42 **Abstract**

43 Soil bioturbation activity affects soil texture, bulk density, soil water content and redistribution of
44 nutrients. All of these parameters influences sediment redistribution, which shapes the earth surface.
45 Hence it is important to include bioturbation into erosion models. However, up to present, the inclusion
46 of bioturbation into erosion models was limited. This is because to realistically include bioturbation into
47 the modelling, the interplay between bioturbation, sediment redistribution and environmental parameters
48 is not understood.

49 Here, we included bioturbation into a soil erosion model and interpreted the impacts of bioturbation on
50 sediment redistribution. To do this, we measured the needed soil properties and location of burrows
51 created by bioturbating animals in four research sites located along the Chilean climate gradient. Then,
52 we parametrized a semi-empirical erosion model by applying machine learning algorithms to upscale
53 soil properties and burrow distribution. We ran the model for a time period of 6 years under two
54 conditions: With and without bioturbation. We validated the model using several sediment fences in the
55 field. We estimated the modelled sediment redistribution and surface runoff in all climate zones. Lastly,
56 we identified environmental parameters determining the positive or negative impact of bioturbation on
57 sediment redistribution.

58 We found that the model with integrated bioturbation performed much better ($R^2 = 0.71$, $RMSE = 0.63$)
59 than the model without integrated bioturbation ($R^2 = 0.17$, $RMSE = 1.18$), meaning that model runs which
60 considered bioturbation predicted the sediment redistribution more realistically. Furthermore,
61 bioturbation increased sediment redistribution in all but the humid climate zone, especially in the
62 Mediterranean zone. The quantity of sediment redistributed due to bioturbation was reliant on an
63 interplay between elevation, slope, surface roughness and sink connectivity. Overall, bioturbation
64 enhances sediment erosion in areas where more erosion is expected, and enhances sediment
65 accumulation in areas which are more prone to accumulate sediment. In other words, considering
66 bioturbation when studying earth surface evolution means an amplification of existing tendencies in
67 sediment redistribution, and leads to a faster hillslope relief equalisation.

83 **1. Introduction**

84 Bioturbation was shown to shape the land surface (Hazelhoff et al., 1981; Istanbuluoglu, 2005; Taylor
85 et al., 2019; Tucker and Hancock, 2010; Whitesides and Butler, 2016; Wilkinson et al., 2009; Corenblit
86 et al., 2021) by influencing surface microtopography (Reichman and Seabloom, 2002; Kinlaw and
87 Grasmueck, 2012; Debruyn and Conacher, 1994), and soil properties such as soil porosity, permeability
88 and infiltration (Reichman and Seabloom, 2002; Yair, 1995; Hancock and Lowry, 2021; Ridd, 1996; Hall
89 et al., 1999; Coombes, 2016; Larsen et al., 2021). Cumulatively, these modifications lead to changes in
90 sediment redistribution (Gabet et al., 2003; Nkem et al., 2000; Wilkinson et al., 2009) and hence have
91 the potential to affect surface topography and nutrient redistribution on large spatial and temporal scale.
92 To quantify these effects, the shared role of climate, landscape characteristics and burrowing dynamics
93 on sediment redistribution needs to be understood.

94 On a local scale, currently used field methods to monitor sediment redistribution under real-life condition
95 are mainly erosion pins, splash boards, or rainfall simulators (Imeson and Kwaad, 1976; Wei et al., 2007;
96 Le Hir et al., 2007; Li et al., 2019a; Li et al., 2019b; Li et al., 2018; Voiculescu et al., 2019; Chen et al.,
97 2021; Übernickel et al., 2021a). The monitoring of box experiments yields a high spatio-temporal
98 resolution, and can also be linked with mathematical equations, such as random walks (Boudreau, 1986;
99 Wheatcroft et al., 1990), stochastic differential equations (Boudreau, 1989; Milstead et al., 2007), finite
100 difference mass balancing (Soetaert et al., 1996; François et al., 1997) or Markov chain theory (Jumars
101 et al., 1981; Foster, 1985; Trauth, 1998; Shull, 2001) to describe sediment redistribution. Another
102 approach offer raster-based soil erosion and landscape evolution models which integrate co-
103 dependencies between bioturbation relevant environmental parameters (Black and Montgomery, 1991;
104 Meysman et al., 2003; Yoo et al., 2005; Schiffers et al., 2011). Most common soil erosion models are
105 empirical (Wischmeier and Smith, 1978; Williams, 1975; Renard et al., 1991), process-based (Morgan
106 et al., 1998; ROO et al., 1996; Nearing et al., 1989; Beasley et al., 1980), or semi-empirical models, the
107 latter of which are a combination of both (Morgan et al., 1984; BEVEN and KIRKBY, 1979). Empirical
108 models are limited to one study site, but they provide highly accurate predictions at low computational
109 costs, as they are based on simple mathematical equations. In contrast, process-based models require
110 an intensive parametrisation and calibration process, however, once calibrated, they can be applied to
111 almost any site (Lal, 2001; Merritt et al., 2003). Semi-empirical models combine semi-empirical
112 equations with a physical basis and thus include the advantages of the both model types (Morgan et al.,
113 1984; Morgan, 2001; Morgan and Duzant, 2008; Devia et al., 2015; Lilhare et al., 2015).

114 Previously used methods have, however, several limitations when studying bioturbation. Field
115 measurements likely lead to an underestimation of sediment fluxes, as they are one-time or seasonal
116 measurements, and thus do not capture the continuous excavation of the sediment by the animal
117 (Grigusova et al., 2022) at a high temporal resolution. Box experiments and from them derived
118 mathematical equations describe bioturbation as an isolated process and ignore surrounding
119 environmental parameters (such as climate or vegetation). Most erosion or landscape evolution models
120 do not yet implement impacts of bioturbators on water and sediment fluxes (Brosens et al., 2020;
121 Anderson et al., 2019; Braun et al., 2016; Cohen et al., 2015; Cohen et al., 2010; Carretier et al., 2014;
122 Welivitiya et al., 2019). Models which include bioturbation as an input factor still have large limitations.
123 They predict landscape evolution on a millennial scale, but ignore processes acting on a daily basis.

124 This rather large spatio-temporal scale also means an omission of the natural variability in burrow sizes
125 and densities, climate zones and seasonality (Temme and Vanwallegghem, 2016; Vanwallegghem et al.,
126 2013; Yoo and Mudd, 2008; Pelletier et al., 2013). The most significant limitation is, however, that in all
127 models bioturbation is hard-coded to have predefined effects on the environment: (i) soil erosion is
128 proportionally increasing with increasing bioturbation, (ii) vertical soil mixing rates are uniform, and (iii)
129 bioturbation is positively linked with vegetation cover. Thus, none of these models consider that the
130 interaction of bioturbation with environmental parameters and the effect on sediment redistribution may
131 not be uniform but context dependent. However, the field measurements showed both, positive
132 (Hazelhoff et al., 1981; Black and Montgomery, 1991; Chen et al., 2021) and negative impact of
133 bioturbation on erosion (Imeson and Kwaad, 1976; Hakonson, 1999). Also, previous field based studies
134 observed an increased bioturbation activity with higher (Milstead et al., 2007; Meserve, 1981; Tews et
135 al., 2004; Wu et al., 2021; Ferro and Barquez, 2009), but also with lower vegetation cover (Simonetti,
136 1989; Zhang et al., 2020; Zhang et al., 2019; Qin et al., 2021). Furthermore, soil mixing rates are not
137 homogenous throughout the year but depend on the animal phenological cycles (Eccard and Herde,
138 2013; Jimenez et al., 1992; Katzman et al., 2018; Malizia, 1998; Morgan and Duzant, 2008; Monteverde
139 and Piudo, 2011; Gray et al., 2020; Yu et al., 2017).

