

1 **Dear Todd Ehlers,**

2

3 **Thank you very much for the review. We included the suggested revisions into the manuscript.**

4

5 *This manuscript received two thorough and thoughtful reviews that identified areas of the manuscript*
6 *where clarification was needed. Both reviewers are experts in either the field of bioturbation and*
7 *landscape modeling approaches. The primary areas where changes were requested included: a)*
8 *clarification of the 'new' aspects of the study and improved comparisons to previous work; b) more*
9 *precise presentation of results in figures and associated text; and c) improved presentation of the*
10 *modeling approach used.*

11

12 *The authors have done a thorough job addressing the reviewer's comments, and I thank them for the*
13 *detailed response to reviews and figure/table/ and text revisions. The text (and figure changes)*
14 *presented in response to reviews nicely address the reviewer's comments - and represent substantial*
15 *revisions.*

16

17 *Unfortunately, (not the author's fault) I didn't see an uploaded version of the revised manuscript text and*
18 *figures on the website. I realize the Copernicus website doesn't explicitly ask for this. However, many*
19 *authors often included the full revised manuscript (with track changes) at the end of their review*
20 *response. Given this, I kindly ask the authors to upload (after some minor suggestions I make below)*
21 *the revised version of their manuscript and figures (with track changes for the text) to the website. This*
22 *version should include the changes indicated in their response to reviews. If the authors did not track*
23 *changes during revisions, then they can (in MS Word at least) use the option to difference the revised*
24 *and original versions of the text to have a succinct summary of changes.*

25

26 **We provide the manuscript with all track changes highlighted in green below this rebuttal letter.**

27

28 *Two additional (minor) changes I ask the authors to make:*

29

30 *First, the text (and response to reviews) repeatedly says "Machine Learning" techniques were used for*
31 *upscaling observations. I didn't see an explanation of how this was done in the text or supplemental*
32 *material. As there are many, many, many different machine learning approaches, I ask the authors to*
33 *revise the text associated with this to explain what technique was used. What the inputs were, what the*
34 *outputs from this are, and how the algorithm was trained (if relevant). A reference(es) for the technique*
35 *used should also be given. The relevant equations should be given if the approach is new. When making*
36 *these changes, please keep in mind that readers of the manuscript should have sufficient knowledge of*
37 *what you did so that they could reproduce your approach.*

38

39 **We have rewritten the section describing the estimation of spatial parameters and put more**
40 **emphasis on applied the machine learning methodology:**

41

42 Lines 447 – 464: For spatial parameterization of the DMMF model, we predicted land cover, soil
43 properties and burrow distribution onto the hillslope catchments using machine learning techniques.
44 We used the approach Meyer et al. 2018. The most important predictors were selected by forward
45 feature selection. The quality of the random forest models was assessed by Leave-Location-Out cross
46 validation. We trained the model stepwise, using in-situ data collected from seven of the hillslope
47 catchments and validated the model using in-situ data from the remaining hillslope catchment (Meyer et
48 al., 2018). The prediction was done at 0.5 m spatial resolution. We used the WorldView-2 layers obtained
49 with a single license from GAF, NDVI, DEM, DSM, slope and roughness as predictors. The PAN-
50 sharpening of the WV-2 layers was done by GAF.

51 For the area-wide prediction of burrow locations across the hillslope catchments, we used the burrow
52 presence and absence data (section 3.1) as the response data within the RF models. The accuracy was
53 0.82 for PdA, 0.77 for SG, 0.75 for LC and 0.85 for NA. The prediction of soil properties was done using
54 soil properties estimated along the track line (see section 3.1) as response data within the RF models.
55 All of the models reached a high accuracy (see Table A1).

56 To obtain land cover classification, we used as the response within the RF models the land cover
57 measured in-situ. The classes were soil without rocks, rocks, biocrusts, grass/herbs, shrubs and trees.
58 Predictor values for each class were extracted from at least 100 polygons per site and class. The
59 accuracy of the RF models was 0.71 for PdA, 0.81 for SG, 0.83 for LC and 0.75 for NA.

60

61 *Second, please add a statement in the acknowledgments (or main text) about where the data and*
62 *models used in the study can be accessed. For example, is there a link (or DOI preferably) for the source*
63 *code and data used in the study? Please also do this for the machine-learning code used. Data or*
64 *software archiving (with a DOI) can easily be done through <https://zenodo.org> or via GFZ data services*
65 *(for EarthShape related research) - note however, the copyright of the erosion modeling software used*
66 *must be honored and you may not be allowed to repost it (hopefully not).*

67

68 **We included in the acknowledgments where the data used, model output and model code can**
69 **be accessed:**

70

71 **Lines 826 – 829: Code/Data availability:** The estimated soil properties (DOI: 10.5678/wsrb-9f70),
72 modelled sediment redistribution (DOI: 10.5678/32wa-d179) and model code ([https://gitlab.uni-](https://gitlab.uni-marburg.de/fb19/ag-bendix/model-sediment-redistribution-caused-by-bioturbating-animals)

124 **Abstract**

125 Animal burrowing activity affects soil texture, bulk density, soil water content and redistribution of
126 nutrients. All of these parameters in turn influence sediment redistribution, which shapes the earth
127 surface. Hence it is important to include bioturbation into hillslope sediment transport models. However,
128 the inclusion of burrowing animals into hillslope-wide models has thus far been limited, and largely
129 omitted vertebrate bioturbators, which can be major agents of bioturbation, especially in drier areas.
130 Here, we included vertebrate bioturbator burrows into a semi-empirical Morgan-Morgan-Finney soil
131 erosion model to allow a general approach to for assessing the impacts of bioturbation on sediment
132 redistribution within four sites along the Chilean climate gradient. For this, we predicted the distribution
133 of burrows by applying machine learning techniques in combination with remotely sensed data into the
134 hillslope catchment. Then, we adjusted the spatial model parameters at predicted burrow locations
135 based on field and laboratory measurements. We validated the model using field sediment fences. We
136 estimated the impact of bioturbator burrows on surface processes. Lastly, we analyse how the impact
137 of bioturbation on sediment redistribution depends on the burrow structure, climate, topography, and
138 adjacent vegetation.

139 Including bioturbation greatly increased model performance and demonstrates the overall importance
140 of vertebrate bioturbators in enhancing both sediment erosion and accumulation along hillslopes, though
141 this impact is clearly staggered according to climatic conditions. Bioturbation had contrasting effects on
142 sediment redistribution in arid than in semi-arid and Mediterranean, as well as in humid climate zone.
143 Burrowing vertebrates increased sediment accumulation by 137.8 % \pm 16.4 % in the arid zone (3.53 kg
144 $\text{ha}^{-1} \text{year}^{-1}$ vs. 48.79 kg $\text{ha}^{-1} \text{year}^{-1}$), sediment erosion by 6.5 % \pm 0.7 % in the semi-arid zone (129.16 kg
145 $\text{ha}^{-1} \text{year}^{-1}$ vs. 122.05 kg $\text{ha}^{-1} \text{year}^{-1}$) and sediment erosion by 15.6 % \pm 0.3 % in the Mediterranean zone
146 (4602.69 kg $\text{ha}^{-1} \text{year}^{-1}$ vs. 3980.96 kg $\text{ha}^{-1} \text{year}^{-1}$). Bioturbating animals seem to play only a negligible
147 role in the humid zone. Within all climate zones, bioturbation did not uniformly increase erosion or
148 accumulation within the whole hillslope catchment. This depended on adjusting environmental
149 parameters. Bioturbation increased erosion with increasing slope, sink connectivity and topography
150 ruggedness, decreasing vegetation cover and soil wetness. Bioturbation increased sediment
151 accumulation with increasing surface roughness, soil wetness and vegetation cover.

165 1. Introduction

166 Bioturbation was shown to shape the land surface (Hazelhoff et al., 1981; Istanbuluoglu, 2005; Taylor
167 et al., 2019; Tucker and Hancock, 2010; Whitesides and Butler, 2016; Wilkinson et al., 2009; Corenblit
168 et al., 2021) by influencing surface microtopography (Reichman and Seabloom, 2002; Kinlaw and
169 Grasmueck, 2012; Debruyne and Conacher, 1994), and soil properties such as soil porosity, permeability
170 and infiltration (Reichman and Seabloom, 2002; Yair, 1995; Hancock and Lowry, 2021; Ridd, 1996; Hall
171 et al., 1999; Coombes, 2016; Larsen et al., 2021). Cumulatively, these modifications lead to changes in
172 sediment redistribution (Gabet et al., 2003; Nkem et al., 2000; Wilkinson et al., 2009) and hence have
173 the potential to affect surface topography and nutrient redistribution on large spatial and temporal scales.
174 To quantify these effects, the shared role of climate, landscape characteristics and burrowing dynamics
175 on sediment redistribution needs to be understood.

