>13</sub>O<sub>8</sub>-RO<sub>2</sub> concentrationsignal. Besides, it can be seen that the increasing extent in C<sub>8</sub>H<sub>13</sub>O<sub>6</sub>-RO<sub>2</sub> is also relatively small before the NO concentration reaches 3 ppb (Figure 5c), indicating that the promotion effect of NO on C<sub>8</sub>H<sub>13</sub>O<sub>6</sub>-RO<sub>2</sub> formation is not that strong at this concentration.

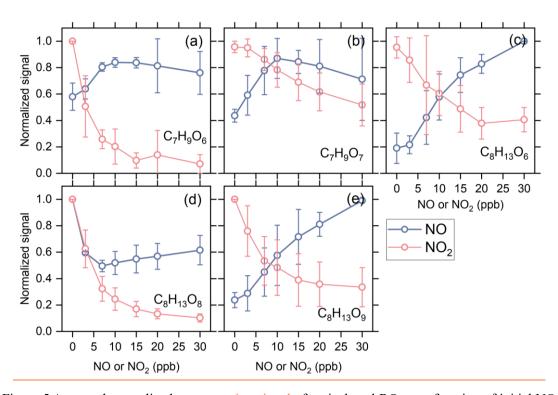

Figure 5 Averaged normalized concentration signal of typical acyl RO<sub>2</sub> as a function of initial NO or NO<sub>2</sub> addition (Exps 1-28 and 33-56).

It is interesting to note that most of the measured highly oxygenated acyl RO2 are formed by the

autoxidation of aldehydic RO<sub>2</sub>, and only the C<sub>8</sub>H<sub>13</sub>O<sub>9</sub>-RO<sub>2</sub> is formed by the H-shift of the RO radical (Figure S9S1+01). The measured concentration-signal of acyl RO<sub>2</sub> from the autoxidation pathway accounts for 96% of all highly oxygenated acyl RO<sub>2</sub> concentrationssignals. Considering that the acyl RO<sub>2</sub> with small molecular size are generally the ring-opened RO<sub>2</sub>, the autoxidation rate constant of their precursor RO<sub>2</sub> is expected to be relatively high (e.g., 1 s<sup>-1</sup>) (Iyer et al. 2021). Taking a RO<sub>2</sub> cross-reaction rate constant of 1 × 10<sup>-12</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> (Zhao et al. 2018) and a model-predicted total RO<sub>2</sub> concentration of 1.7 ppb (Exp 8), the simulated contributions of autoxidation and cross-reactions contribute to 96.0% and 4.0% of the total RO<sub>2</sub> reaction are 96.0% and 4.0%, respectively. Considering a 10 times larger RO<sub>2</sub> cross-reaction rate constant (i.e., 1 × 10<sup>-11</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>), the simulated contributions of RO<sub>2</sub> autoxidation and cross-reactions would be 70.4% and 29.6%, respectively. These calculations simulations suggest that the autoxidation of aldehydic RO<sub>2</sub> plays a dominant role in the formation of the highly oxygenated acyl RO<sub>2</sub>. Although the acyl RO<sub>2</sub> with low oxygen content were not measured in this study, all acyl RO<sub>2</sub> containing oxygen atoms less than 6 seem to be derived from the cleavage of C-C bond or H-shift of RO containing an α-ketone or aldehyde in the currently known reaction mechanisms (Figures 4 and S10S1212).

Recently, Shen et al. (2022) found that the hydrogen abstraction by OH radicals during α-pinene oxidation plays an important role in HOM formation. In such mechanisms, the primary RO<sub>2</sub> reacts with NO and forms RO radicals, which could undergo rapid ring-breaking reactions to form a series of ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>x</sub>-RO<sub>2</sub>, which contains aldehyde functionality and can easily autoxidize to C<sub>10</sub> acyl RO<sub>2</sub>. In the absence of NO, the cross-reactions of RO<sub>2</sub> can also produce RO radicals. However, only a few  $C_{10}$  acyl RO<sub>2</sub> were detected in this study and they contribute less than 1% of the total C<sub>10</sub> RO<sub>2</sub> concentration. This phenomenon could be due to the fact that the primary RO<sub>2</sub>  $(C_{10}H_{15}O_2)$  formed by the hydrogen abstraction by OH radical are least-oxidized with only 2 oxygen atoms, which are expected to have a relatively low cross-reaction rate constant (Berndt et al. 2018, Orlando and Tyndall 2012). As a result, the formation of ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>x</sub>-RO<sub>2</sub> via crossreactions of the primary C<sub>10</sub>H<sub>15</sub>O<sub>2</sub>-RO<sub>2</sub> may not be important. As shown in Figure 6, when the crossreaction rate constants of  $C_{10}H_{15}O_2$ -RO<sub>2</sub> is considered to be  $1\_\times\_10^{-13}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, the simulated contribution of the H-abstraction pathway to the HOM formation is less than 3% under both low (2.4 ppb) and high (9.6 ppb) reacted α-pinene conditions. It should be note that the crossreaction rate constants of the less-oxygenated RO<sub>2</sub> could be even lower (Orlando and Tyndall 2012), therefore the contribution of this pathway to HOM formation could be ignored when NO is absent.