140 To improve this, bioturbation has to be included into erosion models at a high spatial and temporal
141 resolution under real-life conditions across several climate zones. A suitable model which can be
142 extended to include continuous bioturbating activity is the semi-empirical Morgan – Morgan – Finney
143 soil erosion model (Morgan et al., 1984; Morgan, 2001). This model was successfully tested in several
144 climate zones and land use types, such as Mediterranean sites (Jong et al., 1999), rainfed agrosystems,
145 fields and pastures (López-Vicente et al., 2008), East-African Highlands (Vigiak et al., 2005) or humid
146 forests (Vieira et al., 2014). One of the recently developed improvements of this model is the Daily
147 Morgan – Morgan – Finney model (DMMF), which introduces subsurface flow, vegetation structures
148 (type, size, height, root depth), and enables modelling at a high spatial (0.5 m) and temporal (daily)
149 resolution (Choi et al., 2017). These improvements yield the potential to integrate the bioturbation into
150 the model, as the burrowing activity is not constant and depends on vegetation structure (Tews et al.,
151 2004; Ferro and Barquez, 2009).

152 To study the interplay between bioturbation, environmental parameters and sediment redistribution
153 along a climate gradient, we (i) include bioturbation into a semi-empirical soil erosion model (DMMF) at
154 a high temporal and spatial resolution. We specifically not presuppose a homogenous relationship
155 between bioturbation, sediment transport and vegetation cover. Based on (i), we (ii) identify
156 environmental parameters which determine if the bioturbation enhances sediment erosion or sediment
157 accumulation. In order to do this, we included bioturbation into the DMMF while considering (i) variable
158 co-dependency between bioturbation and vegetation type, density and height; (ii) various burrow sizes
159 and burrow densities, (iii) variable soil mixing rates due to continuous reconstruction of the burrow by
160 the animal depending on season and (iv) variable influence of bioturbation on litter and coarse grain
161 size. Furthermore, we set up generalized additive models to unveil significant environmental parameters
162 that determine the impact of bioturbation on sediment redistribution. Lastly, we analyse how the impact
163 of bioturbation on sediment redistribution depends on the burrow structure, climate, topography and

164 surrounding vegetation. Our study shows the importance of including bioturbation into erosion modelling
165 and the interplay between bioturbation, environmental parameters and sediment redistribution.
166

167 2. Study area

168 Our study was performed along a climate and vegetation gradient in Chile (Übernickel et al., 2021b),
169 comprising four study sites in the Chilean Coastal Cordillera: Pan de Azúcar (PdA) National Park (NP),
170 Santa Gracia (SG), La Campana (LC) NP, and Nahuelbuta (NA) NP (Fig. 1). PdA NP is located in the
171 arid zone in a fog-laden environment in the southern part of the Atacama Desert, with almost no rainfall.
172 The vegetation cover is less than 5 % and dominated by small desert shrubs, several types of cacti and
173 biocrusts (Lehnert et al., 2018). SG is a natural reserve located in the semi-arid zone near La Serena,
174 which is dominated by goat grazing. The vegetation consists of shrubs and cacti, covering up to 40 %
175 of the study area. LC NP is part of the Mediterranean-type climate zone in the Valparaíso Region and is
176 also affected by cattle. The study site is dominated by an evergreen sclerophyllous forest with endemic
177 palms. The canopy reaches a height of up to 9 m, and the understory consists of deciduous shrubs and
178 herbs. NA is located in the humid-temperate zone and characterized by a dense evergreen *Araucaria*
179 forest comprising broadleaved trees with heights of up to 14 m. The ground is covered by bamboo,
180 shrubs, and herbs (Bernhard et al., 2018; Oeser et al., 2018). The most common bioturbating vertebrate
181 animal species recorded within these sites are carnivores of the family Canidae (*Lycalopex culpaeus*,
182 *Lycalopex griseus*) as well as rodents of the families Abrocomidae (*Abrocoma bennetti*), Chnichillidae
183 (*Lagidium viscacia*), Cricetidae (*Abrothrix andinus*, *Phyllotis xanthopygus*, *Phyllotis limatus*, *Phyllotis*
184 *darwini*) and Octogontidae (Cerqueira, 1985; Jimenez et al., 1992; Übernickel et al., 2021a).
185

186
187 **Figure 1.** Study area and study sites. Black lines outline the catchments. Along the blue lines, the in situ
188 data (mound locations, soil samples, vegetation mapping) were collected. (a) Position of the study sites
189 along the climate gradient. PdA = Pan de Azúcar, SG = Santa Gracia, LC = La Campana, NA =
190 Nahuelbuta; Positions of plots in (b) PdA; (c) SG; (d) LC; and (e) NA. The background image is an RGB-

191 composite calculated from WorldView-2 satellite imagery. Images were obtained with single license from
 192 GAF AG.

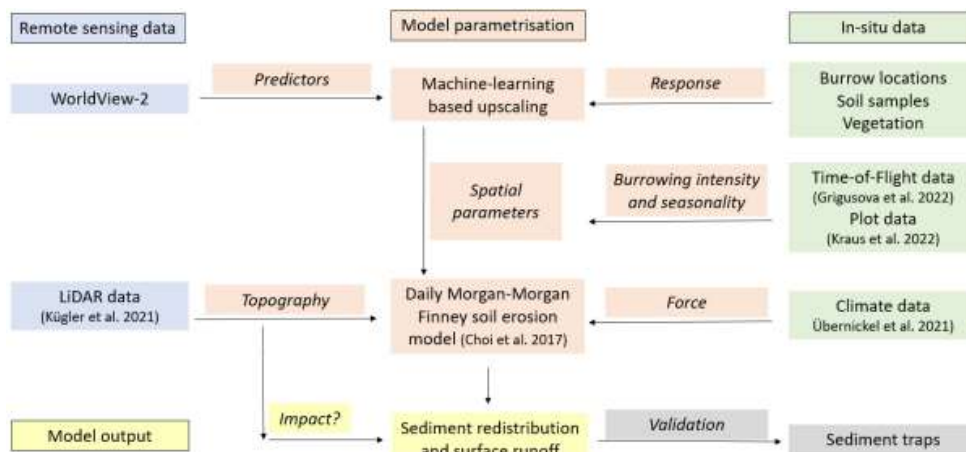

193

194 **3. Methodology**

195 We combined semi-empirical soil erosion modelling with in-situ measurements, remote sensing data
 196 and machine learning methods (Fig. 2). Along 8 catchments within 4 climate zones we mapped locations
 197 of burrows, estimated the vegetation cover and extracted soil samples. We analyzed the soil samples
 198 in the laboratory. Then we used remote sensing datasets and machine learning to upscale burrow
 199 distribution, vegetation cover and soil properties into the catchments. The catchment-wide predictions,
 200 the topographical information retrieved from LiDAR data (Kügler et al., 2022) and the climate information
 201 retrieved from climate stations were the input parameters for our soil erosion model. We ran the model
 202 with and without bioturbation. We included the bioturbation into the model by adjusting the input
 203 parameters at the predicted burrow locations, by including the continuous burrowing activity and soil
 204 mixing (Grigusova et al., 2021), and the seasonality (Kraus et al., 2022).and the animal phenological
 205 cycle as found in (Jimenez et al., 1992). The models were validated using self-constructed sediment
 206 traps. We studied the modeled surface runoff and sediment redistribution. Lastly, we analyzed if and
 207 how the impact of bioturbation on sediment redistribution depends on environmental parameters
 208 (topography, landscape connectivity and vegetation).

209

210

211

212 **Figure 2.** Flow chart of our study. Green color indicates in-situ input data, blue indicates remote sensing
 213 input data. Red indicates Model parametrization. Yellow indicates model output and analysis. Grey
 214 indicates model validation.