176 On a local scale, currently used field methods to monitor sediment redistribution under real-life condition
177 are mainly erosion pins, splash boards, or rainfall simulators (Imeson and Kwaad, 1976; Wei et al., 2007;
178 Le Hir et al., 2007; Li et al., 2019a; Li et al., 2019b; Li et al., 2018; Voiculescu et al., 2019; Chen et al.,
179 2021; Übernickel et al., 2021a). The monitoring of box experiments yields a high spatio-temporal
180 resolution, and can also be linked with mathematical equations, such as random walks (Boudreau, 1986;
181 Wheatcroft et al., 1990), stochastic differential equations (Boudreau, 1989; Milstead et al., 2007), finite
182 difference mass balancing (Soetaert et al., 1996; François et al., 1997) or Markov chain theory (Jumars
183 et al., 1981; Foster, 1985; Trauth, 1998; Shull, 2001) to describe sediment redistribution.

184 Previously used methods have, however, several limitations when studying bioturbation. Field
185 measurements likely lead to an underestimation of sediment fluxes, as they are one-time or seasonal
186 measurements, and thus do not capture the continuous excavation of the sediment by the animal
187 (Grigusova et al., 2022) at a high temporal resolution. Box experiments and from them derived
188 mathematical equations describe bioturbation as an isolated process and ignore adjacent environmental
189 parameters (such as climate or vegetation). However, the field measurements showed both, positive
190 (Hazelhoff et al., 1981; Black and Montgomery, 1991; Chen et al., 2021) and negative impact of
191 bioturbation on erosion (Imeson and Kwaad, 1976; Hakonson, 1999). Also, previous field based studies
192 observed an increased bioturbation activity with higher (Milstead et al., 2007; Meserve, 1981; Tews et
193 al., 2004; Wu et al., 2021; Ferro and Barquez, 2009), but also with lower vegetation cover (Simonetti,
194 1989; Zhang et al., 2020; Zhang et al., 2019; Qin et al., 2021). Furthermore, soil mixing rates are not
195 homogenous throughout the year but depend on the animal phenological cycles (Eccard and Herde,
196 2013; Jimenez et al., 1992; Katzman et al., 2018; Malizia, 1998; Morgan and Duzant, 2008; Monteverde
197 and Piudo, 2011; Gray et al., 2020; Yu et al., 2017).

198 Another approach offer raster-based soil erosion and landscape evolution models which integrate co-
199 dependencies between bioturbation relevant environmental parameters (Black and Montgomery, 1991;
200 Meysman et al., 2003; Yoo et al., 2005; Schiffers et al., 2011). Most common soil erosion models are
201 empirical (Wischmeier and Smith, 1978; Williams, 1975; Renard et al., 1991), process-based (Morgan
202 et al., 1998; ROO et al., 1996; Nearing et al., 1989; Beasley et al., 1980), or semi-empirical models, the
203 latter of which are a combination of both (Morgan et al., 1984; Beven and Kirkby, 1979).

204 **Process-based models are based on a mechanistic understanding of the underlying physical, chemical,
205 and biological processes that govern the behaviour of the system being studied. They must be**

206 parametrised for each site; however, these models explicitly represent the governing equations and
207 simulate the system's behaviour by numerically solving these equations. Process-based models are
208 generally considered to be more realistic and accurate than empirical models because they capture the
209 fundamental processes that drive the system's behaviour. However, process-based models can be
210 computationally expensive, require more data and knowledge of system properties, and may require
211 complex numerical algorithms (Morgan et al., 1998; ROO et al., 1996; Nearing et al., 1989; Beasley et
212 al., 1980).

213 Within empirical models, on the other hand, the physical equations are completely replaced by
214 empirically determined equations which only hold for the specific area they are derived for. These
215 models are generally simpler, less computationally expensive, and require more data and knowledge of
216 system properties than process-based models. However, empirical models also tend to be less accurate
217 than process-based models, particularly when applying beyond the range of data used to fit the model.
218 In contrast to physical-based models, empirical models may not be applicable to new or different
219 conditions, as they are based on observed relationships and do not capture the underlying processes
220 that govern system behaviour (Wischmeier and Smith, 1978; Williams, 1975; Renard et al., 1991).

221 Semi-empirical models combine the advantages of the both model types (Morgan et al., 1984; Morgan,
222 2001; Morgan and Duzant, 2008; Devia et al., 2015; Lilhare et al., 2015).

223 Most landscape models do not yet implement impacts of bioturbators on water and sediment fluxes
224 (Brosens et al., 2020; Anderson et al., 2019; Braun et al., 2016; Cohen et al., 2015; Cohen et al., 2010;
225 Carretier et al., 2014; Welivitiya et al., 2019). There are numerous models describing benthic soil mixing
226 (Francois et al. 1997, Francois et al. 2002, Kadko and Heath 1984, Croix et al. 2002), biodiffusion caused
227 by all invertebrate bioturbators (Maysman et al. 2005, Rakotomalala et al. 2015, Morris et al. 2006) or
228 vertical soil mixing and lateral sediment redistribution caused by single invertebrate species (Orvain et
229 al. 2006, Román – Sánchez et al. 2019, Orvain 2005, Orvain 2003, Sanford 2008). However, there are
230 also models which described the impact of bioturbation on sediment redistribution by the vertebrate
231 animal species: such as the impact of pocket gophers on non-linear hillslope diffusion (Gabet 2000) or
232 on the creation of Mima mounds (Gabet et al. 2014). Several models include soil vertical mixing caused
233 by bioturbation and its effect on landscape evolution on a millennial scale. This rather large spatio-
234 temporal scale however means an omission of the natural variability in burrow sizes and densities,
235 climate zones and seasonality. In these models, soil erosion is proportionally increasing with increasing
236 bioturbation, vertical soil mixing rates are uniform, and bioturbation is positively linked with vegetation
237 cover (Temme and Vanwalleghem, 2016; Vanwalleghem et al., 2013; Yoo and Mudd, 2008; Pelletier et
238 al., 2013). None of the previous studies included vertebrate bioturbator burrows of various sizes and
239 spatial distribution by adjusting the soil properties and topography into a raster-based area-wide soil
240 erosion model. This approach would enable to understand impact of all vertebrate bioturbators by
241 considering the spatial distribution and variable impacts of bioturbator burrows on sediment
242 redistribution. For this, bioturbation has to be included into erosion models at a spatial resolution which
243 allows to imitate the surface processes occurring within and near the burrow, and at a temporal
244 resolution which captures the animal daily burrowing behaviour.

245 A suitable model which can be extended to include continuous bioturbating activity is the semi-empirical
246 Morgan – Morgan – Finney soil erosion model (Morgan et al., 1984; Morgan, 2001). This model was

247 successfully tested in several climate zones and land use types, such as Mediterranean sites (Jong et
248 al., 1999), rainfed agrosystems, fields and pastures (López-Vicente et al., 2008), East-African Highlands
249 (Vigiak et al., 2005) or humid forests (Vieira et al., 2014). One of the recently developed improvements
250 of this model is the Daily Morgan – Morgan – Finney model (DMMF), which introduces subsurface flow,
251 vegetation structures (type, size, height, root depth), and enables modelling at a high spatial (0.5 m) and
252 temporal (daily) resolution (Choi et al., 2017). These improvements yield the potential to integrate the
253 bioturbation into the model, as the burrowing activity is not constant and depends on vegetation structure
254 (Tews et al., 2004; Ferro and Barquez, 2009).

255 In this study, we include vertebrate bioturbator burrows into a semi-empirical soil erosion model (DMMF)
256 at a daily temporal and 0.5 m spatial resolution. For this, we predict the distribution of burrows by
257 applying machine learning techniques in combination with using remotely sensed data as predictors.
258 Then, we adjust soil properties, topography and vegetation properties at predicted burrow locations
259 based on field and laboratory measurements. We validate the model using field sediment fences. We
260 run the model for a time period of 6 years, once with and without burrow adjustments. We estimate the
261 impact of bioturbator burrows on sediment redistribution (including accumulation, erosion, and
262 excavation), and surface runoff within four sites along the Chilean climate gradient. Lastly, we analyse
263 how the impact of bioturbation on sediment redistribution depends on the burrow structure, climate,
264 topography, and adjacent vegetation. Our study shows the importance of including bioturbation into
265 erosion modelling, and describes the interplay between bioturbation, environmental parameters such
266 as... and sediment redistribution.