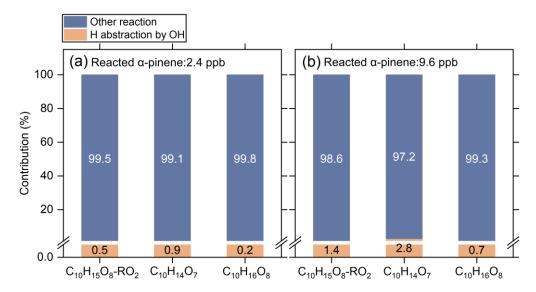

Figure 6 Contributions of the H-abstraction pathways by OH radicals (yellow) and OH addition and ozonolysis pathways (blue) to the formation of typical HOMs under low (a) and high (b) reacted  $\alpha$ -pinene conditions simulated by the kinetic model. The cross-reaction rate constant was set to  $1_{-}\times 10^{-13}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> for the primary  $C_{10}H_{15}O_2$ -RO<sub>2</sub> and  $1_{-}\times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> for the more oxygenated RO<sub>2</sub>.

In the presence of cyclohexane as an OH scavenger (Figure SHS1323, Exp 32), the measured concentrations signals of  $C_{10}H_{17}O_x$ -RO<sub>2</sub> formed via OH addition channel and the corresponding  $C_{10}H_{18}O_x$ -HOMs decrease by more than 70%, while the  $C_{10}H_{15}O_x$ -RO<sub>2</sub> and its related closed-shell products decrease by less than 15%, in good agreement with the measurements in previous studies (Zhao et al. 2018). As the  $C_{10}H_{16}O_8$ -HOM could come from both  $C_{10}H_{15}O_x$ -RO<sub>2</sub> and  $C_{10}H_{17}O_x$ -RO<sub>2</sub>, its reduction is at a medium level. The significantly smaller decrease in the concentrations signals of  $C_{10}H_{15}O_x$ -RO<sub>2</sub> and its corresponding closed-shell products as compared to those of  $C_{10}H_{17}O_x$ -RO<sub>2</sub> and the related closed-shell products further illustrates that the H-abstraction by OH has a minor contribution to HOM formation in the absence of NO.

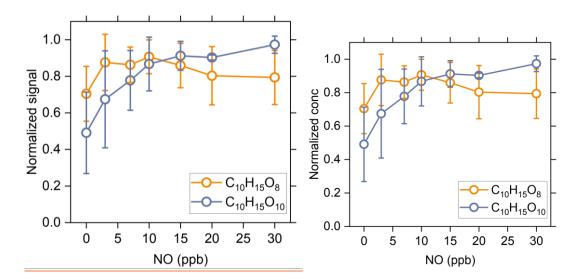

Figure 7 Averaged normalized <u>concentration signal</u> of the measured  $C_{10}H_{15}O_{8}$ - and  $C_{10}H_{15}O_{10}$ -  $RO_2$  as a function of the added NO concentration (Exps 33-56).