215

216 **3.1 In-situ data**

217 The study set-up consisted of eight hillside catchments: one north-facing and one south-facing hillside
 218 catchment per study site. We defined a line with a width of one meter from the top to the base of each

219 hillside catchment (see blue line, Fig. 1). We subdivided the track into tiles of 1 m². We saved the GPS
220 information of each tile.
221 Within each tile of the line, we mapped burrow presence, land cover and extracted soil samples. A
222 burrow consisted of an entrance and a mound (Fig. 3a). Each 1 m² tile with a burrow was described as
223 a presence data point, tiles without a burrow as absence data points. We noted the size of the burrow,
224 vegetation cover and land cover types (bare soil, herbs, shrubs, trees) within the tile. We extracted 162
225 soil samples from soil without a mound at a depth of 10 cm. Additionally, we took a photo of the surface
226 every second tile along the track.
227 To validate the model output, we set up sediment traps (Fig. 3b), with six traps per site, two of which
228 were located at the catchment base and four were located on two random positions within the catchment.
229 The sediment traps consisted of geotextile vertically attached to wooden poles for stability. The traps
230 had a length of 2 m – 5 m, a width of ~1.5 m and a height of ~1 m. 1.5 m of geotextile was laid down at
231 the surface uphill the wooden poles to enable the collection of sediment. The sediment accumulated
232 within the traps was collected after 1 year and its mass [cm³] and dry weight [kg] were estimated.
233 Climate information was retrieved from climate stations located adjacent to the catchments which
234 provide climate data in 5 minute intervals (Übernickel et al. 2021). To force the model on an hourly basis,
235 hourly air temperature, precipitation total and intensity, wind speed, wind direction and humidity was
236 calculated for the study period from 1st April 2016 to 1st December 2021. Evapotranspiration was
237 estimated by the Penman-Monteith equation (Penman, 1948).
238

239
240 **Figure 3.** In-situ constructions. (a) Example of a burrow consisting of burrow entrance and mound. (b)
241 Fence construction used for the collection of eroded sediment to validate the model. Both photos by
242 Paulina Grigusova.
243

244 3.2 Estimation of soil properties

245 We estimated several soil properties from the soil samples and photos collected in-situ ((Grigusova et
246 al., 2022). We estimated above-ground skeleton and debris from the photos taken every second tile.
247 For this, the photos were firstly classified into 5 classes. The classification was unsupervised using k-
248 means (Fig. A1). Then we calculated the ratio of pixels classified as skeleton and / or debris to the
249 overall amount of all pixels to determine the amount of both parameters in percent.

250 In the lab, we estimated soil water content, bulk density, soil particle density, soil texture (sand, silt, clay,
251 coarse / middle / fine sand, coarse / middle / fine silt), soil skeleton, organic matter and organic carbon.
252 Gravimetric soil water content [%] (GSWC) described the mass of water within the soil sample and was
253 estimated as in Eq (1):

$$254 \quad GSWC = \frac{(S_m - S_d)}{S_d} * 100 \quad , \quad (1)$$

255 where S_m [g] is the mass of moist soil measured directly after the extraction and S_d [g] is the mass of
256 soil dried at 105 °C for at least 24 hours. Bulk density [$g\ cm^{-3}$] (BD) was calculated as following:

$$257 \quad BD = \frac{S_d}{S_v} \quad , \quad (2)$$

258 where S_v [cm^{-3}] is the volume of the sample. Soil particle density [$g\ cm^{-3}$] (SPD) was calculated as in Eq
259 (3):

$$260 \quad SPD = \frac{dm}{S_v} \quad , \quad (3)$$

261 where dm [g] is the dry mass of soil particles.

262 Particle size distribution [%] – clay (< 0.002 mm), coarse, middle and fine silt (0.002 mm to 0.02 mm),
263 and coarse, middle and fine sand (0.02 mm to 2 mm) was estimated using a PARIO method (Durner et
264 al., 2017). Soil skeleton was estimated as the ratio of particles with a diameter above 2 mm. Ratio of
265 organic matter (OM) was estimated as in Eq. (4)

$$266 \quad OM = \frac{S_c}{S_d} \quad , \quad (4)$$

267 where S_c is the weight [g] of the sample dried at 500 °C for 16 hours.

268 We used pedotransfer functions to determine porosity, saturated soil moisture, hydraulic conductivity,
269 water content at field capacity, and permanent wilting point. Pore ratio (θ_s) was estimated from bulk and
270 particle density as in Eq. (5):

$$271 \quad \theta_s = \frac{BD}{SPD} \quad (5)$$

272 Saturated water content [$g\ g^{-1}$] (W_s) was estimated as in Eq. (6):

$$273 \quad W_s = \theta_s \frac{p_w}{BD} \quad , \quad (6)$$

274 where p_w [$g\ cm^{-3}$] is the density of water which is set to be 1 $g\ cm^{-3}$ (Pollacco, 2008).

275 Hydraulic conductivity K_s [$m\ s^{-1}$] was estimated as in Eq. (8):

$$276 \quad K_s = 1.15741 * 0.0000001 * \exp(x) \quad , \quad (7)$$

277 where x for sandy soil is:

$$278 \quad x = 9.5 - 1.471 * (BD * BD) - 0.688 * OM + 0.0369 * (OM * OM) - 0.332 * CS \quad , \quad (8)$$

279 and x for loamy and clayey soils is:

$$280 \quad x = -43.1 + 64.8 * BD - 22.21 * (BD * BD) + 7.02 * OM - 0.1562 * (OM * OM) + 0.985 * \ln(OM) - \\ 281 \quad 0.01332 * C * OM - 4.71 * BD * CS \quad , \quad (9)$$

282 where C is percentage of clay and CS is percentage of clay and silt (Wösten, 1997). To estimate water
283 content at field capacity [%] (FC) and permanent wilting point (PWP), we applied functions by (Tomasella
284 et al., 2000) as these were developed for South American soils:

$$285 \quad FC = 4.046 + 0.426 * Si + 0.404 * C \quad , \quad (10)$$

$$286 \quad PWP = 0.91 + 0.15 * Si + 0.396 * C \quad , \quad (11)$$

287 where Si is the percentage of silt.

288

289 **3.3 Processing of remote sensing data**

290 The digital elevation models (DEM) were calculated from the LiDAR data (Kügler et al., 2022; Horn,
291 1981) at a resolution of 0.5 m. Slope was calculated according to Horn (1981). Manning's surface
292 roughness coefficient was estimated following (Li and Zhang, 2001). Topographic position index (TPI)
293 and Topographic ruggedness index were calculated according to (Wilson et al., 2007). Plan and profile
294 curvature were determined after (Zevenbergen and Thorne, 1987). Connectivity indices, Sinks, Wetness
295 index, Flow direction, Flow path, Catchment slope and Catchment were calculated in SAGA GIS.
296 Single license stereo WorldView-2 images with a resolution of 0.5 m were retrieved from GAF Munich
297 GmbH. The topographic correction of WorldView-2 images was done using the LiDAR data, solar
298 elevation angle, solar zenith angle and azimuth angle according to Goslee (2019). The digital surface
299 models (DSMs) were calculated from the stereo images. Additionally, we extracted single bands and
300 calculated the normalized difference vegetation index (NDVI).

301

302 **3.4 The erosion model**

303 **3.4.1 Daily Morgan-Morgan-Finney model**

304 The DMMF model is a combined soil erosion model used to estimate surface runoff and sediment flux
305 on a field scale on a daily basis. Spatially, the DMMF model represents an area as several
306 interconnected elements (e.g. pixels) of uniform topography, soil characteristics, land cover type, and
307 vegetation structure. Through coupling, the model operates with flow direction algorithms: each element
308 receives water and sediments from upslope elements and delivers the generated surface runoff and
309 eroded soils to downslope elements. On a temporal scale, the model estimates surface runoff and
310 sediment flux of each element on a daily basis. The model input parameters include climate, topography,
311 soil properties and land cover information (Choi et al., 2017). Data pre-processing, modelling and
312 analysis (see Fig. 2) was done in R statistic environment. The raster data were cropped to the size of
313 the catchments (Fig. 1). Input parameters are listed in Table 1 and plotted in Fig. A2.