267

268 **2. Study area**

269 Our study was performed along a climate and vegetation gradient in Chile (Übernicket et al., 2021b),
270 comprising four study sites in the Chilean Coastal Cordillera: Pan de Azúcar (PdA) National Park (NP),
271 Santa Gracia (SG), La Campana (LC) NP, and Nahuelbuta (NA) NP (Fig. 1). PdA NP is located in the
272 arid zone in a fog-laden environment in the southern part of the Atacama Desert, with almost no rainfall.
273 The vegetation cover is less than 5 % and dominated by small desert shrubs, several types of cacti and
274 biocrusts (Lehnert et al., 2018). SG is a natural reserve located in the semi-arid zone near La Serena,
275 which is dominated by goat grazing. The vegetation consists of shrubs and cacti, covering up to 40 %
276 of the study area. LC NP is part of the Mediterranean-type climate zone in the Valparaiso Region and is
277 also affected by cattle. The study site is dominated by an evergreen sclerophyllous forest with endemic
278 palms. The canopy reaches a height of up to 9 m, and the understory consists of deciduous shrubs and
279 herbs. NA is located in the humid-temperate zone and characterized by a dense evergreen *Araucaria*
280 forest comprising broadleaved trees with heights of up to 14 m. The ground is covered by bamboo,
281 shrubs, and herbs (Bernhard et al., 2018; Oeser et al., 2018). The most common bioturbating vertebrate
282 animal species recorded within these sites are carnivores of the family Canidae (*Lycalopex culpaeus*,
283 *Lycalopex griseus*) as well as rodents of the families Abrocomidae (*Abrocoma bennetti*), Chnichillidae
284 (*Lagidium viscacia*), Cricetidae (*Abrothrix andinus*, *Phyllotis xanthopygus*, *Phyllotis limatus*, *Phyllotis*
285 *darwini*) and Octogontidae (Cerqueira, 1985; Jimenez et al., 1992; Übernicket et al., 2021a).

286

287
 288 **Figure 1.** Study area and study sites. Black lines outline the hillslope catchments. Along the blue lines,
 289 the in situ data (mound locations, soil samples, vegetation mapping) were collected. (a) Position of the
 290 study sites along the climate gradient. PdA = Pan de Azúcar, SG = Santa Gracia, LC = La Campana,
 291 NA = Nahuelbuta; Positions of plots in (b) PdA; (c) SG; (d) LC; and (e) NA. The background image is an
 292 RGB-composite calculated from WorldView-2 satellite imagery. Images were obtained with single
 293 license from GAF AG. Scale bar is the same for (b), (c), (d) and (e).

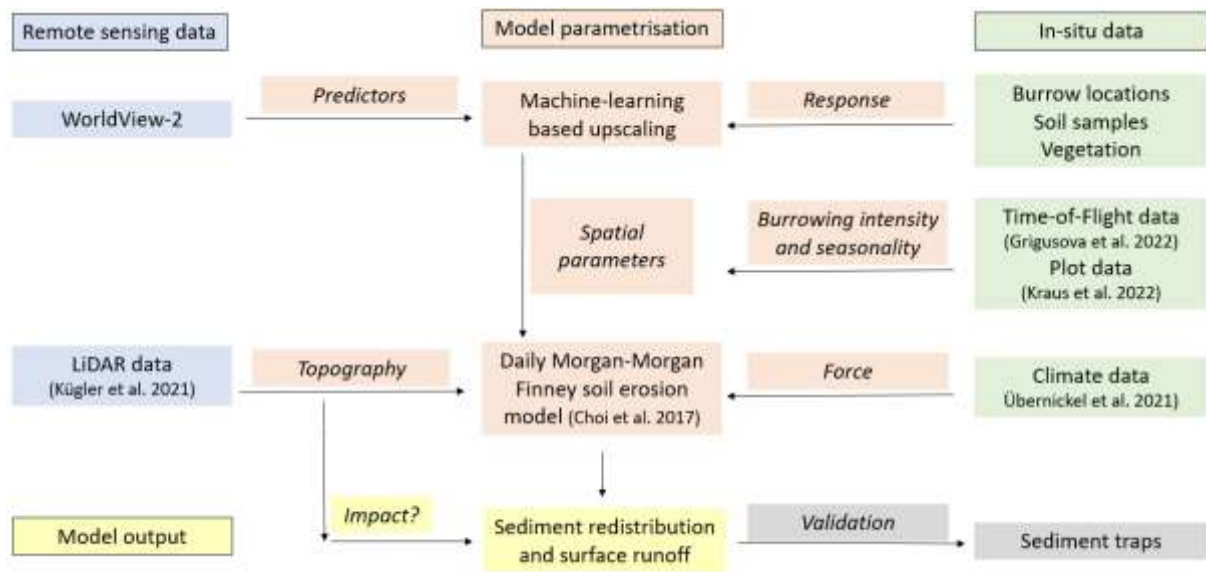

294

295 3. Methodology

296 We combined semi-empirical soil erosion modelling with in-situ measurements, remote sensing data
 297 and machine learning methods (Fig. 2). Along 8 hillslope catchments within 4 climate zones we mapped
 298 locations of burrows, estimated the vegetation cover and extracted soil samples. We analyzed the soil
 299 samples in the laboratory. Then we used remote sensing datasets and machine learning to upscale
 300 burrow distribution, vegetation cover and soil properties into the hillslope catchments. The hillslope
 301 catchment-wide predictions, the topographical information retrieved from LiDAR data (Kügler et al.,
 302 2022) and the climate information retrieved from climate stations were the input parameters for our soil
 303 erosion model. We ran the model with and without bioturbation. We included the bioturbation into the
 304 model by adjusting the input parameters at the predicted burrow locations, by including the continuous
 305 burrowing activity and soil mixing (Grigusova et al., 2021), and the seasonality (Kraus et al., 2022).and
 306 the animal phenological cycle as found in (Jimenez et al., 1992). The models were validated using self-
 307 constructed sediment traps. We studied the modeled surface runoff and sediment redistribution. Lastly,
 308 we analyzed if and how the impact of bioturbation on sediment redistribution depends on environmental
 309 parameters (topography, landscape connectivity and vegetation).

310

311

312
 313 **Figure 2.** Flow chart of our study. Green color indicates in-situ input data, blue indicates remote sensing
 314 input data. Red indicates Model parametrization. Yellow indicates model output and analysis. Grey
 315 indicates model validation.

316
 317 **3.1 In-situ data**

318 The study set-up consisted of eight hillslope catchments: one north-facing and one south-facing hillslope
 319 catchment per study site. We defined a line with a width of one meter from the top to the base of each
 320 hillslope catchment (see blue line, Fig. 1). We subdivided the track into tiles of 1 m². We saved the GPS
 321 information of each tile.

322 Within each tile of the line, we mapped burrow presence, land cover and extracted soil samples. A
 323 burrow consisted of an entrance and a mound (Fig. 3a). Each 1 m² tile with a burrow was described as
 324 a presence data point, tiles without a burrow as absence data points. We noted the size of the burrow,
 325 vegetation cover and land cover types (bare soil, herbs, shrubs, trees) within the tile. We extracted 162
 326 soil samples from soil without a mound at a depth of 10 cm. Additionally, we took a photo of the surface
 327 every second tile along the track.

328 To validate the model output, we set up sediment traps (Fig. 3b), with six traps per site, two of which
 329 were located at the hillslope catchment base and four were located on two random positions within the
 330 hillslope catchment. The sediment traps consisted of geotextile vertically attached to wooden poles for
 331 stability. The traps had a length of 2 m – 5 m, a width of ~1.5 m and a height of ~1 m. 1.5 m of geotextile
 332 was laid down at the surface uphill the wooden poles to enable the collection of sediment. The sediment
 333 accumulated within the traps was collected after 1 year and its mass [cm³] and dry weight [kg] were
 334 estimated.

335 Climate information was retrieved from climate stations located adjacent to the hillslope catchments
 336 which provide climate data in 5 minute intervals (Übernicket et al. 2021). To force the model on an hourly
 337 basis, hourly air temperature, precipitation total and intensity, wind speed, wind direction and humidity
 338 was calculated for the study period from 1st April 2016 to 1st December 2021. Evapotranspiration was
 339 estimated by the Penman-Monteith equation (Penman, 1948).

341
 342 **Figure 3.** In-situ constructions. (a) Example of a burrow consisting of burrow entrance and mound. (b)
 343 Fence construction used for the collection of eroded sediment to validate the model. Both photos by
 344 Paulina Grigusova.