Figure 7 shows the changes in measured concentration signal of C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> and C<sub>10</sub>H<sub>15</sub>O<sub>10</sub>-RO<sub>2</sub> as a function of initial NO concentration (Exps 33-56). It should be noted that due to the existence of O<sub>3</sub> in our experiments, these two RO<sub>2</sub> could come from both O<sub>3</sub> and OH reactions with α-pinene and NO could be rapidly oxidized to NO2 by O3. The normalized concentrations signals of C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> and C<sub>10</sub>H<sub>15</sub>O<sub>10</sub>-RO<sub>2</sub> increase firstly under low NO conditions, which is similar to the change of acyl RO<sub>2</sub> as shown in Figure 5. This increase could be due to two reasons: (1) the promoted formation of C<sub>10</sub>H<sub>15</sub>O<sub>8</sub> and C<sub>10</sub>H<sub>15</sub>O<sub>10</sub> acyl RO<sub>2</sub> from the H-abstraction channel by NO addition and (2) the equilibrium decomposition of ROONO2 formed by the two alkyl RO2 from ozonolysis of α-pinene in the CI inlet (see Section 3.1). As mentioned above, the ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>x</sub>-RO<sub>2</sub> formed from the H-abstraction channel contain aldehyde functionality and can autoxidize rapidly. The F0AM model simulations show that the C<sub>10</sub>H<sub>15</sub>O<sub>8</sub> and C<sub>10</sub>H<sub>15</sub>O<sub>10</sub> acyl RO<sub>2</sub> formed from the H-abstraction channel contribute to 68% and 56% of the total C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> and C<sub>10</sub>H<sub>15</sub>O<sub>10</sub>-RO<sub>2</sub> with the addition of 10 ppb NO, respectively. Therefore, the initial increases of these two RO2 with increasing NO concentration are likely mainly due to the enhanced formation of C<sub>10</sub>H<sub>15</sub>O<sub>8</sub> and C<sub>10</sub>H<sub>15</sub>O<sub>10</sub> acyl RO<sub>2</sub>. When the NO concentration increases to a high level, there are more NO and NO<sub>2</sub> in the system, which promotes the consumption of acyl RO<sub>2</sub>. As a result, C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> exhibits a decreasing trend and the increasing extend of C<sub>10</sub>H<sub>15</sub>O<sub>10</sub>-RO<sub>2</sub> becomes much smaller.

# 3.3 Contributions of acyl RO<sub>2</sub> to the formation of gas-phase HOMs

With the addition of NO<sub>2</sub>, the distribution of gas-phase products in the α-pinene ozonolysis changes significantly (see Figure 1), and the consumption of acyl RO<sub>2</sub> by NO<sub>2</sub> plays an important role. NO<sub>2</sub>

influences the formation of HOM monomers mainly in three ways. Firstly, NO<sub>2</sub> could react rapidly with acyl RO<sub>2</sub> and form RC(O)OONO<sub>2</sub>, thus inhibiting the formation of HOMs with the involvement of acyl RO<sub>2</sub>. Secondly, as mentioned above, although ROONO<sub>2</sub> is thermally unstable, their formation/decomposition equilibrium still consumes a small amount of alkyl RO<sub>2</sub>, resulting in a decrease in HOM formation. Thirdly, NO<sub>2</sub> can consume a part of HO<sub>2</sub> radicals (Figure \$12\$\text{S1434}\$, thus inhibiting the RO<sub>2</sub> + HO<sub>2</sub> reaction pathway.

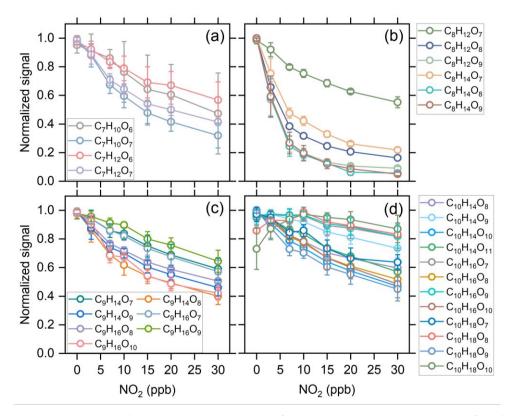

Figure 8 Averaged normalized <u>concentration signal</u> of the measured  $C_7$ - $C_{10}$  HOMs as a function of the added  $NO_2$  concentration (Exps 1-28).

Figure 8 shows the normalized concentration signal of  $C_7$ - $C_{10}$  HOM monomers as a function of initial  $NO_2$  concentration. The  $C_7$ ,  $C_8$ , and some of  $C_9$  HOMs decrease significantly with increasing  $NO_2$  concentration due to the relatively large contribution of acyl  $RO_2$  to the total  $C_7$ - $C_9$   $RO_2$ . The  $C_7$  HOMs decrease by more than 50% when the  $NO_2$  concentration reaches 30 ppb, while  $C_8$  HOMs decrease by more than 70% and some of them even decrease by 90%. The  $C_9$  HOMs decrease by 30%-60% and the species with relatively large decrease are mostly acyl  $RO_2$ -related HOMs. For  $C_{10}$  HOMs, although there is also an obvious decrease in their formation with the addition of  $NO_2$ , most of them have a smaller decreasing extent compared to the  $C_7$ - $C_9$  HOMs due to the low contribution of acyl  $RO_2$  to the  $C_{10}$   $RO_2$ . It is worth noting that a few  $C_{10}$  HOMs increase initially with the addition of  $NO_2$  up to 10 ppb, suggesting that there might be some processes that promote the formation of their precursor  $RO_2$  radicals and thus offset the inhibiting effect of  $NO_2$ .