314

315 **3.4.2 Estimation of spatial parameters**

316 For spatial parameterization of the DMMF model, we upscaled land cover, soil properties and burrow
317 distribution onto the catchments using machine learning techniques. For each parameter, we trained
318 one random forest (RF) model per site. The upscaling was done at 0.5 m spatial resolution. We used
319 the WorldView-2 layers, NDVI, DEM, DSM, slope and roughness as predictors while the response data
320 were the parameters which we measured in-situ (soil properties, vegetation, burrow locations). The most
321 important predictors were selected by forward feature selection. The quality of the random forest models
322 was assessed by Leave-Location-Out cross validation. We trained the model stepwise, using in-situ
323 data collected from seven of the catchments and validated the model using in-situ data from the
324 remaining catchment (Meyer et al., 2018).

325 For the area-wide upscaling of burrow locations across the catchments, we used the burrow presence
326 and absence data (section 3.1) as the response data within the RF models. The accuracy was 0.82 for
327 PdA, 0.77 for SG, 0.75 for LC and 0.85 for NA.

328 The upscaling of soil properties was done using soil properties estimated along the track line (see
329 section 3.1) as response data within the RF models. All of the models reached a high accuracy (Table
330 A1).

331 To upscale the vegetation cover and type, we used as the response within the RF models the land cover
332 measured in-situ. The classes were soil without rocks, rocks, biocrusts, grass/herbs, shrubs and trees.
333 Predictor values for each class were extracted from at least 100 polygons per site and class. The
334 accuracy of the RF models was 0.71 for PdA, 0.81 for SG, 0.83 for LC and 0.75 for NA. The vegetation
335 height measured in plots was averaged for each class per site. All pixels classified as respective class
336 were assigned the same vegetation height information. Vegetation density was estimated per catchment
337 as the amount of vegetation individuals per m². Vegetation diversity was calculated by Shannon index
338 (Shannon, 1948). The interception area was the area not covered by vegetation (herbs, shrubs or trees).

339

340 **3.4.3 Inclusion of bioturbation**

341 In the grid cells with predicted burrow locations, we adapted the values of input parameters to include
342 bioturbation. The adaptations varied with climate zone and burrow size. The size, geometric structure
343 and excavation rates of burrowing animals were previously estimated at a high spatial and temporal
344 resolution (Grigusova et al., 2022). Based on this results, we firstly adjusted the microtopography. We
345 modified the layer depth to represent burrow entrance and elevation to represent animal mound. Mounds
346 were always located downslope of burrow entrances in the direction of flow.

347 Secondly, we adjusted the soil properties. Soil properties texture and organic carbon were estimated
348 from soil extracted from mounds in Kraus et al. (in review). In this study we additionally estimated bulk
349 density, initial water content, soil skeleton, porosity, saturated water content, available water capacity
350 and water content at field capacity from the same dataset (see section 3.2). We calculated the median
351 value of each property for the samples extracted from mounds and for the samples extracted from soil
352 without mounds. Then, we estimated the change in percent between these two values. This was then
353 used to adjust the soil property for each pixel including a mound.

354 Thirdly, modelled mound pixels had to be cleared from ground vegetation cover. For this, we removed
355 ground vegetation cover from pixels with burrow locations and decreased ground vegetation cover,
356 height, diameter and amount of ground vegetation individuals from surrounding pixels as measured in
357 situ. Then, the amount of above-ground skeleton and debris was set as estimated from soil samples
358 (section 3.2)

359 Animal activity has been found to be highly variable throughout the year (Grigusova et al., 2022; Kraus
360 et al., 2022). The density of burrows does not stay stable throughout the year but increases or decreases
361 depending on the season and climate zone. For this, we artificially removed or added burrows into the
362 catchments at the particular seasons. Furthermore, the animals do not burrow at the same pace in the
363 course of the year. There is a 3-month period, during which they are highly active.

364 Lastly, we also included the vertical movement of sediment particles from deeper soil layers to the
365 surface in dependence on climate. The animals were found to reconstruct their burrows after each
366 rainfall event (Grigusova et al., 2022). Corresponding with these findings, we increased the entrance
367 depth and mound height by 30% after each rainfall event.

368

369 **Table 1.** Model input layers and respective changes to layer values at the predicted burrow locations.
 370 Ground vegetation was removed from the respective pixels, while tree canopy was not changed. The
 371 values were estimated as described in 3.5.2. Using the adjusted values, we calculated
 372 Evapotranspiration using Penman-Monteith equation, surface roughness from the elevation layer, and
 373 hydraulic conductivity, water content at field capacity and saturated water content using pedotransfer
 374 functions.

Parameter group	Parameter	Units	Pixel value at burrow locations			
			PdA	SG	LC	NA
Topography	Elevation	m asl	+0.24	+0.23	+0.36	+0.19
	Surface roughness	-	-	-	-	-

375

376 3.5 DMMF model sensitivity test and validation

377 We conducted a sensitivity test to identify the input parameters, which significantly influence the model
 378 output. For this, we estimated the mean, minimum and maximum values of each input parameter. For
 379 this, we first created an artificial catchment of 100 m * 100 m. Then, each pixel received a mean value
 380 of each parameter. We ran the model under these conditions. The model output described: (i) sediment
 381 erosion, (ii) sediment accumulation and (iii) surface runoff. We estimated sediment redistribution by
 382 subtracting the erosion from accumulation for each pixel. Then, we stepwise changed the input
 383 parameter values from their minimum to their maximum values while we did not adjust any other
 384 parameters. To quantify the significance of the input variations, we conducted a t-test (Fig A2). For this,
 385 we compared the amount of redistributed sediment of each model run to the first model run with
 386 homogeneous parameters.

387 For the validation, we ran the model for the time periods between the installation of sediment fences
388 and the collections of sediment. We compared the mass and weight of modelled and collected sediment
389 and estimated R^2 and RMSE. To test the importance of the inclusion of individual bioturbation
390 parameters into the model, we ran the model under 4 conditions: (i) No burrows; (ii) Solely entrances;
391 (iii) Solely mounds; (iv) Entire burrows (entrances and mounds).

392

393 **3.6 Impact of burrows on surface processes**

394 We estimated burrow density, as a ratio of pixels with predicted burrows to all pixels. Additionally, we
395 calculated the ratio of pixels which are part of a burrow aggregation to all pixels which include a burrow.
396 Burrow aggregation describes at least 4 neighboring pixels with predicted burrows. We calculated the
397 amount of excavated sediment as a sum of burrow density and the burrow excavation rate as estimated
398 in Grigusova et al. (2022).

399 To estimate the impact of burrows on sediment redistribution and surface runoff, we ran the DMMF
400 model for the time period from 1st April 2016 until 31st December 2021 for all catchments. We ran the
401 model (i) with no burrows and (ii) with entire burrows. We estimated (i) sediment redistribution
402 (accumulation - erosion) and (ii) surface runoff. We analyzed the redistribution and runoff on the plot (1
403 m²) and catchment (1 ha) scale.

404 Lastly, to analyze under which biotic and abiotic environmental parameters (topography, vegetation
405 cover) the bioturbation enhances sediment erosion or accumulation, we set-up a generalized additive
406 model (GAM) (Wood, 2006). For this, we first subtracted the output of the model with no burrows from
407 the output of the model with entire burrows. Positive pixel values thus meant, bioturbation enhanced
408 sediment accumulation, negative pixel values meant, bioturbation enhanced sediment erosion. We
409 tested following environmental parameters: mound density, vegetation cover, elevation, slope, aspect,
410 TRI, curvature and connectivity and wetness index. The model performance was evaluated by the
411 percentage of explained data variance. We analyzed the impact of environmental parameters within 1-
412 meter and within 10-meter distance from the burrows.