345

346 3.2 Estimation of soil properties

347 We estimated several soil properties from the soil samples and photos collected in-situ (Grigusova et
 348 al., 2022). We estimated the rock coverage on the surface and debris from the photos taken every
 349 second tile. For this, the photos were firstly classified into 5 classes. The classification was unsupervised
 350 using k-means (Fig. A1). Then we calculated the ratio of pixels classified as skeleton and / or debris to
 351 the overall amount of all pixels to determine the amount of both parameters in percent.

352 In the lab, we estimated soil water content, bulk density, soil particle density, soil texture (sand, silt, clay,
 353 coarse / middle / fine sand, coarse / middle / fine silt), soil skeleton, organic matter and organic carbon.
 354 Gravimetric soil water content [%] (GSWC) described the mass of water within the soil sample and was
 355 estimated as in Eq (1):

$$356 \text{GSWC} = \frac{(S_m - S_d)}{S_d} * 100 \quad , \quad (1)$$

357 where S_m [g] is the mass of moist soil measured directly after the extraction and S_d [g] is the mass of
 358 soil dried at 105 °C for at least 24 hours. Bulk density [g cm^{-3}] (BD) was calculated as following:

$$359 \text{BD} = \frac{S_d}{S_v} \quad , \quad (2)$$

360 where S_v [cm^{-3}] is the volume of the sample. Soil particle density [g cm^{-3}] (SPD) was calculated as in Eq
 361 (3):

$$362 \text{SPD} = \frac{dm}{S_v} \quad , \quad (3)$$

363 where dm [g] is the dry mass of soil particles excluding pores.

364 Particle size distribution [%] – clay (< 0.002 mm), coarse, middle and fine silt (0.002 mm to 0.02 mm),
 365 and coarse, middle and fine sand (0.02 mm to 2 mm) was estimated using a PARIO method (Durner et
 366 al., 2017). Soil skeleton was estimated as the ratio of particles with a diameter above 2 mm. Ratio of
 367 organic matter (OM) was estimated as in Eq. (4)

$$368 \text{OM} = 1 - \frac{S_c}{S_d} \quad , \quad (4)$$

369 where S_c is the weight [g] of the sample dried at 500 °C for 16 hours.

370 We used pedotransfer functions to determine porosity, saturated soil moisture, hydraulic conductivity,
 371 water content at field capacity, and permanent wilting point. Pore ratio (θ_s) was estimated from bulk and
 372 particle density as in Eq. (5):

$$373 \theta_s = \frac{BD}{SPD} \quad (5)$$

374 Saturated water content [g g^{-1}] (W_s) was estimated as in Eq. (6):

$$375 W_s = \theta_s \frac{pw}{BD} \quad (6)$$

376 where pw [g cm^{-3}] is the density of water which is set to be 1 g cm^{-3} (Pollacco, 2008).

377 Hydraulic conductivity K_s [m s^{-1}] was estimated as in Eq. (8):

$$378 K_s = 1.15741 * 0.0000001 * \exp(x) \quad (7)$$

379 where x for sandy soil is:

$$380 x = 9.5 - 1.471 * (BD * BD) - 0.688 * OM + 0.0369 * (OM * OM) - 0.332 * CS \quad (8)$$

381 and x for loamy and clayey soils is:

$$382 x = -43.1 + 64.8 * BD - 22.21 * (BD * BD) + 7.02 * OM - 0.1562 * (OM * OM) + 0.985 * \ln(OM) -$$

$$383 0.01332 * C * OM - 4.71 * BD * CS \quad (9)$$

384 where C is percentage of clay and CS is percentage of clay and silt (Wösten, 1997). To estimate water
 385 content at field capacity [%] (FC) and permanent wilting point (PWP), we applied functions by (Tomasella
 386 et al., 2000) as these were developed for South American soils:

$$387 FC = 4.046 + 0.426 * Si + 0.404 * C \quad (10)$$

$$388 PWP = 0.91 + 0.15 * Si + 0.396 * C \quad (11)$$

389 where Si is the percentage of silt.

390

391 3.3 Processing of remote sensing data

392 The digital elevation models (DEM) were calculated from the LiDAR data (Kügler et al., 2022; Horn,
 393 1981) at a resolution of 0.5 m. Slope was calculated according to Horn (1981). Manning's surface
 394 roughness coefficient was estimated following (Li and Zhang, 2001). Topographic position index (TPI)
 395 and Topographic ruggedness index (TRI) were calculated according to (Wilson et al., 2007). **TPI subtract**
 396 **the mean elevation of pixels in a specified range from the elevation of the central pixel. Positive values**
 397 **represent hills while negative values represent valleys. The TRI adds together the elevation differences**
 398 **between a grid cell and its eight neighbours. It measures the relative level of topography irregularity, the**
 399 **higher the value, the more irregular the topography.** Plan and profile curvature were determined after
 400 (Zevenbergen and Thorne, 1987). Connectivity indices, Sinks, Wetness index, Flow direction, Flow path,
 401 Catchment slope and Catchment were calculated in SAGA GIS.

402 Single license stereo WorldView-2 images with a resolution of 0.5 m were retrieved from GAF Munich
 403 GmbH. The topographic correction of WorldView-2 images was done using the LiDAR data, solar
 404 elevation angle, solar zenith angle and azimuth angle according to Goslee (2019). The digital surface
 405 models (DSMs) were calculated from the stereo images. Additionally, we extracted single bands and
 406 calculated the normalized difference vegetation index (NDVI).

407

408 3.4 The erosion model

409 3.4.1 Daily Morgan-Morgan-Finney model

410 The DMMF model is a combined soil erosion model used to estimate surface runoff and sediment flux
411 on a field scale on a daily basis. Spatially, the DMMF model represents an area as several
412 interconnected elements (e.g. pixels) of uniform topography, soil characteristics, land cover type, and
413 vegetation structure. Through coupling, the model operates with flow direction algorithms: each element
414 receives water and sediments from upslope elements and delivers the generated surface runoff and
415 eroded soils to downslope elements. On a temporal scale, the model estimates surface runoff and
416 sediment flux of each element on a daily basis. The model input parameters include climate, topography,
417 soil properties and land cover information (Choi et al., 2017). Data pre-processing, modelling and
418 analysis (see Fig. 2) was done in R statistic environment. The raster data were cropped to the size of
419 the hillslope catchments (Fig. 1). Input parameters are listed in Table 1 and plotted in Fig. A2.

420 During the model simulation, water and sediment are transferred from pixels located at higher elevations
421 to pixels situated at lower elevations. This occurs in two stages: The first stage is the hydrological phase
422 where the model calculates surface runoff which happens when the amount of surface water input
423 exceeds the water-holding capacity. The amount of surface runoff is computed by taking the infiltration
424 capacity of the surface, the volume of surface water input, and the fraction of the impervious area of a
425 pixel into account. Infiltration capacity represents the maximum amount of surface water that can
426 penetrate the subsurface layer. It is determined by the percentage of the impervious area and the
427 available pore space.

428 The second stage is the sediment phase, where the model estimates the sediment budget for each
429 particle size class, based on the surface conditions. The model calculates the detachment and
430 deposition of sediments in a step-by-step process. The sources of sediments are detached particles
431 from the pixel itself due to rainfall and surface runoff, and delivered soil particles from higher elevation
432 pixels. The detachment of soil particles by rainfall occurs when raindrops hit the ground with enough
433 energy to detach soil particles from the surface. Rainfall has different impacts on areas with and without
434 canopy cover, as canopy cover changes the kinetic energy of raindrops.

435 The amount of soil particles detached by raindrops is calculated based on the soil particle detachability,
436 the percentage of each particle size class, the bare soil surface area, and the kinetic energy of effective
437 rainfall. The amount of detached soil particles by surface runoff is calculated based on the soil particle
438 detachability, the amount of runoff, the slope angle of the pixel, and the proportion of the bare surface
439 area. The third source of sediment is from higher elevation pixels and is averaged by the surface area
440 of the pixel.

441 Once sediments are delivered to the surface runoff, a portion of the suspended sediments settles to the
442 bottom due to gravitational force. To calculate this settling, the model requires the flow velocity of the
443 runoff and the settling velocity of each particle size class, which are influenced by the flow depth, slope
444 angle of the pixel, and Manning's roughness coefficient (Choi et ail. 2019).

445

446 **3.4.2 Estimation of spatial parameters**

447 For spatial parameterization of the DMMF model, we predicted land cover, soil properties and burrow
448 distribution onto the hillslope catchments using machine learning techniques.