As mentioned above, the addition of NO<sub>2</sub> has the most significant influence on the formation of small HOM monomers. Combined with the large contribution (67-94%) of acyl RO<sub>2</sub> to the total C<sub>7</sub> and C<sub>8</sub> RO<sub>2</sub> (Figure 3), it can be considered that the reduction in the formation of C<sub>7</sub> and C<sub>8</sub> HOM monomers with NO<sub>2</sub> addition is overwhelmingly due to the consumption of acyl RO<sub>2</sub> by NO<sub>2</sub>. As a result, acyl RO<sub>2</sub> was found to have a contribution of 50-90% to C<sub>7</sub> and C<sub>8</sub> HOM monomer formation during α-pinene ozonolysis. Since acyl RO<sub>2</sub> also have a considerable contribution (32%) to the total C<sub>9</sub> RO<sub>2</sub>, an upper limit (30%-60%) of its contribution to C<sub>9</sub> HOMs could be derived with the assumption that the decrease of C9 HOMs with the addition of NO2 is also mainly due to the consumption of C<sub>9</sub>-acyl RO<sub>2</sub> by NO<sub>2</sub>. By contrast, acyl RO<sub>2</sub> account for a very small fraction (0.54%) of the total  $C_{10}$  RO<sub>2</sub>, and their contribution to  $C_{10}$  HOMs cannot be quantified based solely on the experimental measurements given that the equilibrium reaction between alkyl RO2 and NO2 can also affect the formation of HOMs. Therefore, we used the F0AM model to simulate the contribution of acyl RO<sub>2</sub> to C<sub>10</sub> HOM formation according to the acyl RO<sub>2</sub> measured in this study and displayed the results in Figure 9. It should be noted that the HOMs from the acyl RO<sub>2</sub> and its subsequent RO<sub>2</sub> (formed from acyl RO<sub>2</sub> reactions) are all considered as acyl RO<sub>2</sub>-related HOMs in the model. As mentioned above, the formation of ring-opened  $C_{10}H_{15}O_4$ -RO<sub>2</sub> reported by Iyer et al. (2021) is included in the model, and its autoxidation produces a ring-opened acyl C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub>. When we considered the upper limit of the yield of ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> (89%) in the model and assumes that the other primary RO<sub>2</sub> with the cyclobutyl ring autoxidize at a very slow rate (0.01 s<sup>-1</sup> 1), the simulated acyl C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> would contribute to ~80% of the total C<sub>10</sub> RO<sub>2</sub>. However, we could not see a large decrease in the measured concentration signal of C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-RO<sub>2</sub> and its related HOM monomers with the addition of NO<sub>2</sub>. Similarly, a recent study by Zhao et al. (2022) found that the C<sub>10</sub>H<sub>15</sub>O<sub>8</sub>-related monomers and dimers in α-pinene SOA also-did not show-significantly decreases with NO<sub>2</sub> addition. There might be two-three reasons for the discrepancy between the simulations and measurements. Firstly, the yield of the ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> might be significantly smaller than 89% (Wang et al. 2021, Meder et al. 2023). Secondly, the autoxidation rate of other primary C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> with the cyclobutyl ring could be significantly larger than 0.01  $s^{-1}$ . Thirdly, the ring-opened  $C_{10}H_{15}O_8$ -RO<sub>2</sub>, a highly functionalized acyl RO<sub>2</sub> radical with an -OOH group, may be able to undergo very fast intramolecular H-scrambling reactions to form a peroxy acid as suggested by Knap and Jørgensen (2017), which would compete with the NO<sub>2</sub> reaction and result in a lower reduction in its signal upon NO<sub>2</sub> addition (see details in Section S3). To examine the contributions of acyl RO<sub>2</sub> to C<sub>10</sub> HOM production, Www updated the branching

ratios and autoxidation rates of the primary RO<sub>2</sub> during the α-pinene ozonolysis in the model