413

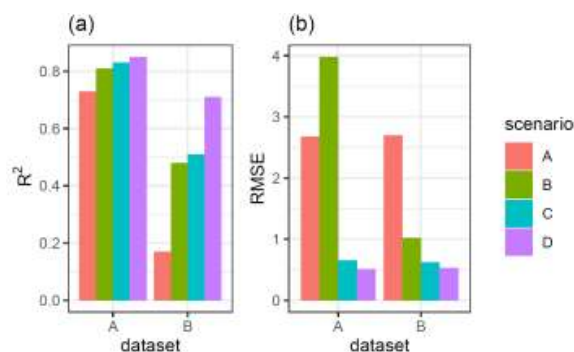

414 **4 Results**

415 **4.1 Model sensitivity test and accuracy**

416 Parameters which significantly influenced the model output were precipitation, slope, vegetation cover,
417 surface roughness, silt content and water content (Table A2). We quantified the model performance by
418 comparing the modelled and measured sediment redistribution. The performance varied depending on
419 the burrow inclusion (Figure 4). The performance of the model without any bioturbation was lower ($R^2 =$
420 0.73 , $RMSE = 1.50$, $MSE = 2.27$), as when burrow entrances ($R^2 = 0.81$, $RMSE = 1.34$, $MSE = 1.16$) or
421 mounds ($R^2 = 0.83$, $RMSE = 1.10$, $MSE = 1.22$) were included. The model had the highest performance
422 when entire burrows were included ($R^2 = 0.85$, $RMSE = 1.01$, $MSE = 1.01$). However, as the scatterplots
423 showed, the model performance seemed to be determined strongly by one measurement (Fig. A3). For
424 this reason, we calculated the metrics without this measurement (Fig. A4). The model without any
425 burrows ($R^2 = 0.17$, $RMSE = 1.18$, $MSE = 1.39$) in this case performed much lower than models with
426 burrows. The model performance continuously strongly increased when burrow entrances ($R^2 = 0.48$,
427 $RMSE = 0.61$, $MSE = 0.78$), mounds ($R^2 = 0.51$, $RMSE = 0.75$, $MSE = 0.57$) were included. The model

428 with whole burrows reached the highest performance ($R^2 = 0.71$, RMSE = 0.63, MSE = 0.39). When we
429 compare the modelled redistribution to the sediment redistribution estimated by Time-of-Flight cameras
430 in Grigusova et al. (2022), then the differences are minor ($R^2 = 0.62$, RMSE = 0.12, MSE = 0.35).
431

432
433 **Figure 4.** R^2 and RMSE of the Morgan-Morgan-Finney soil erosion model. For dataset A, we compared
434 the amount of sediment collected in all sediment fences with the modelled eroded sediment (see Fig.
435 A3). For dataset B, we removed one measurement, as the R^2 seemed to be defined by this
436 measurement (see Fig. A4). For Scenario A, we did not include any burrows into the model. For scenario
437 B, we included burrow entrances and for scenario C, we included mounds. For scenario D, we included
438 whole burrows into the model. The adjustments made to include entrances, mounds and burrows into
439 the model are described in section 3.5.2.

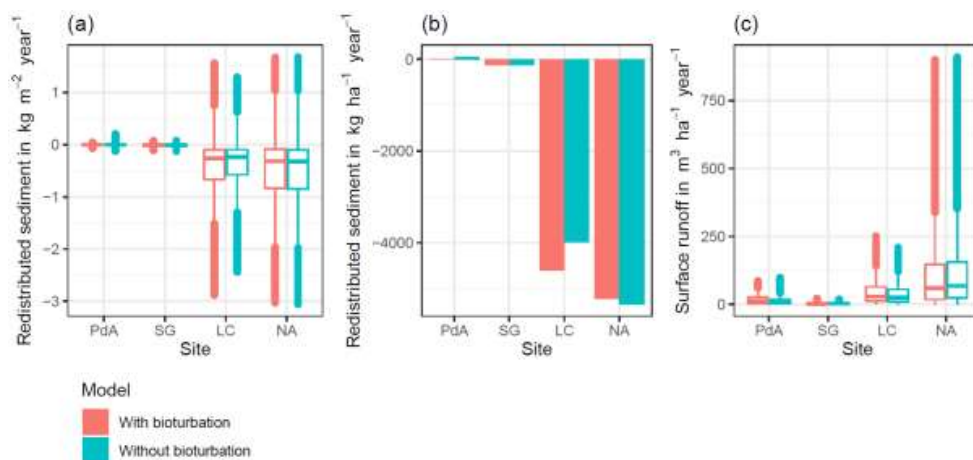

440

441 **4.2 Model output: Surface runoff and sediment redistribution**

442 Catchment – wide sediment redistribution (1 ha resolution) was the highest in humid NA, followed by
443 Mediterranean LC, semi-arid SG and arid PdA (Fig. 5a, 5b, 6). In NA, LC and SG, the erosion processes
444 dominated, while in PdA, more sediment accumulated than eroded. The impact of burrows on sediment
445 redistribution was significant in PdA, SG and LC. Burrows increased sediment erosion by 137.8 % in
446 PdA ($3.53 \text{ kg ha}^{-1} \text{ year}^{-1}$ vs. $48.79 \text{ kg ha}^{-1} \text{ year}^{-1}$), by 6.5 % in SG ($129.16 \text{ kg ha}^{-1} \text{ year}^{-1}$ vs. $122.05 \text{ kg ha}^{-1}$
447 year^{-1}) and by 15.6 % in LC ($4602.69 \text{ kg ha}^{-1} \text{ year}^{-1}$ vs. $3980.96 \text{ kg ha}^{-1} \text{ year}^{-1}$).

448 Surface runoff was the highest in humid NA, followed by Mediterranean LC, arid PdA and semi-arid SG
449 (Figure 5c). The impact of burrows on surface runoff was significant in all climate zones. Burrows
450 increased surface runoff in PdA by 34 %, in SG by 40% and in LC by 4.1 %; and decreased surface
451 runoff by 5.9 % in NA. Catchment-wide maps are shown in Fig. A6-A8.

