**Abstract.** The biogeochemical ~~behaviour~~ behavior of the Southern Ocean is complex and dynamic. ~~The processes that affect this behaviour are highly dependent on and driven by~~ physical, chemical, and biological ~~constraints, which are poorly constrained in Earth System Models. We assess how emissions~~ processes. Such processes leads to the formation of dimethyl sulfide (DMS), ~~a precursor which is produced by marine biogenic activity and is the dominant source~~ of sulfate aerosol; ~~change~~ over the Southern Ocean ~~when the chlorophyll-a distribution, which influences oceanic DMS production, is altered. Using a nudged~~. However, DMS production is poorly constrained in Earth system models. Using an atmosphere-only nudged to observations configuration of the ~~atmosphere-only~~ United Kingdom Earth System Model ~~(UKESM1-AMIP)~~, we performed ~~nine eight~~ 10-year simulations ~~using foreings representative of the period 2009–2018. Four different for the recent past (2009–2018). We tested four~~ seawater DMS data sets ~~are tested as input for these simulations. Three different and three~~ DMS ~~sea-to-air flux parameterizations are also explored. Our goal is to evaluate the changes in transfer velocity parameterizations. All data sets and parameterizations are commonly used by present-day Earth system models, with the exception of one data set that we developed from satellite chlorophyll-a data. We evaluate simulated oceanic DMS, sea-to-air fluxes~~ transfer of DMS, and atmospheric DMS ~~through these different simulations~~ during austral summer. ~~The mean spread across all the~~ In simulations with different ~~oceanic DMS datasets, seawater DMS data sets~~ but the same sea-to-air flux ~~parameterizations, is~~ parameterization. Southern Ocean summertime DMS varies by 112% (3.3 to 6.9 TgS Yr<sup>-1</sup>). ~~The mean spread in~~ This is ~~approximately twice as much as the~~ simulations using the same ~~oceanic DMS dataset, seawater DMS data set~~ but differing sea-to-air flux ~~parameterisations is~~ parameterizations, in which DMS varies by 50-60% (2.9 to 4.7 TgS Yr<sup>-1</sup>). The choice of ~~DMS emission parameterisation~~ oceanic DMS source has a larger influence on atmospheric DMS than the choice of ~~oceanic DMS source. We also find that linear relationships between wind and DMS flux generally compare better to observations than~~ DMS ~~emission. Simulations testing different sea-to-air transfer velocity parameterizations show that simulating a linear dependence of DMS gas transfer velocity as a function of wind speed results in a more accurate representation of atmospheric DMS~~

distributions than using quadratic relationships. Simulations ~~that implement a quadratic emission rate show on average 35% higher DMS mixing ratios than the linear emission rates. Simulations~~ using seawater DMS derived from satellite ~~chlorophyll-a data in combination with a recently-developed flux parameterisation for DMS~~ show the closest ~~chlorophyll-a data show realistic spatiotemporal variability in DMS and when combined with a recently developed transfer velocity parameterization for DMS, the model shows good~~ agreement with atmospheric DMS observations ~~and are recommended to be included in future simulations.~~ As a precursor for natural sulfate aerosol and cloud condensation nuclei, DMS plays an important role in the radiative balance over the Southern Ocean. This work ~~recommends for Earth System Models to include a~~ highlights that the seawater DMS data sets and sea-to-air transfer velocity parameterizations for DMS commonly used in climate models are poorly constrained for the Southern Ocean region. We recommend that models use a DMS sea-to-air parameterization that ~~is appropriate~~ was developed specifically for DMS, and for oceanic DMS datasets to ~~include inter-annual~~ incorporate spatial variability based on observed marine biogenic activity. Such improvements will provide a more accurate process-based representation of oceanic and atmospheric DMS, and therefore sulfate aerosol, in the Southern Ocean region.

## 1 Introduction

The representation of aerosols over the Southern Ocean is a large source of uncertainty in climate models due to the lack of observational data and large seasonal variability (Revell et al., 2019). Poor representation of aerosols contributes to the large biases in future climate projections over the Southern Ocean (Myhre et al., 2014). Sea spray and dimethyl sulfide (DMS;  $\text{CH}_3\text{SCH}_3$ ) are fundamental sources for aerosol formation over this region (Revell et al., 2021; Bhatti et al., 2022). The dominant source of sulfate over the marine atmosphere is the biogenic marine aerosol precursor DMS, controlled by ~~phytoplankton productivity (Keller et al., 1989; Bates et al., 1987; Berndt et al., 2019)~~ marine biota (Keller et al., 1989; Bates et al., 1987; Kiene and Bates, 1990; Curran et al., 1999; Revell et al., 2019) found sulfate aerosol production from DMS was responsible for around 60% of the austral summer aerosol optical depth over the Southern Ocean. Atmospheric DMS therefore has the potential to greatly influence cloud condensation nuclei during austral summer ~~, due to its high rate of emissions~~ (Kloster et al., 2006; Revell et al., 2019; Korhonen et al., 2008; Pandis et al., 1994).

The Southern Ocean contains extremely high phytoplankton ~~and marine biota~~ productivity during austral summer (~~December, January, and February~~ DJF, December–February) (Deppeler and Davidson, 2017). ~~Phytoplankton~~ Marine biogenic activity plays a key role in chlorophyll-*a* (chl-*a*) production and is considered to be a key driver of oceanic DMS production (e.g. Uhlig et al., 2019; Townsend and Keller, 1996; Anderson et al., 2001; Deppeler and Davidson, 2017). Earth System Models (ESMs) represent the process of oceanic DMS formation through multiple ~~mechanisms, with varying focus~~ approaches that are dependent on chl-*a*, nutrients, light, mixed-layer depth, zooplankton, and dimethylsulfoniopropionate concentration (Bock et al., 2021). The UKESM1 and MIROC-ES2L ~~models~~ use a diagnostic approach to represent chl-*a* (Sellar et al., 2019; Anderson et al., 2001; Hajima et al., 2020). ~~The~~ CNRM-ESM2-1 and NorESM2-LM ~~focus on models use~~ a prognostic approach, closely related to zooplankton and dimethylsulfoniopropionate ~~, abundance, which are both~~ precursors of oceanic DMS (Seland et al., 2020; Séférian et al., 2019). ~~Bock et al. (2021) evaluated oceanic DMS in CMIP6 models simulate biases in oceanic DMS production~~

55 ~~compared and found that all models are biased in comparison~~ with observational climatologies of DMS in the Southern Ocean region (~~Bock et al., 2021~~).

Atmosphere-only global climate models use climatologies to ~~approximate~~ prescribe the global concentration of oceanic DMS. Lana et al. (2011) and Kettle et al. (1999) constructed observational climatologies of oceanic DMS which are used ~~within climate by such~~ models. However, there is a limited amount of data available within the Southern Ocean, which can  
60 lead to ~~biases when compared to other regions~~ errors in the representation of oceanic DMS (e.g. Bock et al., 2021; Mulcahy et al., 2020). A limitation of representing oceanic DMS as a static climatology is that it does not account for the large temporal variations in DMS concentrations observed. For instance, El Niño Southern Oscillation (ENSO) events, wildfires, and volcanic eruptions all significantly influence oceanic DMS within the Southern Ocean (e.g. Yoder and Kennelly, 2003; Tang et al., 2021; Wang et al., 2022; Browning et al., 2015; Longman et al., 2022). Calculating oceanic DMS online using a biological proxy  
65 would resolve these perturbing events to some degree (Galí et al., 2018).

~~DMS is emitted~~ The flux of DMS from the ocean to the atmosphere ~~and has a strong dependence on the~~ depends on the gas transfer velocity, which in turn depends on the surface wind speed (e.g. Fairall et al., 2011). ~~A wealth of research has focused on better understanding the relationship between atmospheric DMS and wind speed (Vlahos and Monahan, 2009; Zavarsky et al., 2018; Blomquist et al., 2017). However, the uncertainty in this relationship remains high particularly within the Southern Ocean due to a lack of observational data (e.g. Elliott, 2009; Smith et al., 2018; Zhang et al., 2020), particularly for wind speeds  $\geq 13 \text{ ms}^{-1}$  (Blomquist et al., 2017). Recently, significant progress has been made as recent literature has established that DMS flux has a linear relationship with wind (Goddijn-Murphy et al., 2016; Blomquist et al., 2017; Bell et al., 2015), while Earth System Models continue to use older quadratic relationships to represent DMS emissions Bock et al. (2021) (e.g. Fairall et al., 2011). Many DMS flux parameterizations have been developed, but most use transfer velocities measured for gases other than DMS (Wanninkhof, 1992, 2014; Nightingale et al., 2000; Blomquist et al., 2017) and Yang et al. (2011), used DMS measurements to derive a relationship between wind speed and DMS. Depending on the solubility of the gas measured, gas transfer velocities typically have a linear or quadratic dependence on wind speed. Linear relationships best represent gases with intermediate solubilities, such as DMS (e.g. Blomquist et al., 2017; Goddijn-Murphy et al., 2016; Bell et al., 2015; Yang et al., 2011; Huebert et al., 2010), while quadratic equations are better suited for highly soluble gases like CO<sub>2</sub> (Wanninkhof, 2014; Nightingale et al., 2000; Wanninkhof, 1992).~~  
70 ~~Some studies, including Blomquist et al. (2017) and Yang et al. (2011), used DMS measurements to derive a relationship between wind speed and DMS. Depending on the solubility of the gas measured, gas transfer velocities typically have a linear or quadratic dependence on wind speed. Linear relationships best represent gases with intermediate solubilities, such as DMS (e.g. Blomquist et al., 2017; Goddijn-Murphy et al., 2016; Bell et al., 2015; Yang et al., 2011; Huebert et al., 2010), while quadratic equations are better suited for highly soluble gases like CO<sub>2</sub> (Wanninkhof, 2014; Nightingale et al., 2000; Wanninkhof, 1992).~~