according to the recent studies (Wang et al. 2021, Kurten et al. 2015, Claflin et al. 2018, Berndt 2022) (Table S3), and used a lower limit (30%) of the ring-opened C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> yield reported by Iyer et al. (2021)—was used here. The simulated acyl RO<sub>2</sub>-related HOMs contribute to 14% of the total C<sub>10</sub> HOMs, which is slightly smaller than the measured decrease in C<sub>10</sub> HOMs with the addition of NO<sub>2</sub>. This discrepancy could be due to two reasons. Firstly, the decrease in HOMs can partly result from the consumption of alkyl RO<sub>2</sub> and HO<sub>2</sub> radicals by the addition of NO<sub>2</sub>. Secondly, as mentioned above, there might be other  $C_{10}$  acyl RO<sub>2</sub> that were not observed in this study due to the decomposition of the ROONO2 from the alkyl RO2 with the same formulas. The contributions of acyl RO<sub>2</sub> to the formation of C<sub>7</sub>-C<sub>9</sub> HOMs were also simulated (Figure 9). For C<sub>7</sub> and C<sub>8</sub> HOMs, the model predicts a contribution of 52%-98% from acyl RO2, which is consistent with the measurements (50%-90%). However, the simulated contribution of acyl RO<sub>2</sub> to C<sub>9</sub> HOMs is over 99%, which is not consistent with the measurements (Figure 8c). Recent studies indicated that the CI radicals from α-pinene ozonolysis could not form the alkyl C<sub>9</sub>H<sub>15</sub>O<sub>3</sub>-RO<sub>2</sub> (C96O2 in default MCM v3.3.1) (Berndt 2022, Wang et al. 2021, Kurten et al. 2015). As a result, this primary C<sub>9</sub> alkyl RO2 was not considered in the model, and most of C9 RO2 considered are acyl RO2 or from acyl RO<sub>2</sub> reactions. In view of the significantly lower measured (less than 30-60%) than simulated (over 99%) contribution of acyl RO<sub>2</sub> to C<sub>9</sub> HOMs, we speculate that a small part of CI radicals might be able to form the C<sub>9</sub>H<sub>15</sub>O<sub>3</sub>-RO<sub>2</sub>, which could further react to form highly oxygenated alkyl C<sub>9</sub> RO<sub>2</sub>.

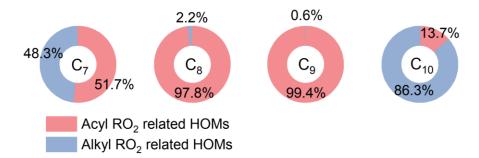

Figure 9 Simulated average contribution of acyl and alkyl RO<sub>2</sub> to C<sub>7</sub>-C<sub>10</sub> HOM formation from ozonolysis of α-pinene under typical experimental conditions (Exps 1, 8, 15, and 22).

A sensitive sensitivity analysis of the alkyl  $C_9H_{15}O_3$ -RO<sub>2</sub> yield was conducted to see its influence on the contribution of acyl RO<sub>2</sub> to the total  $C_9$  HOMs. The model simulations show that when the yield of this  $C_9$  RO<sub>2</sub> from one of the CIs ranges between 0.5% to 2%, the contribution of acyl RO<sub>2</sub> to the total  $C_9$  HOMs ranges from 27.5% to 59.8% (Figure S13S155), which is almost consistent with the measurements. This result indicates that a small part of CIs could generate the  $C_9$  alkyl RO<sub>2</sub>. We note that Wethe small production of  $C_9H_{15}O_3$ -RO<sub>2</sub> from CIs has no significant influence