452

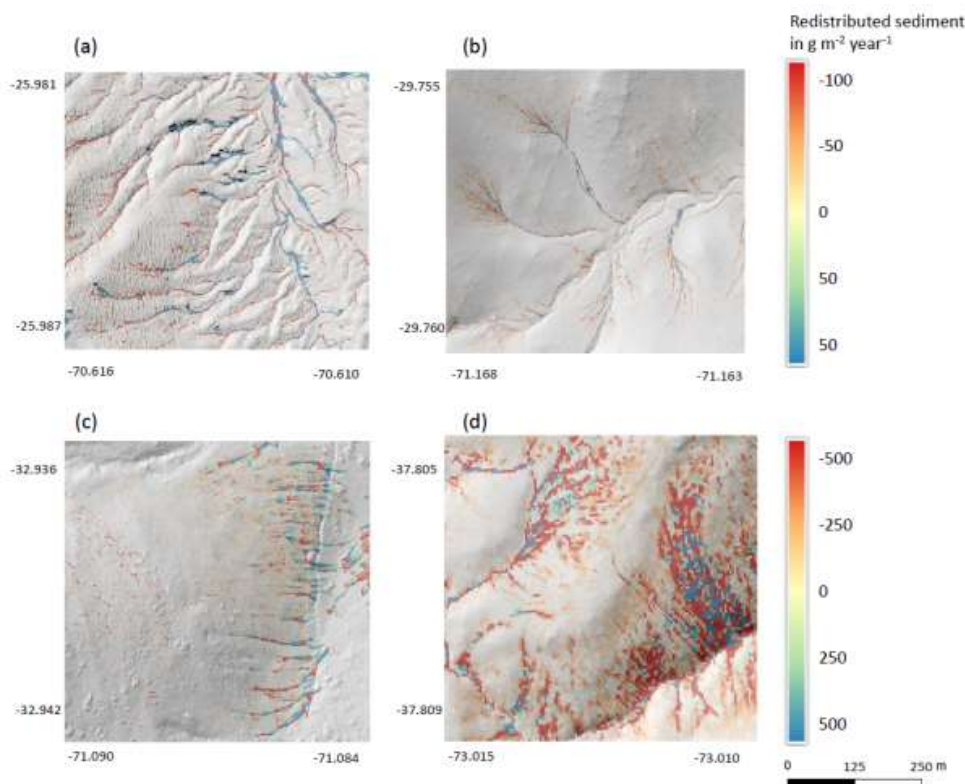

453

454

455 **Figure 5.** Summary of model outputs across the climate gradient. (a) and (b) Modelled sediment
456 redistribution. Positive values indicate sediment accumulation; negative values indicate sediment
457 erosion. (a) Sediment redistribution on a pixel scale in kg m⁻² year⁻¹. (b) Sediment redistribution on the
458 catchment scale in kg ha⁻¹ year⁻¹. The impact of bioturbation on sediment redistribution was estimated
459 by a t-test and was significant in PdA^{***}, SG^{**} and LC^{***}. Bioturbation increased sediment erosion by
460 137.8 % in PdA, by 6.5 % in SG and by 15.6 % in LC. For catchment-wide maps see Fig. A6-A8). (c)
461 Modelled surface runoff on the catchment scale in m³ ha⁻¹ year⁻¹. Impact of bioturbation on surface runoff
462 was estimated by a t-test and was significant at all sites. Bioturbation increased surface runoff in PdA
463 by 34 %, in SG by 40 % and in LC by 4.1 %; and decreased surface runoff by 5.9 % in NA. For catchment-
464 wide maps see Fig. A6.

465

466

467 **Figure 6.** Catchment-wide predicted sediment redistribution. Colours indicate sediment redistribution.
468 Positive values indicate sediment accumulation; negative values indicate sediment erosion. Grey
469 shadows indicate the hill shading calculated from LiDAR data. (a) Pan de Azúcar, (b) Santa Gracia, (c)
470 La Campana, (d) Nahuelbuta.

471

472 **4.3 Role of continuous burrowing activity on sediment redistribution**

473 We included the excavation of the sediment by the animal itself into the model. The density of burrows
474 was the highest in PdA, then LC, SG and the lowest in NA (Table 2). The burrow aggregations were
475 most predominant in LC and SG, almost non-existent in NA. The burrows were of largest size in LC,
476 followed by PdA, SG and NA. Similarly, the highest volume of excavated sediment at the beginning of
477 the modelling period was in LC and PdA. After each rainfall event, the animals reconstructed their
478 burrows as described in Grigusova et al. 2022. Due to various number of rainfall events, the volume of
479 excavated sediment during our modelling period was the highest in NA, followed by LC, SG and PdA.
480 However, when the percentage of sediment which was excavated before and during the modelling to
481 the amount of sediment redistributed during rainfall events was 47 % in PdA, 24 % in SG, 33.5 % in LC
482 and 5.6 % in NA.

483

484 **Table 2.** Impact of animal bioturbation activity on overall sediment redistribution on various scales. The
485 bioturbation activity was estimated using Time-of-Flight based cameras in Grigusova et al. 2022. This

486 study showed that animals reconstruct their burrows after each rainfall events. During this process, 10
 487 % of the overall sediment burrow volume is relocated from within the burrow to the surface. We
 488 integrated this process into our model and calculated the percentage of newly excavated sediment by
 489 the animals to the amount of sediment which was redistributed during rainfalls for the period of one year.

Parameter	Units	PdA	SG	LC	NA
Burrow density	ha ⁻¹	91.35	71.50	84.36	13.30
Burrow aggregations	%	24	62	73	5
Burrow size	m ³	0.015	0.012	0.047	0.008
Sediment at the surface at the start of modelling	m ³ ha ⁻¹	1.35	0.88	4.11	0.10
Sediment excavated after each rainfall	m ³ ha ⁻¹	0.07	0.04	0.22	0.01
Number of rainfall events	year ⁻¹	3	7	16	137
Sediment excavated by the animal after the rain	m ³ ha ⁻¹ year ⁻¹	0.21	0.28	3.52	0.69
Sediment redistributed due to rainfall	m ³ ha ⁻¹ year ⁻¹	0.44	1.17	10.51	12.21
Excavated sediment to redistributed sediment	%	47	24	33.5	5.6

490

491 **4.4 Role of surrounding environment**

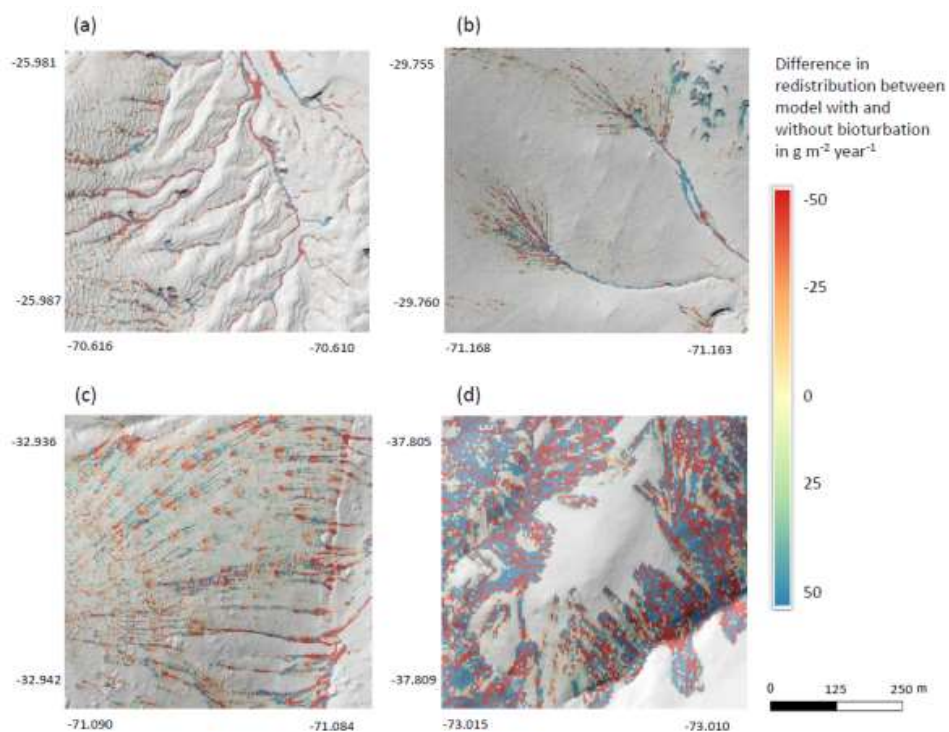

492 We subtracted the output of the model with included burrows from the output of the model without
 493 burrows (Figure A8). Although, the burrows on average enhanced sediment erosion on the catchment
 494 – scale, the high–resolution maps unveiled that burrows enhance sediment erosion within some pixels
 495 while they rather increased sediment accumulation within others.

496 The amount of data variance explained by the GAM models (see section 3.6.) differed between models
 497 (Table A3). Models estimating the impact of environmental parameters on sediment redistribution within
 498 1-meter distance from the burrows, explained 3.84 % of variance in PdA, 37.1 % in SG, 46 % in LC and
 499 42. % in NA. Models estimating the impact of environmental parameters on sediment redistribution
 500 within 10-meter distance from the burrows, explained 1.99 % of variance in PdA, 12.8 % in SG, 52 % in
 501 LC and 72.9 % in NA. The parameters selected for SG were slope, roughness, curvature, TRI and NDVI.
 502 Parameters selected for LC were elevation, slope, NDVI, sinks and roughness. Parameters selected for
 503 NA were elevation, slope, aspect, TRI, sinks and roughness (Table 3).

504 Bioturbation strongly increased sediment redistribution (erosion and accumulation) at high values of
 505 elevation, slope, surface roughness TRI, sinks and topographic wetness index, at the middle values of
 506 elevation and aspect, and at low values of profile curvature and NDVI. From these parameters,
 507 bioturbation increased sediment erosion at high and middle values of elevation, at high values of slope,
 508 sinks and TRI, and at low values of profile curvature. Bioturbation increased sediment accumulation at
 509 high values of surface roughness and topographic wetness index and at low values of NDVI (Fig. A9 –
 510 A14).