~~Oceanic DMS observations~~ Uncertainty in DMS emissions remains high, particularly in the Southern Ocean ~~are highly variable in time and space (Lana et al., 2011; Hulswar et al., 2022; Galí et al., 2018), while the emissions of DMS are also uncertain (e.g. Korhonen et al., 2008; Blomquist et al., 2017). This study sets out to examine whether including oceanic DMS with spatio-temporal variability based on real-world~~ region where wind speeds are high and observational data sparse (e.g. Elliott, 2009; Smith et al., 2018; Zhang et al., 2020). ~~ESMs use a variety of transfer velocities to represent DMS emissions (Bock et al., 2021). UKESM1 uses the Liss and Merlivat (1986) parameterization even though it was constructed for gases other than DMS.~~  
80 ~~Oceanic DMS observations~~ Uncertainty in DMS emissions remains high, particularly in the Southern Ocean ~~are highly variable in time and space (Lana et al., 2011; Hulswar et al., 2022; Galí et al., 2018), while the emissions of DMS are also uncertain (e.g. Korhonen et al., 2008; Blomquist et al., 2017). UKESM1 uses the Liss and Merlivat (1986) parameterization even though it was constructed for gases other than DMS.~~  
85 ~~parameterization even though it was constructed for gases other than DMS.~~

Here we examine whether incorporating realistic oceanic DMS variability, based on remotely-sensed chl-*a* observations improves the simulation of atmospheric DMS. We investigate differences in oceanic DMS and emission parameterizations for forming atmospheric DMS using the nudged to observation configuration of Using a nudged configuration of the atmosphere-only United Kingdom Earth System Model (UKESM1-AMIP. We calculate), we use three established oceanic DMS datasets

90 ~~and three transfer velocity parameterizations. We also test a 10-year monthly time series calculated from chl-*a* in which seawater DMS is calculated offline from MODIS-aqua satellite data implemented within the modified Anderson et al. (2001) parameterization (Sellar et al., 2019). We also test climatologies from Lana et al. (2011), Hulswar et al. (2022), and the DMS climatology used by UKESM1-AMIP (Sellar et al., 2019). chl-*a* data using the Anderson et al. (2001) oceanic DMS parameterization which is used by UKESM1 (Sellar et al., 2019). We evaluate sea-to-air fluxes of DMS and oceanic and atmospheric DMS~~  
95 ~~concentrations relative to station and ship-based observations. The observational data sets are described in Section 2.4, the model configuration is described in Section 2.1, and details of the oceanic DMS emissions are calculated using two quadratic (Wanninkhof, 2014; Nightingale et al., 2000) and two linear (Liss and Merlivat, 1986; Blomquist et al., 2017) data sets and sea-to-air flux parameterizations. Evaluating the process and sensitivity of DMS from the ocean to the atmosphere in climate models is critical for the further development of models and for understanding the biogeochemical cycle. We compare the DMS~~  
100 ~~variability across the Southern Ocean during summer, improving our understanding of the relative importance of choosing the source (oceanic DMS) and emissions. transfer velocity parameterizations tested are in Sections 2.2 and 2.3, respectively. Results follow in Section 3.~~

## 2 Methods

### 2.1 Model Configuration and Evaluation

105 Simulations were performed using the atmosphere-only configuration of the coupled UK Earth System Model (UKESM1; Yool et al., 2020; Sellar et al., 2019; Mulcahy et al., 2020). ~~By default, atmospheric DMS is produced via the Lana et al. (2011) oceanic DMS data set and Liss and Merlivat (1986) sea-to-air transfer velocity parameterization. Atmospheric DMS then oxidises to form sulfate aerosols. In UKESM1 simulates ocean biogeochemistry via an intermediate complexity biogeochemical dynamic model, MEDUSA2.0 (the Model of Ecosystem Dynamics, nutrient Utilization, Sequestration, and Acidification; Yool et al., 2020)~~  
110 ~~. MEDUSA is used in UKESM1 to represent biogeochemical feedbacks within the Nucleus for European Modelling of the Ocean (NEMO) ocean model (Madec and others, 2008). The aerosol component of UKESM1 uses the GLOMAP-mode aerosol scheme, which is described in full by Mulcahy et al. (2020) and Mann et al. (2010, 2012)., aerosol growth, chemistry and removal are handled by the GLOMAP-mode scheme (Mulcahy et al., 2020).~~

Wind and temperatures ~~within the simulations used in this study are nudged 6-hourly to real-world conditions via the~~  
115 ~~use of the are nudged to 6-hourly ERA-5 reanalysis data (Hersbach et al., 2020). The full description of how nudging is incorporated within the UKESM1-AMIP is outlined in more detail by Telford et al. (2008). As noted by Pithan et al. (2022) and Kuma et al. (2020), nudging simulations can enhance the precision of simulations used for assessing atmospheric processes. Specifically, it allows for a more accurate representation of meteorological factors such as wind speed, which play a key role~~  
120 ~~in the nudging configuration is outlined in Telford et al. (2008). Nudging ensures that wind speeds, which are pivotal to the formation of atmospheric DMS. Using nudged runs also allows us to better evaluate our simulations against observational measurements made during voyages.~~

The sea-to-air transfer of DMS in our simulations is discussed in Section 2.3. All simulations in this study, are accurately represented (Pithan et al., 2022; Kuma et al., 2020) and allows like-for-like comparisons against observations. Sea surface temperature and sea ice data from The Hadley Centre Global Sea Ice and Sea Surface Temperature were used (HadISST; Titchner and Rayner, 2014). Simulations are 10 years long, spanning from 2009 to 2018. We focus on the austral summer months (December–February; DJF) due to the summer being the most biologically productive season. This period was chosen to coincide with the availability of recent DMS observations (Section 2.4).

In this paper, we compare observational data to our simulations using the same hourly timescales. Atmospheric DMS concentrations are analyzed at the lowest model level, at 20 m during DJF, which is the most productive season for DMS (Deppeler and Davidson, 2017; Jarman et al., 2019). Hourly output was saved to compare with observations where applicable (for example, voyages provide observations at hourly temporal frequency). To evaluate variability, we use the coefficient of variation (CoV) which is a statistical measure that compares the variability of data by expressing the standard deviation as a percentage of the mean. CoV is used to compare the variability between each of the simulations oceanic DMS, DMS emissions, and atmospheric DMS concentration. A higher CoV suggests that the variability or dispersion of the data is relatively large compared to its mean. Where uncertainty is reported,  $\pm$  standard deviation through time and space one standard deviation calculated over the relevant domain and time period is stated.

## 2.2 Oceanic DMS

We input four oceanic DMS data sets into the atmospheric model: three climatologies and one 10-year time series between 2009 to 2018. Two are observational-based climatologies time series. Observational-based climatologies are from Lana et al. (2011) (hereafter ‘Lana’) and Hulswar et al. (2022) (hereafter ‘Hulswar’). The ‘MEDUSA’ climatology (1979–2014) is sourced originates from the UKESM1 CMIP6 repository, MEDUSA (Yool et al., 2021; Sellar et al., 2019). See (Yool et al., 2021; Sellar et al., 2019) Table 1 for an outline of outlines the oceanic DMS climatologies and dataset used datasets used. Ocean biogeochemistry is simulated in the UKESM1 via MEDUSA2.0 (the Model of Ecosystem Dynamics, nutrient Utilization, Sequestration, and Acidification; Yool et al., 2021). The time series was calculated offline using a combination of satellite data and the UKESM1 approach to calculating seawater DMS, as described below.

The In UKESM1 uses a diagnostic approach in the formulation of oceanic DMS, which is calculated online using oceanic DMS concentrations are calculated using a diagnostic method from Anderson et al. (2001), using surface daily shortwave radiation ( $J$ ), dissolved inorganic nitrogen ( $Q$ ), and surface chl- $a$  ( $C$ ):

$$\text{Oceanic DMS} = a, \text{ for } \log(CJQ) \leq s \quad (1)$$

150

$$\text{Oceanic DMS} = b[\log(CJQ) - s] + 1, \text{ for } \log(CJQ) > s \quad (2)$$

The fitted parameter values are  $a=1$ ,  $b=8$ , and  $s=1.56$ , as described by Sellar et al. (2019). The online oceanic DMS from MEDUSA in the UKESM1 shows small annual variability and therefore a 30-year climatology will represent MEDUSA