520 on the yield of C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> and the subsequent acyl RO<sub>2</sub>. As shown in Figure S16, as the C<sub>9</sub>H<sub>15</sub>O<sub>3</sub>-RO<sub>2</sub> yield increases from 0% to 3%, the simulated concentrations of C<sub>10</sub>H<sub>15</sub>O<sub>4</sub>-RO<sub>2</sub> exhibit 521 negligible to small (5%) changes. As the C<sub>9</sub>H<sub>15</sub>O<sub>3</sub>-RO<sub>2</sub> is considered to only produce highly 522 523 oxygenated alkyl RO<sub>2</sub> in the model, it results in a decrease in the contribution of acyl RO<sub>2</sub> to the 524 total C<sub>9</sub> HOMs. However, the contributions of acyl RO<sub>2</sub> to total C<sub>7</sub>, C<sub>8</sub>, and C<sub>10</sub> HOMs are almost 525 unchanged. The cross-reaction rate constant of acyl RO2 is generally larger than that of alkyl RO2 (Orlando and 526 527 Tyndall 2012, Atkinson et al. 2007), and the fast cross-reaction may lead to an important contribution to the HOM dimer production. The responses of dimer formation to increasing 528 concentration of initial NO<sub>2</sub> during α-pinene ozonolysis are given in Figure 10. The C<sub>14</sub>-C<sub>18</sub> dimers 529 530 decrease by up to 50%-95% with the increase of NO<sub>2</sub> concentration up to 30 ppb (Figures 10a-e). 531 The rapid cross-reaction rate of acyl RO<sub>2</sub>, as well as their dominant contribution to the small RO<sub>2</sub> 532 species makes acyl RO<sub>2</sub> an important contributor to the formation of these dimers. The consumption 533 of acyl RO<sub>2</sub> by NO<sub>2</sub> greatly inhibits the bimolecular reactions involving acyl RO<sub>2</sub>, resulting in a rapid decrease in the concentration signal of the corresponding dimers. Considering the 534 535 predominance of acyl RO2 in small RO2 and their high reaction rate with NO2 compared to the alkyl RO<sub>2</sub>, it can be concluded that the cross-reactions involving acyl RO<sub>2</sub> contribute to roughly 50%-95% 536 537 of the  $C_{14}$ - $C_{18}$  dimer formation. 538 For C<sub>19</sub> dimers, due to the relatively smaller contribution of acyl RO<sub>2</sub> to C<sub>9</sub> and C<sub>10</sub> RO<sub>2</sub>, their 539 concentration signal decreases only by 10%-40%, and this reduction have contributions from both 540 acyl and alkyl RO<sub>2</sub>. For C<sub>20</sub> dimers, their concentration-signal changes with the addition of NO<sub>2</sub> can 541 be discussed according to the number of hydrogen atoms in the molecules. Firstly, the concentration 542 signal of C<sub>20</sub>H<sub>30</sub>O<sub>7</sub> and C<sub>20</sub>H<sub>30</sub>O<sub>9</sub> decreases by 40-60% with the addition of 30 ppb NO<sub>2</sub>, indicating 543 a significant contribution of acyl RO<sub>2</sub> such as C<sub>10</sub>H<sub>15</sub>O<sub>5</sub>-RO<sub>2</sub> (acyl RO<sub>2</sub> in default MCM v3.3.1) and 544  $C_{10}H_{15}O_7$ -RO<sub>2</sub> in their formation, while other  $C_{20}H_{30}O_x$  dimers decrease by ~30%. The  $C_{20}H_{32}O_x$ 545 dimer series also exhibits a small reduction (less than 20%) with the addition of NO<sub>2</sub>. However, the 546 C<sub>20</sub>H<sub>34</sub>O<sub>x</sub> series shows an unexpected increase with the addition of NO<sub>2</sub> up to 10 ppb and almost 547 remains unchanged with the further increase of NO<sub>2</sub> concentration. Given that the cross-reaction 548 rate constant of acyl RO<sub>2</sub> can be orders of magnitude higher than that of counterpart alkyl RO<sub>2</sub> 549 (Orlando and Tyndall 2012, Atkinson et al. 2007), the rapid consumption of acyl RO<sub>2</sub> by NO<sub>2</sub> would 550 preserve the alkyl RO<sub>2</sub> that tend to react with acyl RO<sub>2</sub> at a fast rate in the absence of NO<sub>2</sub>, which 551 to some extent would elevate the concentration of alkyl RO2 in the system and thus promote the less competitive alkyl RO<sub>2</sub> + alkyl RO<sub>2</sub> reactions to form C<sub>20</sub>H<sub>34</sub>O<sub>x</sub> dimers. The slight increase of some 552

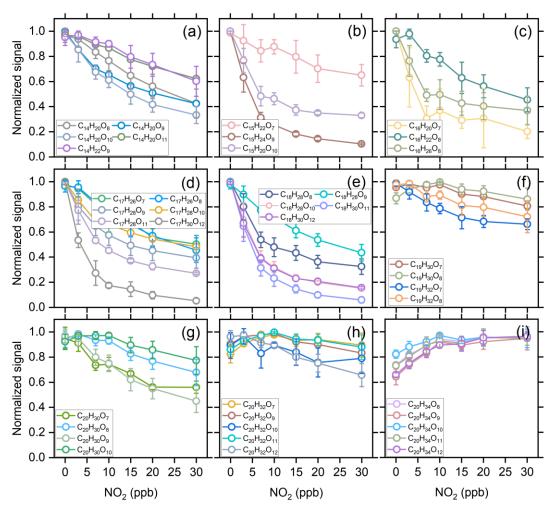

Figure 10 Averaged normalized concentration signal of the measured  $C_{14}$ - $C_{20}$  dimers as a function of the added  $NO_2$  concentration (Exps 1-28).