449 We used the approach Meyer et al. 2018. The most important predictors were selected by forward
450 feature selection. The quality of the random forest models was assessed by Leave-Location-Out cross

451 validation. We trained the model stepwise, using in-situ data collected from seven of the hillslope
452 catchments and validated the model using in-situ data from the remaining hillslope catchment (Meyer et
453 al., 2018). The prediction was done at 0.5 m spatial resolution. We used the WorldView-2 layers obtained
454 with a single license from GAF, NDVI, DEM, DSM, slope and roughness as predictors. The PAN-
455 sharpening of the WV-2 layers was done by GAF.

456 For the area-wide prediction of burrow locations across the hillslope catchments, we used the burrow
457 presence and absence data (section 3.1) as the response data within the RF models. The accuracy was
458 0.82 for PdA, 0.77 for SG, 0.75 for LC and 0.85 for NA. The prediction of soil properties was done using
459 soil properties estimated along the track line (see section 3.1) as response data within the RF models.
460 All of the models reached a high accuracy (see Table A1).

461 To obtain land cover classification, we used as the response within the RF models the land cover
462 measured in-situ. The classes were soil without rocks, rocks, biocrusts, grass/herbs, shrubs and trees.
463 Predictor values for each class were extracted from at least 100 polygons per site and class. The
464 accuracy of the RF models was 0.71 for PdA, 0.81 for SG, 0.83 for LC and 0.75 for NA.

465 The vegetation height measured in plots was averaged for each class per site. All pixels classified as
466 respective class were assigned the same vegetation height information. Vegetation density was
467 estimated per hillslope catchment as the amount of vegetation individuals per m². Vegetation diversity
468 was calculated by Shannon index (Shannon, 1948). The interception area was the area not covered by
469 vegetation (herbs, shrubs or trees).

470

471

472 **3.4.3 Inclusion of bioturbation**

473 In the grid cells with predicted burrow locations, we adapted the values of input parameters to include
474 bioturbation. The adaptations varied with climate zone and burrow size. The size, geometric structure
475 and excavation rates of burrowing animals were previously estimated at a high spatial and temporal
476 resolution (Grigusova et al., 2022). Based on this results, we firstly adjusted the microtopography. We
477 modified the layer depth to represent burrow entrance and elevation to represent animal mound. Mounds
478 were always located downslope of burrow entrances in the direction of flow.

479 Secondly, we adjusted the soil properties. Soil properties texture and organic carbon were estimated
480 from soil extracted from mounds in Kraus et al. (2022). In this study we additionally estimated bulk
481 density, initial water content, soil skeleton, porosity, saturated water content, available water capacity
482 and water content at field capacity from the same dataset (see section 3.2). We calculated the median
483 value of each property for the samples extracted from mounds and for the samples extracted from soil
484 without mounds. Then, we estimated the change in percent between these two values. This was then
485 used to adjust the soil property for each pixel including a mound.

486 Thirdly, modelled mound pixels had to be cleared from ground vegetation cover. For this, we removed
487 ground vegetation cover from pixels with burrow locations and decreased ground vegetation cover,
488 height, diameter and amount of ground vegetation individuals from adjacent pixels as measured in situ.
489 Then, the amount of rocks and debris was set as estimated from soil samples (section 3.2)

490 Animal activity has been found to be highly variable throughout the year (Grigusova et al., 2022; Kraus
491 et al., 2022). The density of burrows does not stay stable throughout the year but increases or decreases

492 depending on the season and climate zone. We therefore artificially removed or added burrows into the
 493 hillslope catchments at the particular seasons. For this, we adapted the density of soil, the topography
 494 and vegetation cover accordingly. We created a 3D-model of the burrow structure, adjusted subsurface
 495 soil properties and properties of soil excavated to the surface; the removed vegetation within the pixel
 496 with a predicted burrow and decreased adjacent vegetation cover. Animal burrowing activity varies
 497 throughout the course of the year, and there is a three-month period during which they are mostly active,
 498 which we considered using/doing xxx
 499 Lastly, we also included the vertical movement of sediment particles from deeper soil layers to the
 500 surface in dependence on climate. Animals were found to reconstruct their burrows after each rainfall
 501 event (Grigusova et al., 2022). Corresponding with these findings, we increased the entrance depth and
 502 mound height by 30% after each rainfall event, which represents the averaged value found in the
 503 previous study (Grigusova et al., 2022).
 504 For the validation, we ran the model for the time periods between the installation of sediment fences
 505 and the collections of sediment. We compared the mass and weight of modelled and collected sediment
 506 and estimated R² and RMSE. To test the importance of the inclusion of individual bioturbation
 507 parameters into the model, we ran the model under 4 conditions: (i) No burrows; (ii) Solely entrances;
 508 (iii) Solely mounds; (iv) Entire burrows (entrances and mounds).

509
 510 **Table 1.** Model input layers and respective changes to layer values at the predicted burrow locations.
 511 Ground vegetation was removed from the respective pixels, while tree canopy was not changed. The
 512 values were estimated as described in 3.5.2. Using the adjusted values, we calculated
 513 evapotranspiration using the Penman-Monteith equation, surface roughness from the elevation layer,
 514 and hydraulic conductivity, water content at field capacity and saturated water content using
 515 pedotransfer functions.

Derivation	Parameter	Units	Pixel value at burrow locations			
			PdA	SG	LC	NA
DEM	Elevation	m asl	+0.24	+0.23	+0.36	+0.19
	Surface roughness	-	-	-	-	-
	Depth	m	-0.23	-0.41	-0.22	-0.04
Soil samples	Water content	%	+120	-6	-68	-62
	Bulk density	g cm ⁻³	-	-6	-17	-
	Sand	%	-29	-12	+57	-43
	Silt	%	+54	+22	+23	ns
	Clay	%	+145	+44	+19	-73
	Organic carbon	%	+168	+72	+105	+25
Pedotransfer functions	Hydraulic conductivity	m s ⁻¹	-	-	-	-
	Water content at field capacity	%	-	-	-	-
	Saturated water content	%	-	-	-	-
	Ground vegetation cover	%	0	0	0	0

Land cover classification	Soil and debris	%	100	100	100	100
	Skeleton	%	0	0	0	0
	Average plant height	m	0	0	0	0
	Average plant diameter	m	0	0	0	0
	Number of plants	n m ⁻²	0	0	0	0

516

517 **3.5 DMMF model sensitivity test**

518 We conducted a sensitivity test to identify those input parameters which significantly influence the model
519 output. For this, we first estimated the mean value of each input parameter. Then, we created an artificial
520 hillslope catchment of 100 m * 100 m. To start the test, each pixel received the mean value of each
521 parameter. We ran the model for one rainfall event. Then, we stepwise changed the single input
522 parameter values from their minimum to their maximum values while we did not adjust any other
523 parameters. To quantify the significance of the input variations, we conducted a t-test (Table A2). For
524 this, we compared the amount of redistributed sediment of each model run to the first model run.

525

526 **3.6 Impact of burrows on surface processes**

527 We estimated burrow density, as a ratio of pixels with predicted burrows to all pixels. Additionally, we
528 calculated the ratio of pixels which are part of a burrow aggregation to all pixels which include a burrow.
529 Burrow aggregation describes at least 4 neighboring pixels with predicted burrows. We calculated the
530 amount of excavated sediment as a sum of burrow density and the burrow excavation rate as estimated
531 in Grigusova et al. (2022).

532 To estimate the impact of burrows on sediment redistribution and surface runoff, we ran the DMMF
533 model for the time period from 1st April 2016 until 31th December 2021 for all hillslope catchments. We
534 ran the model (i) with no burrows and (ii) with entire burrows. We estimated (i) sediment redistribution
535 (accumulation - erosion) and (ii) surface runoff. We analyzed the redistribution and runoff on the plot (1
536 m²) and hillslope catchment (1 ha) scale.

537 Lastly, to analyze under which biotic and abiotic environmental parameters (topography, vegetation
538 cover) the bioturbation enhances sediment erosion or accumulation, we set-up a generalized additive
539 model (GAM) (Wood, 2006). For this, we first subtracted the output of the model with no burrows from
540 the output of the model with entire burrows. Within each pixel, two processes are happening
541 simultaneously: a certain amount of sediment erodes, and a certain amount of sediment accumulates. To
542 estimate the sediment redistribution for each pixel of each model run, we estimate which of these processes
543 dominated. Positive pixel values thus mean, bioturbation enhanced sediment accumulation, negative
544 pixel values mean, bioturbation enhanced sediment erosion. We tested the following environmental
545 parameters: mound density, vegetation cover, elevation, slope, aspect, TRI, TPI, curvature and
546 connectivity and wetness index. The model performance was evaluated by the percentage of explained
547 data variance. We analyzed the impact of environmental parameters within 1-meter and within 10-meter
548 distance from the burrows.