**Table 1.** Oceanic DMS data sets used in the model simulations.

Oceanic DMS dataset	Source	Citation	Year of Data
Lana	Oceanic DMS observations	Lana et al. (2011)	1972 - 2009
Hulswar	Oceanic DMS observations	Hulswar et al. (2022)	1972 - 2021
MEDUSA	UKESM1 CMIP6 simulations	Anderson et al. (2001); Sellar et al. (2019)	1979 - 2014
MODIS-DMS	MODIS-aqua chlorophyll- <i>a</i> via Anderson et al. (2001)	N/A (produced for this study)	2009 - 2018

well.  $Q$  and  $chl-a$  are taken from MEDUSA, and  $J$  is from the atmosphere component of the UKESM1, the Unified Model.  $chl-a$  is used to calculate oceanic DMS concentrations in other are averaged from CMIP6 models, such as MIROC-ES2L, and within algorithms such as that detailed by Galf et al. (2018). The Anderson et al. (2001) parameterization is a widely used for the MEDUSA climatology. The Anderson et al. (2001) parameterization produces positive biases in DMS over the Southern Ocean within MEDUSA (Bock et al., 2021) due to the set minimum oceanic concentration of 1, which leads to large average DMS concentrations (Yool et al., 2021; Bock et al., 2021). Recent research suggests that  $chl-a$  may not be an appropriate proxy for oceanic DMS (Uhlig et al., 2019; Bell et al., 2021), and well-validated method for calculating oceanic DMS in UKESM1. Here, we have tested a modified version of it using the MODIS-aqua future work will explore alternative methods for calculating oceanic DMS within UKESM1. Nonetheless,  $chl-a$  is widely used by CMIP6-era models to calculate oceanic DMS, and we explore here whether using an observationally derived  $chl-a$  dataset. This data set, concentration field leads to changes in the spatial and temporal variability of atmospheric DMS. Monthly-mean  $chl-a$  concentrations from the Moderate Resolution Imaging Spectroradiometer (MODIS)-aqua satellite instrument were used to construct a time series of oceanic DMS between 2009–2018 (Table 1; Hu et al., 2019; O’Reilly and Werdell, 2019). This time series, which we term the ‘MODIS-DMS’, is a continuous time series between 2009 to 2018. MODIS-DMS is data set, is calculated offline using the same diagnostic parameterization (Anderson et al., 2001; Sellar et al., 2019) as Equations 1 and 2. The UKESM1 has a +6  $W\ m^{-2}$  bias for  $J$  within CMIP6 over the Southern Ocean, which may result in slightly higher oceanic DMS concentrations (Schuddeboom and McDonald, 2021). The  $J$  and  $Q$  used to calculate MODIS-DMS remain the same to MEDUSA, but a new monthly-mean as MEDUSA. Through this, we capture spatial and interannual  $chl-a$  field ( $C$ ) is introduced via Moderate Resolution Imaging Spectroradiometer (MODIS)-Aqua Level-3 ocean-color  $chl-a$  (Table 1; e.g. Hu et al., 2019; O’Reilly and Werdell, 2019) variability, indicating biological productivity. Bi-linear interpolation is used to fill in small gaps (around 1% for monthly averages) of spatial  $chl-a$  data. Using the MODIS-Aqua  $chl-a$  satellite data, oceanic DMS concentrations were calculated each month for our 10 year period. From this, we capture the annual variability of the distribution in ocean biological productivity (referenced in this work as MODIS-DMS). Our goal is to understand the relationship between oceanic biological productivity, as represented by  $chl-a$ , and atmospheric DMS concentrations in the Southern Ocean during austral summer. We then evaluate which oceanic DMS sources produce the best distribution compared to observations. Oceanic DMS concentrations are masked where they coincide within the sea-ice zone from HadISST.

180 Several studies have validated the In general, the MODIS-aqua Ocean Color chl-*a* retrieval, finding it to generally underestimate Southern Ocean conditions (Zeng et al., 2016; Haëntjens et al., 2017; Jena, 2017). Satellites can also overestimate chl-*a* measurements due to the scattering of light from aerosols (Schollaert et al., 2003). However, Marrari et al. (2006) found satellite chl-*a* is accurate within the Southern Ocean during summer. Therefore the underestimates Southern Ocean chlorophyll concentrations (Zeng et al., 2016; Haëntjens et al., 2017; Jena, 2017; Gregg and Casey, 2007; Johnson et al., 2013). Simulated oceanic DMS  
185 may therefore be systematically underestimated. Nonetheless, the high spatial and temporal availability of summertime data makes chl-*a* a viable option for estimating phytoplankton productivity and oceanic DMS. Using the MODIS-DMS data set, we aim to accurately simulate maxima and minima in oceanic DMS concentrations comparable to observations. By comparing the model results with observations, we can identify and understand the impact of phytoplankton bloom events and annual variability which can not be captured by climatologies. observations during summertime makes it useful to explore spatiotemporal  
190 variability in atmospheric DMS.

### 2.3 DMS Sea-to-Air Flux

To calculate the transfer of DMS from the ocean to the atmosphere, a parameterization is used which is controlled by wind speed. The formulation of the transfer velocity is derived from observational measurements of a particular gas. Many flux parameterisations have been developed, but these have mostly been based on gases such as CO<sub>2</sub> (e.g. Wanninkhof, 2014). These  
195 parameterizations are widely implemented within climate models to represent DMS but vary depending on the model. We tested three flux parameterisations shown in Three DMS transfer velocities are tested (Figure 1. Blomquist et al. (2017) (hereafter ‘B17’) used DMS measurements to derive a relationship between wind speed and DMS, whereas Wanninkhof (2014) (W14) and Liss and Merlivat (1986) (, Table 2). Two are linear equations from Liss and Merlivat (1986) (hereafter ‘LM86’) used CO<sub>2</sub>, and other high solubility gases. Sea-to-air parameterizations are typically linear or quadratic, depending on the solubility of the gas.  
200 Linear equations best represent gases with intermediate solubilities, such as DMS (e.g. Blomquist et al., 2017; Goddijn-Murphy et al., 2016), while quadratic equations are better suited for highly soluble gases like CO<sub>2</sub> (Wanninkhof, 2014; Nightingale et al., 2000; Wanninkhof, 19). This study uses two linear equations from LM86 and ‘) and Blomquist et al. (2017) (hereafter ‘B17’ to represent DMS emissions more accurately compared with observations, as suggested by Blomquist et al. (2017) and Goddijn-Murphy et al. (2016). LM86 is a piecewise function consisting of three lines with different gradients and intercepts, depending on the wind speed (Figure 1’).  
205 LM86 is used as the default flux parameterization within the default parameterization within UKESM1 (Sellar et al., 2019) and is thus used on with oceanic DMS datasets was evaluated in combination with all oceanic DMS data sets. The quadratic formula from Wanninkhof (2014) (hereafter ‘W14’) is also tested. Using these different parameterizations provides an estimate of appropriate estimate for the spread of DMS emissions. The Lana oceanic DMS climatology is tested with the W14, and B17 fluxes, as Lana is currently the most widely used climatology within climate models (Bhatti et al., 2022). We also apply  
210 the W14 and B17 flux parameterisations to the MODIS-DMS oceanic DMS dataset to test the due to the upper and lower limits of oceanic DMS concentrations to assess the variation from the time-series DMS transfer velocity tested from in-situ DMS measurements (e.g. Goddijn-Murphy et al., 2016; Blomquist et al., 2017). Table 2 outlines the sensitivity simulations performed for this study, described by summarizes the sensitivity simulation names performed. Simulations are named with the

**Table 2.** Simulations used in this study, named with the oceanic DMS data-sets-as-the-name concentration used, followed by subscripted with the DMS flux parameterization sea-to-air transfer velocity used.

Simulation name	Oceanic DMS source	DMS flux-transfer velocity parameterization
Lana <sub>LM86</sub>	Lana et al. (2011)	Liss and Merlivat (1986)
Lana <sub>B17</sub>	Lana et al. (2011)	Blomquist et al. (2017)
Lana <sub>W14</sub>	Lana et al. (2011)	Wanninkhof (2014)
Hulswar <sub>LM86</sub>	Hulswar et al. (2022)	Liss and Merlivat (1986)
MEDUSA <sub>LM86</sub>	Anderson et al. (2001); Sellar et al. (2019)	Liss and Merlivat (1986)
MODIS <sub>LM86</sub>	N/A (produced for this study)	Liss and Merlivat (1986)
MODIS <sub>B17</sub>	N/A (produced for this study)	Blomquist et al. (2017)

<u>MODIS<sub>B17</sub>-CLIM</u>	<u>N/A (climatology produced for this study)</u>	<u>Blomquist et al. (2017)</u>

oceanic DMS concentration used, subscripted with the sea-to-air flux-transfer velocity used. For example, Lana<sub>LM86</sub> means  
 215 that the simulation used the Lana et al. (2011) climatology as its oceanic DMS source, and the DMS flux-parameterisation transfer velocity parameterization of Liss and Merlivat (1986).

~~To calculate the flux of DMS, the Schmidt number of DMS is required~~The Schmidt number for DMS is used to calculate the DMS emission. The Schmidt number ~~describes the mixing efficiency of a substance in a fluid and is used to calculate the transfer velocity of gas from the sea to air~~represents the viscosity/diffusion properties of a gas, varying with respect to sea  
 220 surface temperature (T in °C). We update the Schmidt number of DMS ( $S_{c_{DMS}}$ ) used in the UKESM1 from the formulation used in Saltzman et al. (1993) to Wanninkhof (2014), as shown in Equation 3:

$$S_{c_{DMS}} = 2855.7 + (-177.63 + (6.0438 + (-0.11645 + 0.00094743 \cdot T) \cdot T) \cdot T) \cdot T \quad (3)$$