511 Bioturbation somewhat enhanced sediment erosion at medium values of surface roughness, NDVI and
 512 sinks, and at low values of topographic wetness index. Bioturbation somewhat increased sediment
 513 accumulation at low values of slope and TRI, at low and medium values of elevation and at high values
 514 of profile curvature.

545

546 **5. Discussion**

547 **5.1 The inclusion of bioturbation increases model performance**

548 Overall, our DMMF model including bioturbation performed much better than the model without
549 bioturbation. The DMMF model without bioturbation performed worse (RMSE of $1.18 \text{ kg ha}^{-1} \text{ year}^{-1}$ and
550 R^2 of 0.17) than the model with bioturbation (RMSE was $0.63 \text{ kg ha}^{-1} \text{ year}^{-1}$ and R^2 was 0.71).

551 We hence argue that the higher accuracy of our model can be explained with the inclusion of
552 bioturbation. This is confirmed by the fact that our model run without bioturbation performed similarly to
553 previously run models without bioturbation: In earlier studies, the accuracy of the MMF model reached
554 an RMSE in between 4.9 and $8.2 \text{ kg ha}^{-1} \text{ year}^{-1}$, with an estimated R^2 of in between 0.21 and 0.57 (Jong
555 et al., 1999; Vigiak et al., 2005; López-Vicente et al., 2008; Vieira et al., 2014; Choi et al., 2017).
556 However, we acknowledge that previous studies were all conducted in more temperate climate zones.
557 To be able to compare our results with previous studies, we calculated the model performance
558 considering solely the Mediterranean and humid climate zone. Here, our model performed better than
559 when we considered all climate zones ($R^2 = 0.72$, $\text{RMSE} = 0.45 \text{ kg ha}^{-1} \text{ year}^{-1}$), confirming the conclusion
560 that bioturbation increased model performance. Additionally, we compared the model output with the
561 values on sediment redistribution estimated in previous studies. Again, these were solely conducted in
562 more humid climate regions. In the humid zone, our model predicted an erosion up to $3.5 \text{ kg m}^{-2} \text{ year}^{-1}$.
563 This estimation is in line with erosion rates due to bioturbation established by in-situ measurements in
564 other studies (between $1.5 \text{ kg m}^{-2} \text{ year}^{-1}$ and $3.7 \text{ kg m}^{-2} \text{ year}^{-1}$) (Black and Montgomery, 1991; Yoo and
565 Mudd, 2008; Yoo et al., 2005; Rutin, 1996). This also confirms the reliability of our approach.

566

567 **5.2 The relevance of bioturbation for sediment redistribution depends on the landscape context**

568 On the catchment scale (1 ha), our study finds that bioturbation increases erosion in all climatic zones
569 except within the humid zone (Figure 5b). In contrast, bioturbation increases both, erosion and
570 accumulation, on the plot scale (1 m²) (Figure 5a). On this scale, in the arid and semi-arid zone, sediment
571 erosion and accumulation were predicted to be about equal ((erosion and accumulation both up to 0.1
572 kg m⁻² year⁻¹ in the arid zone, and erosion and accumulation both up to 0.2 kg m⁻² year⁻¹ in the semi-arid
573 zone (see Figure 5a)). Bioturbation marginally increased erosion and decreased accumulation in the
574 semi-arid zone, but reduced by twofold the accumulation in the arid zone. In contrast, in the
575 Mediterranean and humid zone, erosion was predicted to be almost double when compared to
576 accumulation (predicted erosion up to 2.5 kg m⁻² year⁻¹, and accumulation up to 1.4 kg m⁻² year⁻¹).
577 Inclusion of bioturbation increased erosion up to 3 kg m⁻² year⁻¹, and accumulation up to 1.6 kg m⁻² year⁻¹
578 in the Mediterranean zone, while it had no significant effect in humid zone. We argue that sediment
579 redistribution due to bioturbation is heavily influenced by meso-topographic structures which determine
580 the creation of surface runoff. Due to this, the erosion and accumulation on the plots scale is heavier
581 impacted by bioturbation with increasing surface runoff.

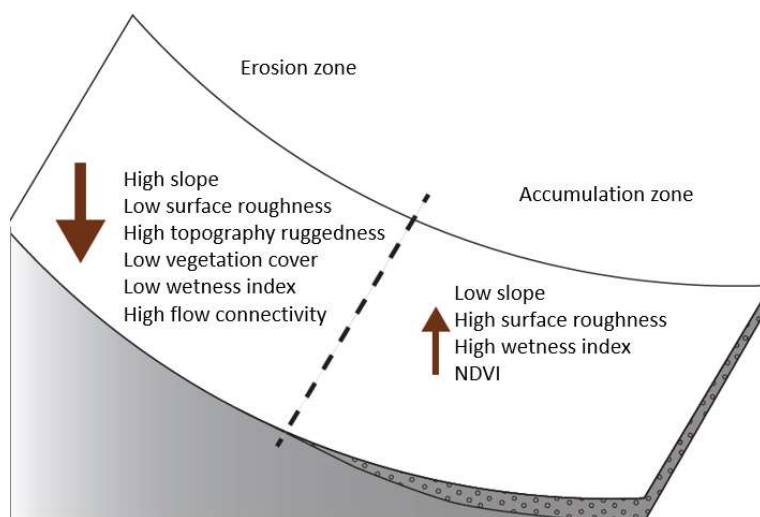

582 According to our analysis, bioturbation increases erosion or accumulation of sediment mostly based on
583 an interplay between topographic structures elevation, slope and TRI (Table 3). Over all research sites,
584 this study found that bioturbation leads to an increase in surface erosion in areas where erosional
585 processes dominate (upper, and/or steeper slopes), and tends to increase sediment accumulation in
586 areas where sediment is naturally deposited, e.g. lower slopes or shallow depressions (Figure 8). This
587 finding is based on the fact that erosion in general is positively affected by slope, and negatively by
588 surface roughness and vegetation (Rodríguez-Caballero et al., 2012; Wang et al., 2013; Kirols et al.,
589 2015). Additionally, the redistribution of sediment is largely affected by topographic meso-/macroforms,
590 such as rills or cliffs. These can be quantified by topographic ruggedness index (TRI) which describes
591 the amount of elevation drop between adjusting cells of DEM (Wilson et al., 2007). At high values of this
592 index, we would therefore expect high erosion rate, due to concentrated runoff within the connected rills
593 or undisturbed flow of runoff from the cliffs downslope.

594 Our data show that one burrow provides up to 0.43 m³ of additional loose sediment at the surface (Table
595 2), while the surface roughness increases up to 200 % (Grigusova et al., 2022). When including burrows
596 into the model, at the slope values from 0 to 5 degrees, the presence of burrows had no impact on
597 sediment redistribution. From 5 degrees onwards it increased sediment erosion proportionally to the
598 slope of the hillside (an increased erosion from 0.4 g ha⁻¹ year⁻¹ in the semi-arid zone until up to 150 kg
599 ha⁻¹ year⁻¹ in the Mediterranean zone, Fig. A9 and A12). Similarly, at locations with sudden elevation
600 drops 0 m until 0.2 m (lower TRI values), the presence of burrows had no impact. However, at locations
601 with elevation drops of 0.2 until 0.5 m (higher TRI values), bioturbation increases sediment erosion by
602 1.5 kg ha⁻¹ year⁻¹ (Fig. A9, A12-A14). Lastly, bioturbation proportionally increased accumulation when
603 the surface roughness values were above 0.5 (an increased accumulation from 0.2 g ha⁻¹ year⁻¹ in semi-
604 arid zone until 5000 kg ha⁻¹ year⁻¹ in the Mediterranean zone, Fig. A9 and A12).