549

550 **4 Results**

551 **4.1 Model sensitivity test and accuracy**

552 Parameters which significantly influenced the model output were precipitation, slope, vegetation cover,
553 surface roughness, silt content and water content (Table A2). There was correlation between some of
554 the spatial model parameters (Fig. A10), especially between the initial and saturated water content;
555 between water content and vegetation cover; and between clay content and field capacity. However, a
556 high correlation between spatial parameters does not mean that these parameters impact the sediment
557 redistribution in a similar way.

558 We quantified the model performance by comparing the modelled and measured sediment
559 redistribution. The performance varied depending on the burrow inclusion (Figure 4 and 5). The
560 performance of the model without any bioturbation was lower ($R^2 = 0.73$, RMSE = 1.50, MSE = 2.27),
561 as when burrow entrances ($R^2 = 0.81$, RMSE = 1.34, MSE = 1.16) or mounds ($R^2 = 0.83$, RMSE = 1.10,
562 MSE = 1.22) were included. The model had the highest performance when entire burrows were included
563 ($R^2 = 0.85$, RMSE = 1.01, MSE = 1.01). However, as the scatterplots showed, the model performance
564 seemed to be determined strongly by one measurement (Fig. 5). For this reason, we calculated the
565 metrics without this measurement (Fig. A2). The model without any burrows ($R^2 = 0.17$, RMSE = 1.18,
566 MSE = 1.39) in this case performed much lower than models with burrows. The model performance
567 continuously strongly increased when burrow entrances ($R^2 = 0.48$, RMSE = 0.61, MSE = 0.78), or
568 mounds ($R^2 = 0.51$, RMSE = 0.75, MSE = 0.57) were included. The model with whole burrows reached
569 the highest performance ($R^2 = 0.71$, RMSE = 0.63, MSE = 0.39). When we compare the modelled
570 redistribution to the sediment redistribution estimated using Time-of-Flight cameras in Grigusova et al.
571 (2022), the differences appear to be minor ($R^2 = 0.62$, RMSE = 0.12, MSE = 0.35).

572

573

574 **Figure 4.** R^2 and RMSE of the Morgan-Morgan-Finney soil erosion model. For dataset A, we compared
575 the amount of sediment collected in all sediment fences with the modelled eroded sediment (see Fig.
576 A3). For dataset B, we removed one measurement, as the R^2 seemed to be defined by this
577 measurement (see Fig. A4). For Scenario A, we did not include any burrows into the model. For scenario
578 B, we included burrow entrances and for scenario C, we included mounds. For scenario D, we included
579 whole burrows into the model. The adjustments made to include entrances, mounds and burrows into
580 the model are described in section 3.5.2.

581

582
583

584 **Figure 5.** Measured and modelled redistributed sediment without an outlier. (a) Model without
585 bioturbation. (b) Model with entrances. (c) Model with mounds. (d) model with burrows.

586

587 **4.2 Model output: Surface runoff and sediment redistribution**

588 Hillslope catchment – wide sediment redistribution (1 ha resolution) was the highest in humid NA,
589 followed by Mediterranean LC, semi-arid SG and arid PdA (Fig. 6a, 6b, 8). In NA, LC and SG, the erosion
590 processes dominated, while in PdA, more sediment accumulated than eroded. **The impact of burrows
591 on sediment redistribution was significant in arid PdA, semi-arid SG and Mediterranean LC. Burrows
592 increased sediment redistribution by 137.8 % ±16.4 % in arid PdA (3.53 kg ha⁻¹ year⁻¹ vs. 48.79 kg ha⁻¹
593 year⁻¹), by 6.5 % ±0.7 % in semi-arid SG (129.16 kg ha⁻¹ year⁻¹ vs. 122.05 kg ha⁻¹ year⁻¹) and by 15.6 %
594 ±0.3 % in Mediterranean LC (4602.69 kg ha⁻¹ year⁻¹ vs. 3980.96 kg ha⁻¹ year⁻¹). Overall, bioturbation
595 increased sediment accumulation in the arid zone (as the magnitude of the sediment excavation by the
596 animal exceeded sediment erosion which occurs during rainfall events), but increased sediment erosion
597 in semi-arid and Mediterranean climate (where animal burrowing activity and rainfall is present). The
598 largest impact was found under Mediterranean conditions. We found no significant effect on
599 redistribution in the humid zone (Figure 7). However, impact of bioturbation varied throughout the
600 hillslope catchment (Figure 7, 8 and 9) – it depended on a specific context if bioturbation supports
601 sediment erosion or accumulation.**

602 Surface runoff was the highest in humid NA, followed by Mediterranean LC, arid PdA and semi-arid SG
603 (Figure 6c). The impact of burrows on surface runoff was significant in all climate zones. Burrows
604 increased surface runoff in PdA by 34 %, in SG by 40% and in LC by 4.1 %; and decreased surface
605 runoff by 5.9 % in NA. Hillslope catchment-wide maps are shown in Fig. A6-A8.

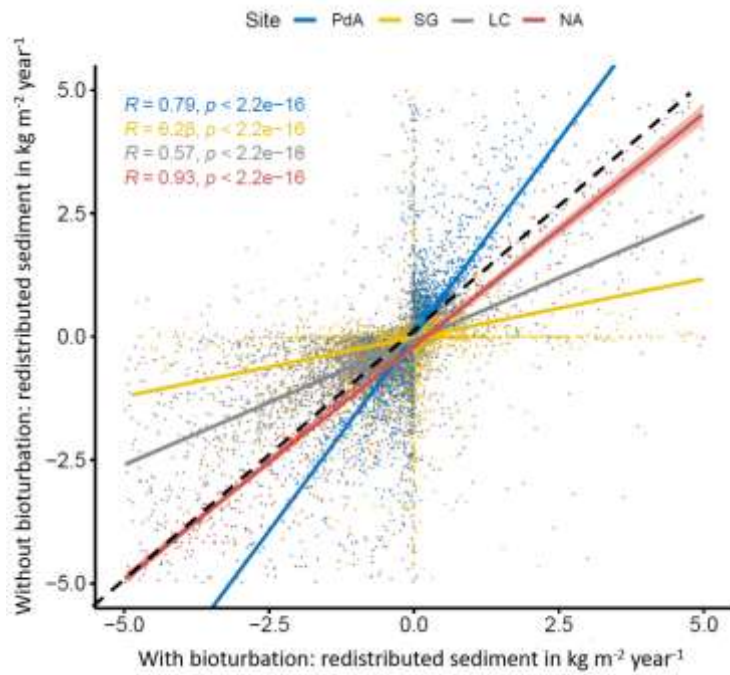

606

607
608

609 **Figure 6.** Summary of model outputs across the climate gradient. PdA is arid Pan de Azúcar, SG is
610 semi-arid Santa Gracia, LC is Mediterranean La Campana, NA is humid Nahuelbuta. Graphs (a) and
611 (b) show the modelled sediment redistribution. Positive values indicate sediment accumulation; negative
612 values indicate sediment erosion, in (a) sediment redistribution is shown on a pixel scale in $\text{kg m}^{-2} \text{ year}^{-1}$,
613 while in (b) sediment redistribution is shown on the hillslope catchment scale in $\text{kg ha}^{-1} \text{ year}^{-1}$. The
614 impact of bioturbation on sediment redistribution was estimated by a t-test and was significant in three
615 sites: PdA^{***}, SG^{**} and LC^{***}. Bioturbation increased sediment redistribution by 137.8 % in PdA, by 6.5
616 % in SG and by 15.6 % in LC. For hillslope catchment-wide maps see Fig. A6-A8. Graph (c) represents
617 the modelled surface runoff on the hillslope catchment scale in $\text{m}^3 \text{ ha}^{-1} \text{ year}^{-1}$. The impact of bioturbation
618 on surface runoff was estimated by a t-test and was significant at all sites. Bioturbation increased surface
619 runoff in PdA by 34 %, in SG by 40 % and in LC by 4.1 %; and decreased surface runoff by 5.9 % in
620 NA. For hillslope catchment-wide maps see Fig. A6.