~~T is the sea-surface temperature derived from The Hadley Centre Global Sea Ice and Sea Surface Temperature (HadISST) within the model (Titchner and Rayner, 2014). LM86 was constructed based on gases other than DMS, but is often used for~~  
 225 ~~DMS emissions within CMIP6 Earth System and climate models (e.g. Horowitz et al., 2020; Tang et al., 2019; Yukimoto et al., 2019)~~  
~~. In equation 4, Where T is derived from HadISST (Titchner and Rayner, 2014).  $U_{10}$  is the wind speed at (m s<sup>-1</sup>) represents near-surface (10m above the surface - m) wind speed and  $K_w$  (cm h<sup>-1</sup>) represents the transfer velocity of DMS. Equation 4 represents the LM86 transfer velocity of DMS:~~

for  $u_{10} \leq 3.6$ :

$$K_w = 0.17 \left( \frac{600}{Sc_{DMS}} \right)^{\frac{2}{3}} u_{10},$$

for  $3.6 \leq u_{10} < 13$ :

$$K_w = 2.85 \left( \frac{600}{Sc_{DMS}} \right)^{\frac{1}{2}} (u_{10} - 3.6) + 0.612 \left( \frac{600}{Sc_{DMS}} \right)^{\frac{2}{3}},$$

for  $u_{10} > 13$ :

$$K_w = 5.9(u_{10} - 13) \left( \frac{600}{Sc_{DMS}} \right)^{\frac{1}{2}} + 26.79(u_{10} - 3.6) \left( \frac{600}{Sc_{DMS}} \right)^{\frac{1}{2}} + 0.612 \left( \frac{600}{Sc_{DMS}} \right)^{\frac{2}{3}} \quad (4)$$

230 W14 uses a quadratic formula (equation 5) ~~to empirically fit observations of CO<sub>2</sub> as a for~~ sea-to-air transfer. W14 is also ~~very frequently~~ used to calculate DMS emissions amongst CMIP6 ~~simulations~~ ~~models~~ (e.g. Tjiputra et al., 2020).

$$K_w = 0.251 \cdot u_{10}^2 \left( \frac{660}{Sc_{DMS}} \right)^{\frac{1}{2}} \quad (5)$$

235 ~~Finally,~~ B17 is the only parameterization ~~used~~ ~~tested~~ in this study ~~which calculates a transfer velocity for which the transfer velocity is~~ based on real-world observation of DMS (~~equation~~ ~~Equation~~ 6). B17 is a superlinear ~~and sub-quadratic~~ parameterization, however, for simplicity and the wind speeds used in this study, we label B17 as a linear parameterization.

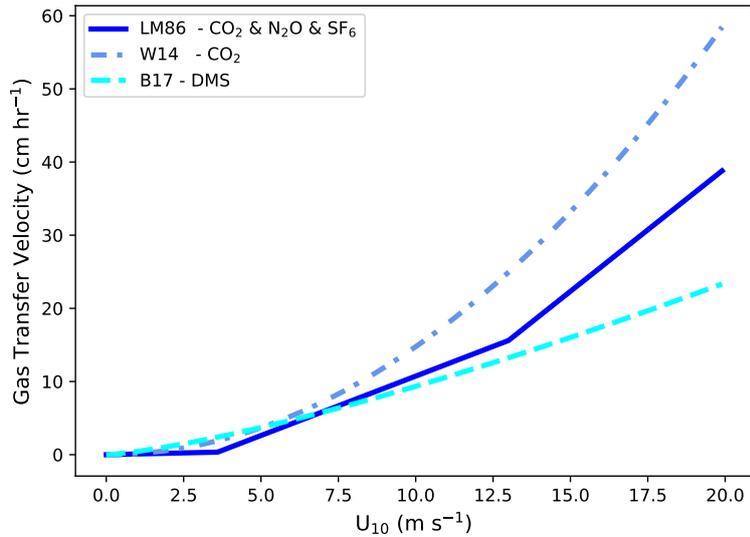

$$K_w = 0.7432 \cdot u_{10}^{1.33} \left( \frac{660}{Sc_{DMS}} \right)^{\frac{1}{2}} \quad (6)$$

240 ~~To assess the inter-annual variability of DMS emissions and atmospheric DMS concentrations, we performed an additional 10-year simulation, MODIS<sub>B17</sub>-CLIM. While MODIS<sub>B17</sub> used a 10-year time series of oceanic DMS derived from MODIS chlorophyll-a data, MODIS<sub>B17</sub>-CLIM used a climatology calculated from monthly-mean data for the 10-year MODIS<sub>B17</sub> time series.~~

## 2.4 Observational Datasets

### 2.4.1 ~~DMS Datasets~~

Two Southern Ocean voyages are used to ~~validate~~ ~~evaluate~~ our simulations: the SOAP (~~Surface Ocean Aerosol Production; Bell et al., 2015~~ ~~campaign~~ ~~campaign~~ (Surface Ocean Aerosol Production; Bell et al., 2015; Law et al., 2017) and RV Tangaroa voyage (TAN1802; 245 Kremser et al., 2021). The SOAP voyage measured oceanic and atmospheric DMS from Feb-March 2012 near the Chatham Rise (within 42–47 °S, 172–180 °E) off the east coast of New Zealand, ~~a highly biologically productive region of the Southern Ocean~~ (Bell et al., 2015; Smith et al., 2018). The TAN1802 voyage measured oceanic DMS along ~~a transect in~~ the Southern

**Figure 1.** DMS sea-to-air flux parameterizations transfer velocities tested in this study. LM86 = Liss and Merlivat (1986); W14 = Wanninkhof (2014) and B17 represents Blomquist et al. (2017). The gases labelled in the legend are the measurements taken to identify the gas exchange relationship.

Ocean during Feb-March 2018 between latitudes 40 °S to 70 °S, 180 °E (Kremser et al., 2021). Other voyages outside the years covered by our nudged simulations, but included in the atmospheric DMS analysis are the SOIREE and ANDREXII voyages, used to calculate the observational atmospheric DMS. SOIREE occurred in We also extend the simulations to cover the ANDREXII voyage between Feb - April 2019 for atmospheric DMS concentrations as this voyage mostly measured during autumn (Wohl et al., 2020). ANDREXII traveled longitudinally around 60 °S. Although outside our simulation range, we also consider SOIREE for atmospheric DMS analysis from Feb 1999 and measured atmospheric DMS concentration (Boyd and Law, 2001) between 42 - 63 °S, 139–172 °E. ANDREXII (Wohl et al., 2020) travelled longitudinally around 60 °S, between February to April 2019.

We used oceanic DMS measurements for TAN1802 Kremser et al. (2021), SOAP (Bell et al., 2015), and ERA-5 surface wind speeds (Hersbach et al., 2020) to calculate hourly DMS emissions. The Wanninkhof (2014) Wanninkhof (2014) DMS Schmidt number is calculated using the same parameters used within the simulations, for consistency with comparisons to simulated fluxes. Sea ice and sea surface temperature data are from the Met Office Hadley Centre’s sea ice and sea surface temperature (HadISST; Titchner and Rayner, 2014), where sea surface temperature represents T in Equation 3. The HadISST and ERA-5 wind speed data were obtained for the same time and location as the two voyages (within the nearest neighbour neighbor grid cell). We applied three different sea-to-air flux parameterizations (LM86, B17, and W14) to both SOAP and TAN1802 voyage paths (See section 3.2).

We compare our simulations to the voyage dataset using the hourly model output and identify the nearest ~~neighbour~~neighbor grid cell to the ship location. Analysis of oceanic DMS data used in the models is also synchronized to TAN1802 and SOAP voyages, using the same timescales for comparing the voyages with model data.

We also validate the model using atmospheric DMS concentrations measured at ~~three~~two stations: Cape Grim (1989 to 1996; 41 °S and 145 °E) ; ~~Amsterdam Island (1987 to 2008; 38 °S, 78 °E)~~; and King Sejong Station (2018 to 2020; 62 °S, 58 °W). King Sejong is located on the Antarctic Peninsula, where sea ice melt occurs during our study period, which can profoundly increase DMS emissions, as previously found by Berresheim et al. (1998); Read et al. (2008). ~~The climatologies from Amsterdam Island and Cape Grim stations~~

## 2.4.2 Cloud and Aerosol Observations

~~MODIS-aqua aerosol optical depth (AOD) measurements at 550 nm (Platnick et al., 2017) are compared with the model climatology of atmospheric DMS. The King Sejong measurements align with our simulation period, and so we compare both datasets on the same timescale~~each daily-mean model output. Daily-averaged observations from Grosvenor et al. (2018) and Bennartz and Rausch (2017) were used to compare the cloud droplet number concentration (CDNC) with our daily-averaged simulations. Finally, to evaluate cloud condensation nuclei (CCN), we used Choudhury and Tesche (2023) at 818 m, in comparison with simulated CCN at 800 m. The description and evaluation of using MODIS-observed AOD compared with a related configuration of UKESM1-AMIP is discussed in more detail in Revell et al. (2019) and Mulcahy et al. (2020). We calculate an austral summertime climatology for these observational datasets, which we use over the Southern Ocean.