605 We conclude that in locations with slope values over 5 degrees, or at locations with sudden drops in
606 elevation (high TRI) and connected rills, more sediment is eroding than accumulating. Here, additional
607 surface sediments generated by bioturbators provides more source material for erosion and thus

608 bioturbation increases sediment erosion at these locations (Table 3). In contrast, at locations with a
609 slope below 5 degrees, where processes are dominantly controlled by surface roughness, sediment
610 accumulation caused by bioturbation increases proportionally when the surface roughness has a value
611 above 0.5. This is likely because burrows through their above-ground structures heavily increase surface
612 roughness (Grigusova et al., 2022), and hence the presence of bioturbating animals leads to an increase
613 in sediment accumulation.
614 Additionally, we hypothesize that it is not only the additional availability of sediment on the surface and
615 the topography of the vicinity which controls the contribution of bioturbation to sediment surface flux, but
616 also the spatial distribution of animal burrows. We interpret that in locations with high burrow
617 aggregation, surface flow might be redirected and centralized around the aggregates and thus increase
618 the sediment erosion in the areas surrounding burrow aggregates (Figure A15). This mechanism could
619 explain, why bioturbation promotes sediment erosion especially in the Mediterranean zone. The relative
620 role of burrow aggregation should be studied in detail and included in future studies.

621
622 **Figure 8.** Bioturbation amplifies erosion within the erosion zone and accumulation within the
623 accumulation zone. The zones were defined based on the values of surrounding environmental
624 parameters. The arrow direction indicates decrease or increase of sediment amount within a pixel and
625 thus erosion or accumulation. The arrow thickness indicates the amount of redistributed sediment.
626 Please note that the location of the erosion zone on the upper hillside and of the accumulation zone on
627 the lower hillside is purely conceptual. Should the respective values of environmental parameters listed
628 for the erosion zone be found on the lower hillside, it would still be erosion zone. Vice versa for the
629 accumulation zone. The importance of the parameters is ranked and described in section 5.3.

630
631

632 6. Conclusion

633 In summary, our results show that the presence of animal burrows leads to an increase in erosion and
634 net sediment loss. According to our results, bioturbation enhances sediment erosion in areas where

635 more erosion is expected and enhances sediment accumulation in areas which are more prone to
636 accumulate sediment.

637 On geological time scales, as burrowing animals increase both, erosion in steeper zones, and
638 accumulation in areas with gentler slopes and higher roughness, hillslope relief should become faster
639 equalised and overall more flat. This tendency is the most pronounced in the Mediterranean zone with
640 high burrow density and excavation rates, as well as high precipitation rates. Our study furthermore
641 shows that the impact of bioturbation heavily depends on the surrounding environmental parameters.

642

643 **Funding:** This study was funded by the German Research Foundation, DFG [grant numbers
644 BE1780/52-1, LA3521/1-1, FA 925/12-1, BR 1293-18-1], and is part of the DFG Priority Programme
645 SPP 1803: EarthShape: Earth Surface Shaping by Biota, sub-project "Effects of bioturbation on rates
646 of vertical and horizontal sediment and nutrient fluxes".

647 **Institutional Review Board Statement:** Not applicable.

648 **Informed Consent Statement:** Not applicable.

649 **Acknowledgments:** We thank CONAF for the kind support provided during our field campaign.

650 **Competing interests:** There is no conflict of interest.

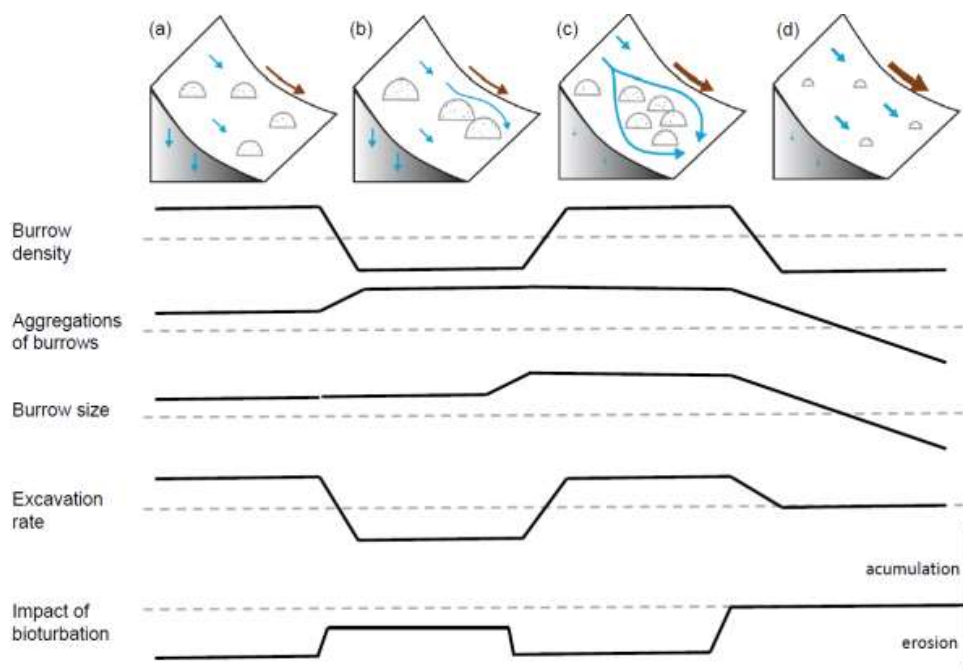

651 **Author contribution:** PG set up the model, analysed the data and wrote the manuscript draft; PG and
652 AL performed the measurements AL, JB, NF, RB, DK, PP, LP, CdR reviewed and edited the manuscript.

653 **Code/Data availability:** Code and all raw data can be provided by the corresponding author upon
654 request.

655 **Special Issue statement:** I would like to stress that the submission should be part of the Copernicus
656 special Issue (Earth surface shaping by biota (ESurf/BG/ESD/ESSD/SOIL inter-journal SI) initiated by
657 the EarthShape consortium.

667 **Supplementary material**

668 **Table A1:** R^2 and RMSE of random forest models trained for the prediction of soil properties needed for
 669 model parametrization. RMSE is root mean square error.

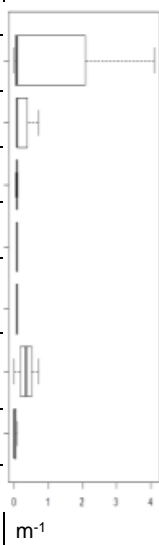

Variable	R^2	RMSE
Soil water content	0.80	0.05
Bulk density	0.60	0.22
Porosity	0.63	0.09
Silt	0.64	0.04
Middle silt	0.64	0.04
Sand	0.68	0.09
Middle sand	0.64	0.05
Organic components	0.77	0.05
Organic carbon	0.70	0.03

670

671

672 **Table A2.** Model sensitivity analysis. For the analysis, the minimum, maximum and mean value of each
 673 parameter was calculated. The model was run for a catchment of 1km² with homogenous mean
 674 parameters. Then, the minimum and maximum values of each parameter were tested. Each parameter
 675 was stepwise changed to its minimum or maximum value while the remaining parameters stayed
 676 homogenous. The significance of the parameter was estimated by a t-test conducted between the
 677 erosion estimated by the model with homogenous mean parameters and the erosion estimated by the
 678 model with varying minimum and maximum parameter values. Only significant parameters are shown.

Abbre- viation	Parameter	mean value	min value	max value	mean erosion	min erosion	max erosion

687

688 **Figure A1.** Example of the unsupervised k-means classification of the surface photo from La Campana.
 689 Original photo was taken by Paulina Grigusova. The collection of in-situ data is explained in section 3.1.,
 690 the estimation of soil properties in section 3.2. The image was classified into 5 classes using
 691 unsupervised k-means classification; the land cover was then assigned manually. In some cases, like
 692 in this case for rocks, multiple k-means classes stand for the same land cover. These were then unified
 693 to the class “rocks”.