621

622

623 **Figure 7.** Comparison of the model outputs with and without bioturbation of each pixel (0.5 m) in all

624 study sites. The x-axis shows the output of the model with bioturbation, the y-axis the model output

625 without bioturbation. PdA is arid Pan de Azúcar, SG is semi-arid Santa Gracia, LC is Mediterranean La

626 Campana, NA is humid Nahuelbuta. Points represent single pixel values; lines show linear regressions

627 for the sites. The lower R, the higher the impact of burrows on sediment redistribution at the resolution

628 of 0.5 m. The black dashed line symbolizes a perfect correlation – along this line the bioturbation would

629 have no effect on sediment redistribution. Bioturbation lead to more accumulation if the regression line

630 representing results from a particular climate zone is steeper than the perfect correlation line.

631 Bioturbation lead to more erosion if the regression line representing results from a particular climate

632 zone is flatter than the perfect correlation line. Bioturbation increases sediment accumulation in arid

633 PdA (through the high burrowing rate, more sediment is accumulated on the surface than eroded during

634 rainfall events). Bioturbation increases sediment erosion in semi-arid SG and Mediterranean LC.

635 Absolutely, the highest impact on sediment redistribution is in the Mediterranean climate zone. The

636 lowest impact is in the humid zone.

637

638
 639 **Figure 8.** Hillslope catchment-wide predicted sediment redistribution. Colours indicate sediment
 640 redistribution. Grey shadows indicate the hill shading calculated from LiDAR data. (a) Pan de Azúcar,
 641 (b) Santa Gracia, (c) La Campana, (d) Nahuelbuta.

642

643 **4.3 Role of continuous burrowing activity on sediment redistribution**

644 We included the excavation of the sediment by the animal itself into the model. The density of burrows
 645 was the highest in arid PdA, then Mediterranean LC, semi-arid SG and the lowest in humid NA. Burrows
 646 were mostly distributed within groups of several burrows in Mediterranean LC and semi-arid SG, while
 647 they were more evenly distributed in arid PdA and humid NA. The burrows were of largest size in
 648 Mediterranean LC, followed by arid PdA, semi-arid SG and humid NA. Similarly, the highest volume of
 649 excavated sediment at the beginning of the modelling period was in Mediterranean LC and arid PdA.
 650 The volume of excavated sediment during the burrow reconstruction after rainfall events was the highest
 651 in humid NA, followed by Mediterranean LC, semi-arid SG and arid PdA. The percentage of sediment
 652 excavated by the animal to sediment redistributed during rainfall events was 128 % in PdA, 24 % in SG,
 653 33.5 % in LC and 5.6 % in NA.

654

655 **Table 2.** Impact of animal bioturbation activity on overall sediment redistribution on various scales. The
 656 bioturbation activity was estimated using Time-of-Flight based cameras in Grigusova et al. 2022. This
 657 study showed that animals reconstruct their burrows after each rainfall events. During this process, 10
 658 % of the overall sediment burrow volume is relocated from within the burrow to the surface. We

659 integrated this process into our model and calculated the percentage of newly excavated sediment by
 660 the animals to the amount of sediment which was redistributed during rainfalls for the period of one year.

Parameter	Units	PdA	SG	LC	NA
Burrow density	ha ⁻¹	91.35	71.50	84.36	13.30
Burrow aggregations	%	24	62	73	5
Burrow size	m ³	0.015	0.012	0.047	0.008
Sediment at the surface at the start of modelling	m ³ ha ⁻¹	1.35	0.88	4.11	0.10
Sediment excavated after each rainfall	m ³ ha ⁻¹	0.07	0.04	0.22	0.01
Number of rainfall events	year ⁻¹	3	7	16	137
Sediment excavated by the animal after the rain	m ³ ha ⁻¹ year ⁻¹	0.21	0.28	3.52	0.69
Sediment redistributed due to rainfall	m ³ ha ⁻¹ year ⁻¹	0.44	1.17	10.51	12.21
Excavated sediment to redistributed sediment	%	47	24	33.5	5.6

661

662 4.4 Role of adjacent environment

663 We subtracted the output of the model with included burrows from the output of the model without
 664 burrows (Figure A8). Although, the burrows on average enhanced sediment erosion on the hillslope
 665 catchment – scale, the high-resolution maps unveiled that burrows enhance sediment erosion within
 666 some pixels while they rather increased sediment accumulation within others.

667 The amount of data variance explained by the GAM models (see section 3.6.) differed between models
 668 (Table A3). Models estimating the impact of environmental parameters on sediment redistribution within
 669 1-meter distance from the burrows, explained 3.84 % of variance in PdA, 37.1 % in SG, 46 % in LC and
 670 42. % in NA. Models estimating the impact of environmental parameters on sediment redistribution
 671 within 10-meter distance from the burrows, explained 1.99 % of variance in PdA, 12.8 % in SG, 52 % in
 672 LC and 72.9 % in NA. The parameters selected for SG were slope, roughness, curvature, TRI and NDVI.
 673 Parameters selected for LC were elevation, slope, NDVI, sinks and roughness. Parameters selected for
 674 NA were elevation, slope, aspect, TRI, sinks and roughness (Figure 10).

675 Bioturbation strongly increased sediment redistribution (erosion and accumulation) at high values of
 676 elevation, slope, surface roughness TRI, sinks and topographic wetness index, at the middle values of
 677 elevation and aspect, and at low values of profile curvature and NDVI. From these parameters,
 678 bioturbation increased sediment erosion at high and middle values of elevation, at high values of slope,
 679 sinks and TRI, and at low values of profile curvature. Bioturbation increased sediment accumulation at
 680 high values of surface roughness and topographic wetness index and at low values of NDVI (Fig. A3 –
 681 A8).

682 Bioturbation somewhat enhanced sediment erosion at medium values of surface roughness, NDVI and
 683 sinks, and at low values of topographic wetness index. Bioturbation somewhat increased sediment
 684 accumulation at low values of slope and TRI, at low and medium values of elevation and at high values
 685 of profile curvature.

686

687
 688 **Figure 9.** Hillslope catchment-wide impact of bioturbation on sediment redistribution. Colour indicates
 689 the impact. Positive values indicate bioturbation enhanced sediment accumulation, negative values
 690 indicate bioturbation enhanced sediment erosion. Grey shadows indicate the hill shading calculated
 691 from LIDAR data. (a) Pan de Azúcar, (b) Santa Gracia, (c) La Campana, (d) Nahuelbuta.
 692

693
 694 **Figure 10.** This figure is a conceptual summary of the detailed results from figures A3 – A8. Bioturbation
 695 increases erosion or accumulation depending on the values of environmental parameters. The
 696 dependencies are the same for all climate zones. The figure is the conceptual summary for all climate
 697 zones, therefore, there are no values stated on the x- and y-axes. The x-axis shows if bioturbation
 698 increases erosion or accumulation. The y-axis are environmental parameters. Line thicknesses indicate
 699 the magnitude of impact. Please note that bioturbation has no impact on sediment redistribution in
 700 regions with low sink connectivity and topographic ruggedness. The relationship between the values of
 701 environmental parameters and the impact of bioturbation is not linear: Bioturbation can have the same
 702 impact on sediment redistribution at high or low values of an environmental parameter, but a contrasting
 703 impact at middle values of this parameter (as in this case for elevation, slope or surface roughness).

704
 705 **5. Discussion**

706 **5.1 The inclusion of bioturbation increases model performance**

707 Overall, our DMMF model including bioturbation performed much better than the model without
 708 bioturbation. The DMMF model without bioturbation performed worse (RMSE of $1.18 \text{ kg ha}^{-1} \text{ year}^{-1}$ and
 709 R^2 of 0.17) than the model with bioturbation (RMSE was $0.63 \text{ kg ha}^{-1} \text{ year}^{-1}$ and R^2 was 0.71).