## 3 Results and Discussion

### 3.1 Oceanic DMS

Figure 2a-d shows the spatial distribution of ~~the oceanic DMS from the different datasets used in this study~~each oceanic DMS dataset. Each distribution has key defining characteristics, although Hulswar (Figure 2d) is ~~similar~~an update to Lana (Figure 2c)~~as it is an updated version. When the dataset includes chlorophyll-a (chl-a), oceanic DMS has distinguishable features across latitudes, partly due to the influence of the Southern Hemisphere westerly jet, driving ocean circulation and transporting phytoplankton (e.g. Allison et al., 2010; Li et al., 2016). The only difference between the calculation of~~. ~~The distinction between~~ MODIS-DMS and MEDUSA oceanic DMS ~~is the calculations is~~ chl-a input, however, their distributions of oceanic DMS in the Southern Ocean are largely different, as illustrated which results in distinctly different distributions, as shown in Figure 2e. Observational-based climatologies, ~~such as in~~like Lana or Hulswar (Figure 2c, d), ~~do not consider other proxies of oceanic DMS (Lana et al., 2011; Hulswar et al., 2022). Lana and Hulswar (Figure 2c,d), do not match the distribution of,~~ do not align with the chl-a distribution in the Southern Ocean, particularly along the Antarctic Circumpolar Current, ~~as oceanic DMS concentrations are focused to a specific region, concentrating oceanic DMS in specific regions~~ based only on observations of oceanic DMS (Lana et al., 2011; Hulswar et al., 2022). The mean difference between the ~~mean~~of

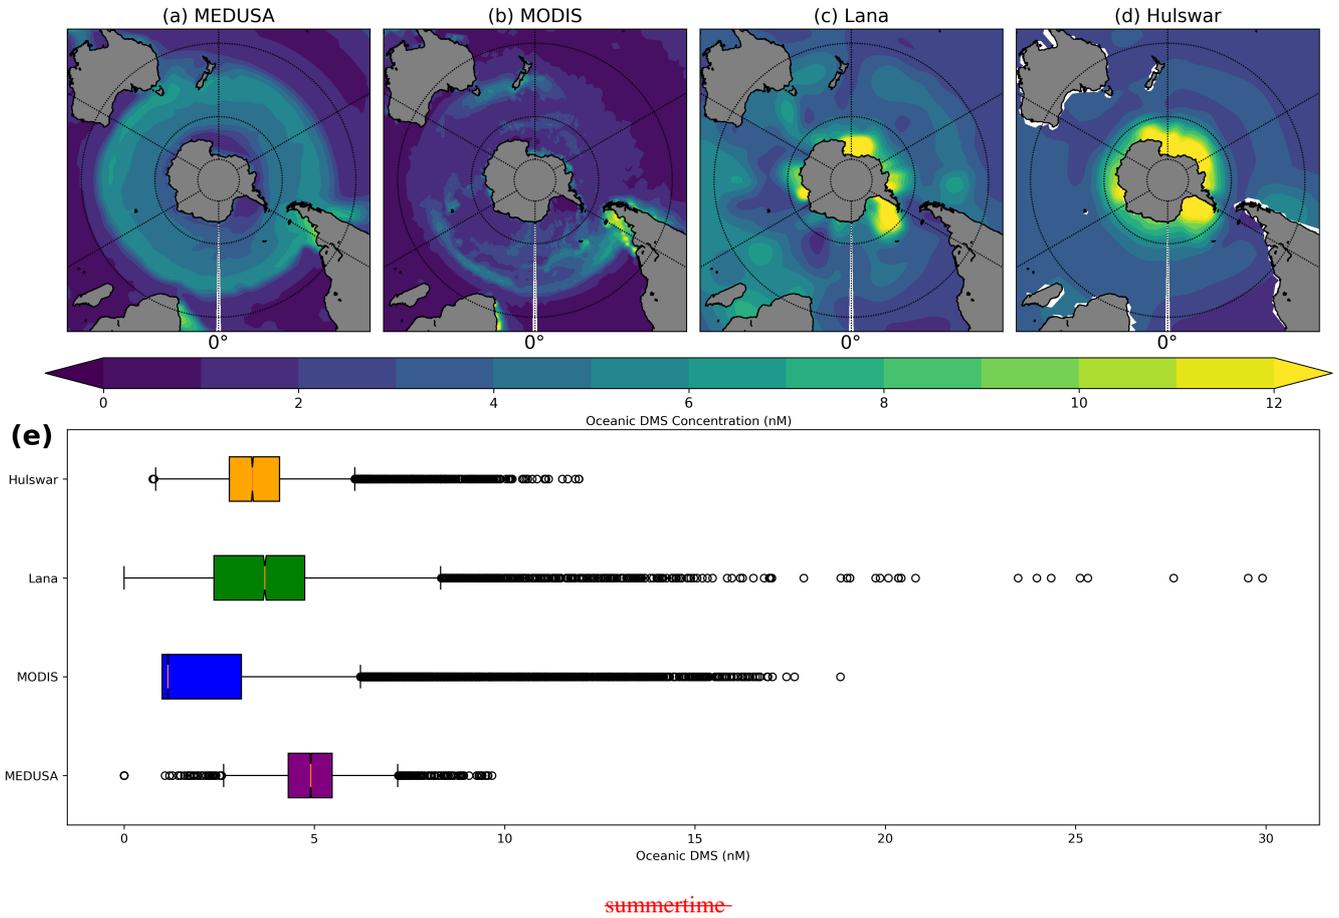

295 ~~MODIS and MEDUSA (the lowest and highest lowest (MODIS-DMS) and highest (MEDUSA) mean of all the oceanic DMS datasets used ) is 107%, respectively.~~

MEDUSA produces the most homogeneous oceanic DMS distribution in the summertime Southern Ocean, with the highest mean ~~of 4.88 nM. Additionally, it has the and~~ smallest standard deviation ~~of (4.88±0.87 nM (and)). It also has~~ the lowest CoV of ±17% indicating a small spread of variance). ~~The chl-<sub>a</sub> calculated by MEDUSA has in MEDUSA shows~~ a positive bias ~~when compared to against summer~~ observations in the Southern Ocean ~~during summer (Yool et al., 2013, 2021)~~ ~~, resulting in higher oceanic DMS concentrations than other datasets (Yool et al., 2013, 2021).~~ In contrast, ~~the~~ MODIS-DMS ~~dataset produces has~~ low oceanic DMS concentrations in open ocean regions, ~~but very and~~ high concentrations in biologically productive regions (near the subtropical front), such as the Chatham Rise and coastal South America (Behrens and Bostock, 2023). MODIS-DMS ~~exhibits large variability due to locally enhanced chl-<sub>a</sub> concentrations along coastal regions and the~~ ~~mid-latitudes (40-50 °S) of the Southern Ocean. Oceanic DMS from MODIS has a mean of has the largest spatial variability in~~ oceanic DMS overall (CoV 67%). ~~The mean oceanic DMS in MODIS-DMS is~~ 2.36±1.57 nM (CoV of 67%), which is outside the range of ~~oceanic DMS produced by~~ MEDUSA, highlighting the sensitivity of the Anderson et al. (2001) parameterization to ~~the chl-<sub>a</sub> concentration concentrations.~~

~~In the~~ MODIS-DMS ~~simulation,~~ oceanic DMS concentrations vary each ~~summertime summer~~ across the Southern Ocean ~~during the 10 year over a 10 year~~ climatology (See Figure ?? in the supplementary materials ?? a in the appendix). The year with the highest mean oceanic DMS concentration observed by the MODIS-DMS dataset (2.58±2.12 nM) occurred in 2010 (Figure ??), with a 16.2% higher concentration than the lowest concentration in 2015 (2.22±1.88 nM). The largest interannual variability in MODIS-DMS ~~most significant interannual variability~~ occurs around New Zealand and ~~the East Coast of South America and is likely caused by specific phytoplankton bloom events, possibly being~~ South America's East Coast, likely from ~~phytoplankton blooms~~ influenced by ENSO (e.g. Santoso et al., 2017; Thompson et al., 2015; Yoder and Kennelly, 2003) ~~. Oceanic DMS climatologies do not capture these inter-annual oceanic events. Furthermore, voyages that measure oceanic DMS often have specific research targets which can cause a sampling bias within the climatologies compiled from in-situ observations. Voyages also only collect data during specific months within specific regions. For example, the SOAP voyage targeted phytoplankton blooms and their accompanying high oceanic DMS concentrations (Bell et al., 2015).~~

320 ~~Factors such as melting sea ice can also affect chl-<sub>a</sub>, and therefore oceanic DMS (Behera et al., 2020; Berresheim et al., 1998) . Phytoplankton activity, such as bloom events, affect chl-<sub>a</sub> concentrations (e.g. Uhlig et al., 2019; Matrai et al., 1993) and will be captured by the MODIS-DMS simulations, but not by the climatologies; MEDUSA currently lacks the ability to represent realistic phytoplankton blooms in chl-<sub>a</sub> concentrations (Yool et al., 2021).~~

~~(Figure 2a). The~~ Lana and Hulswar ~~simulations~~ have similar means ~~and CoV, respectively, across the entire Southern Ocean during austral summer (3.87 nM and 3.51 nM; CoV of 31% and 32%). However, the distribution of both datasets , respectively) but differ in their distribution~~ (Figure 2e) ~~is different: Lana contains much higher concentrations, maximizing . Oceanic DMS maximises~~ at 30 nM ~~compared to in Lana, and at 14 nM from Hulswar. Using in Hulswar. The MEDUSA simulation using the Anderson et al. (2001) parameterization while changing the chl-<sub>a</sub> input, MEDUSA calculates a peak DMS concentration shows oceanic DMS maximising~~ at 11 nM, ~~whereas MODIS-DMS is 64% greater, maximizing while when a variable chl-<sub>a</sub>~~