According to the noticeable increasing trend in  $C_{20}H_{34}O_x$  as compared to other  $C_{20}$  dimers, we speculate that acyl RO<sub>2</sub> react faster with  $C_{10}H_{17}O_x$  alkyl RO<sub>2</sub> than with  $C_{10}H_{15}O_x$  alkyl RO<sub>2</sub>. Therefore, when the acyl RO<sub>2</sub> is depleted, the preservation of  $C_{10}H_{17}O_x$ -RO<sub>2</sub> is more significant and the promotion of their cross-reactions to form  $C_{20}H_{34}O_x$  is more evident. It is also possible that the reaction of NO<sub>2</sub> with  $C_{10}H_{17}O_x$  alkyl RO<sub>2</sub> is less efficient compared to the reaction with  $C_{10}H_{15}O_x$  alkyl RO<sub>2</sub>, so more  $C_{10}H_{17}O_x$  than  $C_{10}H_{15}O_x$  are available for dimer formation in the presence of NO<sub>2</sub>.

To further prove the above two speculations, we performed sensitivity analyses for the reaction rates of  $C_{10}H_{17}O_x$ -RO<sub>2</sub> using the F0AM model. Figures 11a show the changes in  $C_{20}H_{34}O_x$  dimers with NO<sub>2</sub> addition at different  $C_{10}H_{17}O_x$ -RO<sub>2</sub> + NO<sub>2</sub> reaction rates under the conditions of Exps 8-14. As the reaction rate varies from  $51 \times 10^{-14} - 13$  to  $1 \times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, the increasing trend of

 $C_{20}H_{34}O_x$  dimers versus the added  $NO_2$  concentration is significantly weakened and the simulations are-is\_more deviated from the measurements. When the reaction rate increases to  $7.5\_\times10^{-12}$  cm³ molecule-1 s-1, the  $C_{20}H_{34}O_x$  dimers decrease significantly with increasing  $NO_2$ , which is in striking contrast to the measurements. Figure 11b presents the sensitivity analysis results for the cross-reaction rate constants of acyl  $RO_2 + C_{10}H_{17}O_x$ - $RO_2$ . As this rate constant varies from  $1\_\times10^{-12}$  to  $1\times10^{-10}$  cm³ molecule-1 s-1, the increasing trend of  $C_{20}H_{34}O_x$  versus the  $NO_2$  concentration is more pronounced and more consistent with the measurements. These sensitivity analyses support our speculation that the  $C_{10}H_{17}O_x$  alkyl  $RO_2$  may be different from other alkyl  $RO_2$  radicals in terms of the reaction efficiency with  $RO_2$  and acyl  $RO_2$  species, which leads to different responses of  $C_{20}H_{34}O_x$  dimers to  $RO_2$  addition compared to other  $RO_2$ 0 dimers. These results also suggest that the presence of acyl  $RO_2$ 0 could affect the fate and contribution of alkyl  $RO_2$ 1 to  $RO_2$ 1 hom formation in atmospheric oxidation systems given the different reactivity of acyl  $RO_2$ 2 from alkyl  $RO_2$ 2.

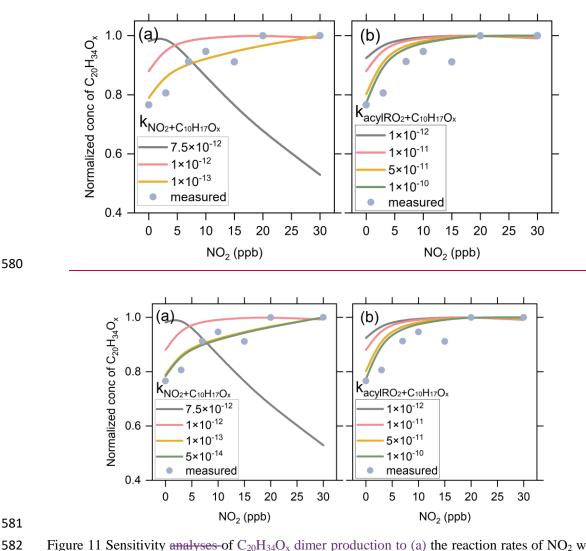

Figure 11 Sensitivity analyses of  $\underline{C_{20}H_{34}O_x}$  dimer production to (a) the reaction rates of  $NO_2$  with  $C_{10}H_{17}O_x$ - $RO_2$ -(a), and (b) the cross-reaction rate of acyl  $RO_2$  with  $C_{10}H_{17}O_x$ - $RO_2$  (b), considering

a  $C_{10}H_{17}O_x-RO_2 + NO_2$  reaction rate of  $1 \times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> for  $C_{10}H_{17}O_x-RO_2 + NO_2$ .