710 We hence argue that the higher accuracy of our model can be explained with the inclusion of
 711 bioturbation. This is confirmed by the fact that our model run without bioturbation performed similarly to

712 previously run models without bioturbation: In earlier studies, the accuracy of the MMF model reached
713 an RMSE in between 4.9 and 8.2 kg ha⁻¹ year⁻¹, with an estimated R² of in between 0.21 and 0.57 (Jong
714 et al., 1999; Vigiak et al., 2005; López-Vicente et al., 2008; Vieira et al., 2014; Choi et al., 2017).
715 However, we acknowledge that previous studies were all conducted in more temperate climate zones.
716 To be able to compare our results with previous studies, we calculated the model performance
717 considering solely the Mediterranean and humid climate zone, which are more similar in climate to the
718 more temperate locations of previous studies. The performance of the model was still high (R² = 0.72,
719 RMSE = 0.45 kg ha⁻¹ year⁻¹), confirming the conclusion that bioturbation increased model performance.
720 We compared the modelled impact of bioturbation on sediment redistribution with the impact of
721 bioturbation estimated in previous studies. In the humid zone, our model predicted an erosion up to 3.5
722 kg m⁻² year⁻¹. This estimation is in line with erosion rates established by in-situ measurements in other
723 studies conducted in a more humid climate zone (between 1.5 kg m⁻² year⁻¹ and 3.7 kg m⁻² year⁻¹) (Black
724 and Montgomery, 1991; Yoo and Mudd, 2008; Yoo et al., 2005; Rutin, 1996). This also confirms the
725 reliability of our approach. Previous authors estimated the impacts using rainfall simulators, erosion pins
726 or splash boards. The measurements were conducted for a time period between 3 months and 3 years
727 and the sites were revisited for each estimation. We do not compare our results with studies which
728 previously applied models to estimate impacts of bioturbation, as, to our knowledge, none of the
729 previous studies integrated vertebrate burrow structures into a soil erosion model and ran the model on
730 a daily basis.

731

732 **5.2 The relevance of bioturbation for sediment redistribution depends on the environmental** 733 **context**

734 On the hillslope catchment scale (1 ha), our study finds that bioturbation increases erosion in semi-arid
735 and Mediterranean zone, accumulation in the arid zone and has no impact within the humid zone (Figure
736 6b). In contrast, bioturbation increases both, erosion, and accumulation, on the plot scale (1 m²) (Figure
737 6a). On this scale, in the arid and semi-arid zone, sediment erosion and accumulation were predicted to
738 be about equal (erosion and accumulation both up to 0.1 kg m⁻² year⁻¹ in the arid zone, and erosion and
739 accumulation both up to 0.2 kg m⁻² year⁻¹ in the semi-arid zone (see Figure 6a)). Bioturbation marginally
740 increased erosion and decreased accumulation in the semi-arid zone but reduced by twofold
741 accumulation in the arid zone. In contrast, in the Mediterranean and humid zone, erosion was predicted
742 to be almost double when compared to accumulation (predicted erosion up to 2.5 kg m⁻² year⁻¹, and
743 accumulation up to 1.4 kg m⁻² year⁻¹). Inclusion of bioturbation increased erosion up to 3 kg m⁻² year⁻¹,
744 and accumulation up to 1.6 kg m⁻² year⁻¹ in the Mediterranean zone, while it had no significant effect in
745 the humid zone. We argue that sediment redistribution due to bioturbation is heavily influenced by meso-
746 topographic structures which determine the flow path of surface runoff and influence the infiltration
747 processes. Due to this, the erosion and accumulation on the plots scale is heavier impacted by
748 bioturbation with increasing surface runoff.

749 Our study found an increase of erosion in the semi-arid and Mediterranean climate zone to be between
750 6.5 % and 15.6 % due to bioturbation. Previous studies found that already a small increase of erosion
751 has significant impacts on the whole hillslope catchment. A 10% increase in erosion rates over a 10-

752 year period can lead to significant changes in the landscape, including e.g. a 20-30% reduction in soil
753 thickness and an increase in sediment transport in nearby rivers (Kuhn 2016).

754 According to our analysis, bioturbation increases erosion or accumulation of sediment mostly based on
755 an interplay between topographic structures elevation, slope and TRI (Figure 10). Over all research
756 sites, this study found that bioturbation leads to an increase in surface erosion in areas where erosional
757 processes dominate (upper, and/or steeper slopes), and tends to increase sediment accumulation in
758 areas where sediment is naturally deposited, e.g. lower slopes or shallow depressions (Figure 10). This
759 finding is based on the fact that erosion in general is positively affected by slope, and negatively by
760 surface roughness and vegetation (Rodríguez-Caballero et al., 2012; Wang et al., 2013; Kirols et al.,
761 2015). Additionally, the redistribution of sediment is largely affected by topographic meso-/macroforms,
762 such as rills or cliffs. These can be quantified by topographic ruggedness index (TRI) which describes
763 the amount of elevation drop between adjacent cells of DEM (Wilson et al., 2007). At high values of this
764 index, we would therefore expect high erosion rate, due to concentrated runoff within the connected rills
765 or undisturbed flow of runoff from the cliffs downslope.

766 Our data show that one burrow provides up to 0.43 m³ of additional loose sediment at the surface (Table
767 2), while the surface roughness increases up to 200 % (Grigusova et al., 2022). When including burrows
768 into the model, at the slope values from 0 to 5 degrees, the presence of burrows had no impact on
769 sediment redistribution. From 5 degrees onwards it increased sediment erosion proportionally to the
770 slope of the hillside (an increased erosion from 0.4 g ha⁻¹ year⁻¹ in the semi-arid zone until up to 150 kg
771 ha⁻¹ year⁻¹ in the Mediterranean zone, Fig. A3 – A6). Similarly, at locations with elevation drops ranging
772 from 0 m until 0.2 m (lower TRI values), the presence of burrows had no impact. However, at locations
773 with elevation drops of 0.2 until 0.5 m (higher TRI values), bioturbation increases sediment erosion by
774 1.5 kg ha⁻¹ year⁻¹ (Fig. A3 – A8). Lastly, bioturbation proportionally increased accumulation when the
775 surface roughness values were above 0.5 (an increased accumulation from 0.2 g ha⁻¹ year⁻¹ in semi-arid
776 zone until 5000 kg ha⁻¹ year⁻¹ in the Mediterranean zone, Fig. A3 – A6).

777 We conclude that in locations with slope values over 5 degrees, or at locations with sudden drops in
778 elevation (high TRI), and connected rills, more sediment is eroding than accumulating. Here, additional
779 surface sediments generated by bioturbators provides more source material for erosion and thus
780 bioturbation increases sediment erosion at these locations (Figure 10 and 11). In contrast, at locations
781 with a slope below 5 degrees, where processes are dominantly controlled by surface roughness,
782 sediment accumulation caused by bioturbation increases proportionally when the surface roughness
783 has a value above 0.5. This is likely because burrows through their above-ground structures heavily
784 increase surface roughness (Grigusova et al., 2022), and hence the presence of bioturbating animals
785 leads to an increase in sediment accumulation.

786 Additionally, we hypothesize that it is not only the additional availability of sediment on the surface and
787 the topography of the vicinity which controls the contribution of bioturbation to sediment surface flux, but
788 also the spatial distribution of animal burrows. We interpret that in locations with high burrow
789 aggregation, surface flow might be redirected and centralized around the aggregates and thus increase
790 sediment erosion in the areas adjacent burrow aggregates (Figure 11). This mechanism could explain
791 why bioturbation promotes sediment erosion especially in the Mediterranean zone where burrows are

792 more aggregated. The relative role of burrow aggregation should be studied in detail and included in
 793 future studies.
 794

795

800
 801
 802 **6. Conclusion**

803 Our study found that the inclusion of vertebrate bioturbators' burrows into a soil erosion model
 804 significantly increases its reliability. Vertebrate bioturbators increase sediment accumulation in the arid
 805 climate zone, sediment erosion in the semi-arid and Mediterranean zone and have no impact on
 806 sediment redistribution in the humid. Our study furthermore shows that the impact of bioturbation heavily
 807 depends on the adjacent environmental parameters. The burrows increase sediment erosion at high
 808 and low values of elevation, at high values of slope, sink connectivity and topography ruggedness, and
 809 at low values of vegetation cover. The burrows increase accumulation at high values of surface
 810 roughness and soil wetness. This means that overall, on geological time scales, as burrowing animals
 811 increase both, erosion in steeper zones, and accumulation in areas with gentler slopes and higher
 812 roughness, hillslope relief should become faster equalised and overall, more flat. This tendency is most
 813 pronounced in the Mediterranean zone with high burrow density and excavation rates, as well as
 814 comparably high precipitation rates.

841 **Table A2.** Model sensitivity analysis. For the analysis, the minimum, maximum and mean value of each
842 parameter was calculated. The model was run for a hillslope catchment of 1km² with homogenous mean
843 parameters. Then, the minimum and maximum values of each parameter were tested. Each parameter
844 was stepwise changed to its minimum or maximum value while the remaining parameters stayed
845 homogenous. The significance of the parameter was estimated by a t-test conducted between the

846 erosion estimated by the model with homogenous mean parameters and the erosion estimated by the
 847 model with varying minimum and maximum parameter values. Only significant parameters are shown.

Parameter	mean value	min value	max value	mean erosion [kg m ⁻¹]	Min erosion [kg m ⁻¹]	Max erosion [kg m ⁻¹]	Erosion [kg m ⁻¹]