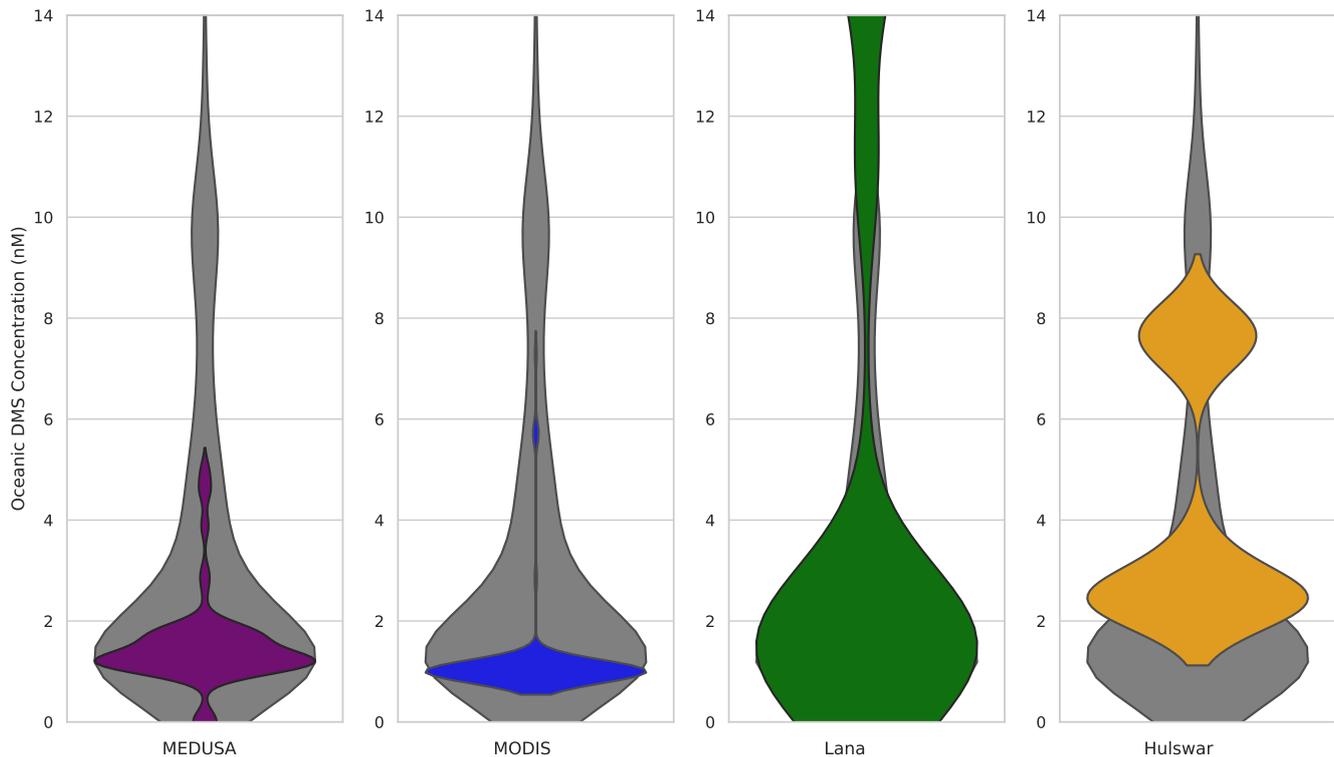

**Figure 2.** Summertime (DJF) Oceanic DMS in the Southern Ocean (40 - 60 °S). The spatial distribution (a-d) shows the (a) UKESM1 climatology from MEDUSA, (b) the climatology from MODIS-DMS, and observational-based climatologies of (c) Lana and (d) Hulswar. (e) The box plot shows the distribution of each oceanic DMS dataset used. ~~The data points outside the whiskers represent 0.7%, where MODIS-DMS contains all 10 years of the dataset data, highlighting while the outliers of the distribution climatologies contain 12 months.~~

330 concentration field is used in the MODIS-DMS simulation, oceanic DMS maximises at 18 nM (64% higher than in the MEDUSA simulation).

~~By examining localized oceanic DMS measurements within the Southern Ocean obtained during the~~ To examine how the  
~~simulations compare with observations, we compare the oceanic DMS distribution against TAN1802 and SOAP voyages for~~ the regions and times at which those voyages took place (Figure 3) ~~and SOAP (, Figure 4)~~ voyages in comparison to each  
335 ~~model input data, we can determine the variations across each simulation. The oceanic DMS from the model overlays the~~  
~~respective voyage data (grey) in Figure 3 and Figure 4. Lana fits.~~ For the TAN1802 voyage (40–70°S, 180°E), the distribution  
~~of TAN1802 more closely than the other datasets, as illustrated by the higher DMS concentrations. The differences between the~~  
~~two climatologies are a result of additional observational datasets within Hulswar.~~ measured oceanic DMS aligns closely with  
the Lana simulation. MODIS-DMS and MEDUSA have ~~the lowest means,~~ lower means of 1.19 and 1.52 nM, respectively, but  
340 MODIS-DMS has a ~~higher~~ high CoV of 79% due to higher concentrations at lower latitudes (45 °S) of the Southern Ocean.  
~~TAN1802 has a CoV of 105%, similar to Lana's 114%. Hulswar~~ Oceanic DMS in the Hulswar simulation overestimates DMS  
concentrations by a factor of two between ~~45 and 65~~ 45–65 °S. ~~Observation-based climatologies capture high oceanic DMS~~  
~~concentrations better than parameterization-based concentrations, as illustrated by the violin plot in Figure 3.~~

~~SOAP voyage data represents oceanic DMS concentrations during~~ For the SOAP voyage, which targeted phytoplankton  
345 ~~bloom events , therefore the shape of the observed DMS distribution (Fig. 4) is quite different to~~ (42–47°S, 172–180°E),  
~~the measured DMS distribution is skewed toward higher concentrations compared with the TAN1802 data (Fig. 3) and would~~  
~~be expected to be highly biased. All of the oceanic DMS datasets~~ voyage (Figure 4). In contrast, TAN1802 transected the  
Southern Ocean without specific focus on bloom activity, yielding a range of DMS concentrations. We consider that SOAP is  
still useful as it offers insights into extreme conditions not reflected in other data sets. All simulations fail to capture the higher  
350 ~~concentrations measured by SOAP, displaying a positively skewed distribution (Bell et al., 2015); with most concentrations~~  
~~clustered between 2–4 nM.~~ Oceanic DMS in the MODIS-DMS has the greatest exhibits the highest variability (CoV of 36%),  
~~highest average, and largest mean, and~~ maximum concentration. MODIS-DMS also ~~has the best linear relationship~~ aligns  
best with SOAP, ~~where in~~ that it captures some of the high DMS concentrations resulting from phytoplankton blooms. The  
~~MODIS-DMS follows the concentrations through space and time better than the other datasets. For example, when SOAP~~  
355 ~~measures its lowest oceanic DMS concentrations following the voyage, simulation captures around half of the variability of~~  
~~SOAP measurements, whereas the other simulations only match between 7% to 18%. MODIS-DMS also simulates its lowest~~  
~~concentrations. Additionally, when SOAP observations are at their highest concentrations (25 nM), MODIS-DMS displays its~~  
~~highest concentration (over 10 nM)~~ is within 11% of the SOAP mean, whereas the other simulations are 22% to 218% lower.  
See Figure ?? and ?? for simulated comparisons of DMS emission to SOAP and TAN1802.

360 ~~Lana, Hulswar, and MEDUSA fail to represent high biological variability in the Chatham Rise region of the Southern~~  
~~Ocean, as confirmed via comparison with TAN1802 between 45 °S to 60 °S. MODIS-DMS does not capture the heightened~~  
~~concentrations from SOAP or TAN1802, but it aligns more closely with the observations than the climatologies. This is likely~~  
~~due to the MODIS-DMS simulations using the chl-*a* data during the period of each voyage, and nudging model conditions to~~

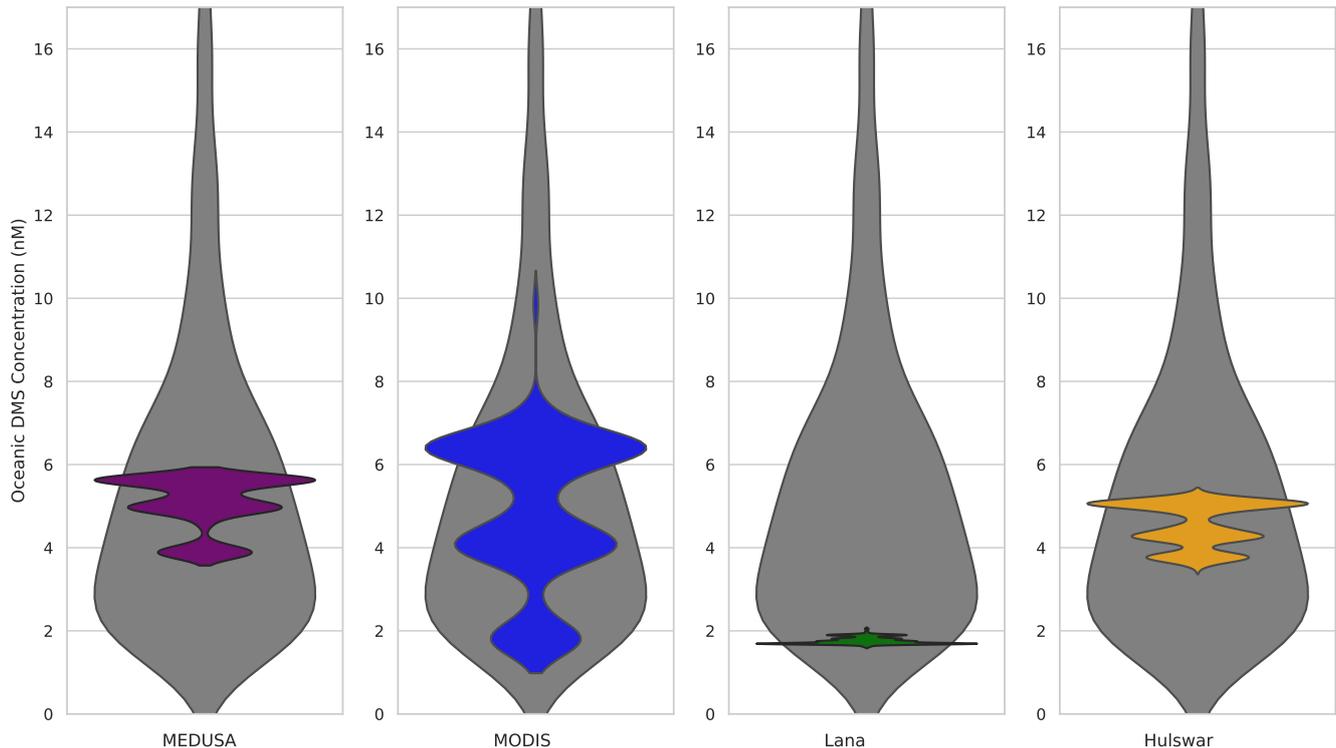

**Figure 3.** Violin plots of TAN1802 data (grey). Overlaid are the oceanic DMS datasets used in the model simulations (Feb to March 2018, 40 °S to 70 °S, 180 °E) from MEDUSA (purple), MODIS-DMS (blue), Lana (green), and Hulswar (yellow). Violin plots depict data distribution and density. The width of each 'violin' corresponds to the frequency of data points within that value range, while the length indicates the range of values. The frequency axis, represented by the width, allows for an immediate visual comparison of how often particular ranges of values occur in each category. This offers a comprehensive view of both the distribution and frequency of data across different categories.