615 616 In this study, the molecular identities, formation mechanisms, and contributions of acyl RO<sub>2</sub> to the formation of HOMs during ozonolysis of α-pinene are investigated using a combination of flow reactor experiments and detailed kinetic model simulations. Based on the marked decrease in RO2 concentration-signal as a function of initial NO<sub>2</sub> concentration, a total of 10 acyl RO<sub>2</sub> are identified during α-pinene ozonolysis. The acyl RO<sub>2</sub> contributes to 67%, 94% and 32% of C<sub>7</sub>, C<sub>8</sub> and C<sub>9</sub> highly oxygenated RO<sub>2</sub> but only 0.45% of C<sub>10</sub> highly oxygenated RO<sub>2</sub>, respectively. Three main pathways are identified for the formation of monoterpene-derived acyl RO2: (i) the autoxidation of RO2 containing aldehyde groups, (ii) the cleavage of C-C bond of RO containing an α-ketone group, and (iii) the intramolecular H-shift of RO containing an aldehyde group. The autoxidation of aldehydic RO<sub>2</sub> formed involving multiple RO decomposition or ring-opening steps plays a dominant role in the formation of the highly oxygenated acyl RO<sub>2</sub> radicals (oxygen atom number  $\geq$  6), while the less-oxygenated acyl RO2 (oxygen atom number < 6) are mainly derived from the other two pathways. The acyl RO<sub>2</sub>-involved reactions explain 50-90% of C<sub>7</sub> and C<sub>8</sub> HOM monomers and 14% of C<sub>10</sub> HOMs, respectively. For C<sub>9</sub> HOMs, this contribution can be up to 30%-60%. For the HOM dimers, acyl RO<sub>2</sub>-involved reactions contribute 50%-95% to the formation of C<sub>14</sub>-C<sub>18</sub> dimers. Owing to the higher cross-reaction rate constant of acyl RO<sub>2</sub> compared to alkyl RO<sub>2</sub>, the acyl RO<sub>2</sub> + alkyl RO<sub>2</sub> reaction would outcompete the alkyl  $RO_2$  + alkyl  $RO_2$  reaction. Therefore, the rapid consumption of acyl RO<sub>2</sub> by NO<sub>2</sub> in the experiments (as well as in polluted atmospheres) would make the alkyl RO<sub>2</sub> that are supposed to react with acyl RO<sub>2</sub> retained, which to some extent elevates the concentration of alkyl RO<sub>2</sub> in the system and thus promotes the reaction of alkyl RO<sub>2</sub> + alkyl RO<sub>2</sub> to form dimers such as  $C_{20}H_{34}O_x$ . The contribution of H-abstraction of  $\alpha$ -pinene by OH radical to the formation of acyl RO<sub>2</sub> and HOMs is found to be negligible in the absence of NO. This is because the primary C<sub>10</sub>H<sub>15</sub>O<sub>2</sub>-RO<sub>2</sub> radicals formed in such pathways are least-oxidized and thus have relatively low cross-reaction efficiency to produce RO radicals, which are the key intermediates for the formation of acyl RO<sub>2</sub> and HOMs in that channel. However, in the presence of NO, the formation of highly oxygenated acyl RO2 via the H-abstraction pathway is demonstrated, consistent with previous studies (Shen et al., 2022). In this study, acyl RO<sub>2</sub> species are identified according to a dramatic decrease in their concentration

In this study, acyl RO<sub>2</sub> species are identified according to a dramatic decrease in their concentration signal with the addition of NO<sub>2</sub>. It should be noted that the presence of NO<sub>2</sub> could also inhibit the formation of alkyl RO<sub>2</sub> species involving acyl RO<sub>2</sub> reactions. If there are any contributions of alkyl

- 617 RO<sub>2</sub> to acyl RO<sub>2</sub> identified in this study, the influence of such alkyl RO<sub>2</sub> species on HOM formation would reflect an indirect effect of acyl RO2. However, given that the formation of most of the acyl 618 RO<sub>2</sub> identified in this study can be reasonably explained by the proposed mechanisms and verified 619 by their responses to the addition of NO, the acyl RO2 identified here are expected to have no 620 significant contributions from alkyl RO2. Currently, the reaction kinetics of monoterpene-derived 621 622 acyl RO2 are still poorly understood. Considering the important contribution of acyl RO2 to HOM 623 formation, further kinetic studies are needed to get more specific rate constants for their autoxidation and cross-reactions, thereby deepening our understanding of the role of acyl RO2 in HOM and SOA 624
- formation under atmospheric conditions.