similar conditions. From this, implementing the inclusion of satellite chl-*a* in oceanic DMS calculations improves the accuracy of DMS distribution in lower latitudes.

365

The Anderson et al. (2001) oceanic DMS parameterization assumes chl-*a* has a central role in forming oceanic DMS. The known global correlation is central to oceanic DMS formation. Previous correlations between chl-*a* and oceanic DMS, described given by the coefficient of determination ( $r^2$ ), is between range globally from 0.11 to 0.818, where higher latitudes tend to have higher  $r^2$  0.93, with higher latitudes having increased  $R^2$  values due to factors like nutrient availability and prolonged summer daylight, coupled with heightened wind speeds (Uhlig et al., 2019; Townsend and Keller, 1996; Tison et al., 2010; Ma-  
 370 traï et al., 1993). The Anderson et al. (2001) parameterization used Gros et al. (2023) estimated an  $R^2$  of 0.93 towards sea ice latitudes, while Bell et al. (2021) found chl-*a* explains just 15% of oceanic DMS variability. Using the Anderson et al. (2001) parameterization in MODIS-DMS, has a strong  $r^2$  we determined a large  $R^2$  value of 0.75 in the Southern Ocean, validating

**Figure 4.** Same as Figure 3, but for the SOAP 2012 voyage (Feb to March 2012, 42–47 °S, 172–180 °E).

375 ~~this parameterization for simulating oceanic DMS. The Anderson et al. (2001) parameterization using~~ While associating  
~~chl-*a* with oceanic DMS has discrepancies (Gros et al., 2023; Bell et al., 2021), we show that using Anderson et al. (2001)~~  
~~with satellite chl-*a* provides a better representation of austral summer oceanic DMS conditions within the Southern Ocean data~~  
~~better represents Southern Ocean summertime DMS compared with the Anderson et al. (2001)-MEDUSA configuration.~~

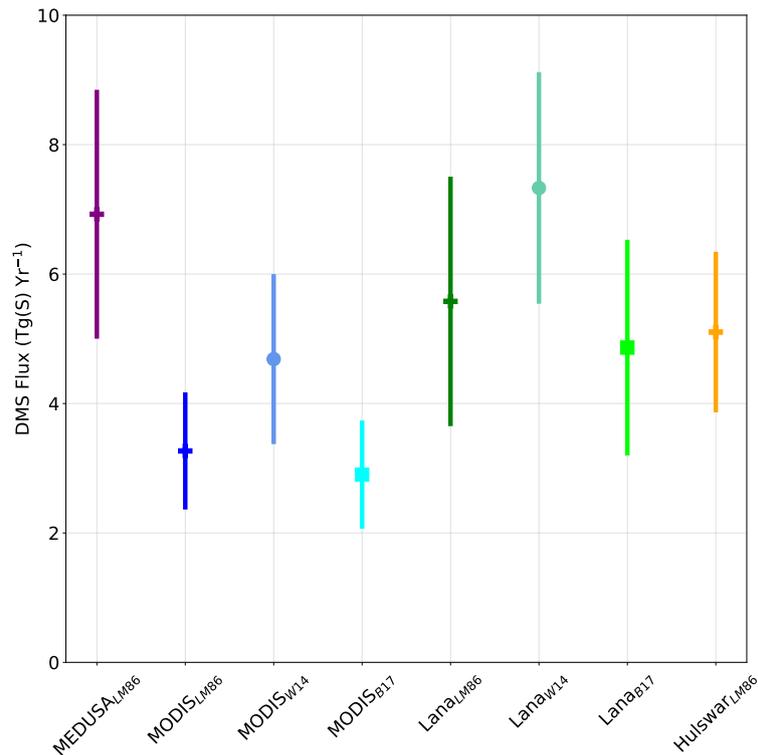

380 ~~Chl-*a* is used to calculate oceanic DMS within half the Earth System Models in two of the four ESMs with interactive~~  
~~biogeochemistry participating in CMIP6 (Bock et al., 2021). These models reveal discrepancies between each other and~~  
~~observed oceanic DMS data sets, indicating ongoing uncertainties in CMIP6 ESMs concerning oceanic DMS and its flux~~  
~~to the atmosphere (Bock et al., 2021). Bock et al. (2021) emphasizes the need for enhanced understanding and observations to~~  
~~accurately capture DMS–climate feedbacks. CNRM-ESM2-1 uses a comprehensive prognostic approach that considers grazing~~  
~~by adopts an approach considering zooplankton and DMSP, rather than chl-*a*. However, this is very difficult to validate~~  
~~due to the lack of widespread data availability. Here we suggest that a realistic biological proxy, such as chl-*a*, is useful to~~  
385 ~~construct an oceanic DMS dataset, but its validation is challenging due to limited observational data (Belviso et al., 2012).~~  
~~NorESM2 uses an alternative mechanism for DMS production, by using detritus export production and sea surface temperature~~  
~~(Tjiputra et al., 2020). An oceanic DMS algorithm developed by Galí et al. (2018) includes sea-surface temperature, chl-*a*,~~  
~~photosynthetically active radiation, and the mixed layer depth, where but oceanic DMS has a general overestimation along~~

coastal regions (Galí et al., 2019; Hayashida et al., 2020). Galí et al. (2018) also produced a time series of oceanic DMS  
390 over parts of the Northern Hemisphere, finding similar high inter-annual variability by using chl-*a* satellite data. ~~We concur~~  
~~with Galí et al. (2018) that a move beyond classical climatologies is an important step in developing future climate models.~~  
~~We suggest using temporally varying input instead of climatology to allow the capture~~ Adopting temporally variable oceanic  
DMS inputs within the model may better reflect inter-annual ~~variability over the Southern Ocean, particularly from Southern~~  
Ocean variability due to ENSO events and biologically productive years. One such way to achieve this for future projections  
395 would be through a stochastic approach of capturing all chl-*a* years from the satellite (e.g. SeaWiFS and MODIS-aqua) archive,  
~~including high biological productivity years, such as 2010 and 2020, or low productivity such as in 2015 (Figure ??).~~

### 3.2 DMS Flux

Having established that ~~the oceanic DMS from the MODIS-DMS data set produces simulated oceanic DMS in good agreement~~  
~~with observations (simulation aligns well with summertime observational voyages as seen in Figure 3), we now test~~, 4, we  
400 now assess the sensitivity of atmospheric DMS to ~~a suite of various~~ sea-to-air transfer functions ~~for different oceanic DMS~~  
~~sources (Figure 5, ??)~~. Figure 5 shows the DMS flux during ~~austral summer across all simulations integrated over the austral~~  
summer in the Southern Ocean ~~region (40 to 60 °S), which ranges, on average, , averaging~~ between 2.9 to 7.3 TgS Yr<sup>-1</sup>. ~~The~~  
~~spread of~~ This is consistent with Jarníková and Tortell (2016) estimation of 3.4 Tg S, aligning most with the MODIS-DMS  
linear parameterizations (LM86 and B17). The spread in average Southern Ocean summertime DMS fluxes across the mean  
405 fluxes across all eight simulations is 153%, which is greater than the ~~difference spread~~ between all the ~~oceanic DMS inputs, a~~  
simulations testing different oceanic DMS sources, at 107% ~~spread in mean oceanic DMS concentration~~. The lowest ~~CoV value~~  
CoVs within both oceanic DMS and DMS emissions are found in the MODIS-DMS simulations, specifically, the Blomquist  
et al. (2017) parameterization (MODIS<sub>B17</sub>) with a mean of  $2.9 \pm 0.84$  TgS Yr<sup>-1</sup>. The upper range of simulated DMS flux,  $7.3$   
 $\pm 1.8$  TgS Yr<sup>-1</sup>, comes from the W14 quadratic formula used with the Lana DMS climatology (Lana<sub>W14</sub>).

410 The largest DMS emissions are seen in the MEDUSA<sub>LM86</sub> simulations, due to the relatively large underlying seawater  
DMS source spread throughout the Southern Ocean (Figure 2a). The Lana<sub>w14</sub> simulation also shows large DMS emissions  
due to the quadratic dependence of the gas transfer velocity on wind speed (Figure 1). Overall, the W14 quadratic formula  
yields about 33% more emissions than the LM86 has a and B17 linear formulas. For the transfer velocity parameterizations  
using a linear relationship to wind (LM86 and B17), LM86 exhibits a higher transfer velocity than B17 for wind speeds  
415 greater than above 7.5 m s<sup>-1</sup> (Figure 1). ~~The Southern Ocean has the highest wind speeds over any ocean region, with wind~~  
~~speeds very frequently above 7.5 m s<sup>-1</sup> (Bracegirdle et al., 2020b), therefore our simulations show Liss and Merlivat (1986)~~  
~~flux produces~~ Given the Southern Ocean's predominant high wind speeds (Bracegirdle et al., 2020a), simulations indicate that  
LM86 yields 14% more emissions of DMS than Blomquist et al. (2017) emitted DMS than B17 (Figure 1). Lana is widely  
used by climate models (e.g. Sellar et al., 2019; Horowitz et al., 2020; Bhatti et al., 2022). Implementing a DMS flux based on  
420 DMS observations within this climatology (Lana<sub>B17</sub>) results in a  $4.86 \pm 1.67$  TgS Yr<sup>-1</sup> flux, which is within the range of all  
the simulations (Figure 5).

**Figure 5.** Summertime (December – February) Southern Ocean sulfur emissions in  $\text{Tg Year}^{-1}$  in all model simulations performed. The error bars represent the spatial and temporal standard deviation. The different colors represent different oceanic DMS climatologies (Purple: MEDUSA ((Sellar et al., 2019; Anderson et al., 2001), Green: (Lana et al., 2011) and Orange: Hulswar ((Hulswar et al., 2022), and time series (Blue: derived from MODIS-DMS chl- $a$ ) used in this work. + marker represents simulations performed with the Liss and Merlivat (1986) sea-to-air flux, the dot marker represents Wanninkhof (2014), and the square marker represents Blomquist et al. (2017).

For simulations using the same The LM86 sea-to-air flux parameterizations, but different flux parameterisation was tested with all oceanic DMS sources, the spread of all means is as it is currently the parameterisation used by default in UKESM1-AMIP. Simulations using LM86 have a spread in average summertime Southern Ocean DMS emissions of 112% (3.3 to 6.9  $\text{TgS Yr}^{-1}$ ).

425 The means derived from different DMS In contrast, simulations using the same oceanic DMS source (MODIS-DMS and Lana) but flux parameterizations (LM86, B17, and W14) within MODIS-DMS and Lana are spread between have a spread in average summertime Southern Ocean DMS emissions of 51% (MODIS-DMS simulations) to 62% (Lana simulations). The choice of the oceanic DMS source is therefore more important than the choice of DMS emission flux. Changing oceanic DMS within the model produces a larger impact on the resultant atmospheric DMS than the flux parameterization used. The emission of DMS

430 from the ocean, over the Southern Ocean, results in a slightly higher spread between all the simulations of 6%. For a given oceanic DMS source, the quadratic formula of W14 produces around 33% more DMS emissions than the linear formulas of LM86 and B17 therefore impacts DMS emissions more than the transfer velocity parameterization within these simulations.

The selection of a DMS flux parameterization has a large impact on the emissions of oceanic DMS. The W14 parameterization generates excessive DMS emissions, accurately representing the highest 10% (see Figure ??) but overestimating the rest of the distribution. Using W14, or similar quadratic fluxes (such as Nightingale et al. (2000)) within climate models for DMS emissions could therefore result in an overproduction of DMS. See Figure ?? for a visual overview of DMS across all simulations.

Table 3 presents simulated daily Southern Ocean DMS fluxes details simulated daily DMS fluxes over the Western Antarctic Peninsula during the austral summer. The total annual DMS emissions which occur during DJF are presented as a percentage and as a daily flux. DMS emissions during austral summer make up 32-46, for comparison with observations, including Webb et al. (2019). DMS emissions in this period constitute 33-52% of the annual flux, substantially lower than contrasting with the 72% reported by Webb et al. (2019). However, Webb et al. (2019) measured DMS in Ryder Bay, near the Antarctic Peninsula (67.54 °S, 68.35 °W), an area known for high levels of sea-ice melt and high DMS emissions during DJF. Our simulations daily mean flux from our simulations during DJF is  $22.2-4.6 \pm 5.13-4 \mu\text{mol m}^{-2} \text{d}^{-1}$ . Compared with the 22.7, below Webb et al. (2019)'s  $29 \mu\text{mol m}^{-2} \text{d}^{-1}$  flux reported by Webb et al. (2019) for Ryder Bay during the summer, our simulations therefore represent fluxes within the expected range. Additionally, a (67.54 °S, 68.35 °W). However, our results align with the emissions from Jarníková and Tortell (2016); Berresheim et al. (1998); Asher et al. (2017). Like in Jarníková and Tortell (2016) and Webb et al. (2019), we find periodic hot spots of DMS emissions above  $50 \mu\text{mol m}^{-2} \text{d}^{-1}$  over these sub-Antarctic regions, but at 10% the magnitude of the maximum found by Webb et al. (2019).

A 2018 Southern Ocean voyage during February calculated reported a mean daily flux to be between of  $2.6 \pm 3.5 \mu\text{mol m}^{-2} \text{d}^{-1}$  within over the open ocean (Zhang et al., 2020). Tracking this voyage through space and time with our simulations shows fluxes varied between Our simulations are in good agreement with this, showing DMS fluxes of  $2.7 \mu\text{mol m}^{-2} \text{d}^{-1}$  from (MODIS<sub>B17</sub>) to  $8.9 \mu\text{mol m}^{-2} \text{d}^{-1}$  in (Lana<sub>W14</sub>) for the same region and period of time. Shon et al. (2001) estimated the daily flux between 40 °S to 55 °S around early December to be a daily flux of  $2.6 \pm 1.8 \mu\text{mol m}^{-2} \text{d}^{-1}$ . Only around early December. Only the MODIS<sub>B17</sub> coincides with simulation matches these daily fluxes across this latitudinal region. Our. Furthermore, the linear MODIS-DMS simulations using a linear flux parameterisation (LM86 and B17) also align (MODIS<sub>LM86</sub> and MODIS<sub>B17</sub>) are in good agreement with the  $12 \pm 15 \mu\text{mol m}^{-2} \text{d}^{-1}$  measured by Marandino et al. (2009) and the  $2.8 \mu\text{mol m}^{-2} \text{d}^{-1}$  measured by Lee et al. (2010) in the Southern Ocean.

Pandis et al. (1994) estimates that for aerosol nucleation to occur from DMS emissions, the flux must be above  $2.5 \mu\text{mol m}^{-2} \text{d}^{-1}$ . Our simulations show that DMS emissions are above this threshold between 52% (MODIS<sub>B17</sub>) and 88% of the time (MEDUSA<sub>LM86</sub>) during summertime. This range agrees with Webb et al. (2019), who measured the flux to be over this threshold around 63% of the year. MODIS<sub>LM86</sub> (at 61%) and Lana<sub>LM86</sub> (at 62%) compare best to the observed value, although Webb et al. (2019) is likely positively skewed based on their location in an area characterised by large DMS emissions. As the UKESM1 underestimates AOD during austral summer (Mulleahy et al., 2020), MEDUSA<sub>LM86</sub> also produces the highest daily DMS flux over the Southern Ocean, suggesting a bias may be present during the formation of aerosols. This may be a result of the chemistry scheme used in the formation of aerosols as a compensating bias, which will be addressed in future work.

**Table 3.** Mean daily DMS flux over the Southern Ocean-Western Antarctic Peninsula, by Ryder Bay during the austral summer period for each simulation. The percentage shows the proportions of the total annual DMS flux which occurs during the summer months. Additionally, the total DJF flux shows the mean daily DMS flux ( $\mu\text{mol m}^{-2} \text{d}^{-1}$ ) and standard deviations. ~~The last row outlines the overall DMS flux volume, simulated above the  $2.5 \mu\text{mol m}^{-2} \text{d}^{-1}$  threshold for aerosol nucleation to occur from DMS emissions, as a percentage.~~

Many CMIP6 models use the quadratic sea-to-air flux parameterization detailed in Wanninkhof (2014) ~~to calculate for~~ DMS emissions (e.g. Salzmann et al., 2022; Seland et al., 2019; Neubauer et al., 2019; Tatebe and Watanabe, 2018; Wu et al., 2019); ~~however, recent literature suggests that DMS has.~~ Yet, recent studies indicate a linear relationship with between DMS and wind speed (e.g. Blomquist et al., 2017; Goddijn-Murphy et al., 2016; Bell et al., 2013; Zavarsky et al., 2018; Vlahos and Monahan, 2009; Bell et al., 2015). We ~~show demonstrate~~ that linear DMS ~~emissions may not represent the upper ranges of~~ DMS flux as well as quadratic flux emissions, where wind and oceanic DMS concentrations are high. Extreme concentrations of oceanic DMS can result in very high emissions. Lana<sub>W14</sub> simulates these higher concentrations similar to the higher fluxes from TAN1802 (Figure ??) but result in an overestimation for the lower emissions of the distribution. MEDUSA<sub>LM86</sub> emits DMS similarly to the quadratic formulation of Lana<sub>W14</sub>, within the higher ranges of emissions. Therefore, using a formula developed specifically for DMS, such as Blomquist et al. (2017) may generally better represent DMS emissions in the UKESM1. Additionally, simulations of atmospheric DMS with UKESM1 are improved when using observed chl-*a* concentrations to calculate historical oceanic DMS transfer velocities represent the DMS flux ranges better than the quadratic W14 flux when compared to Southern Ocean observations.

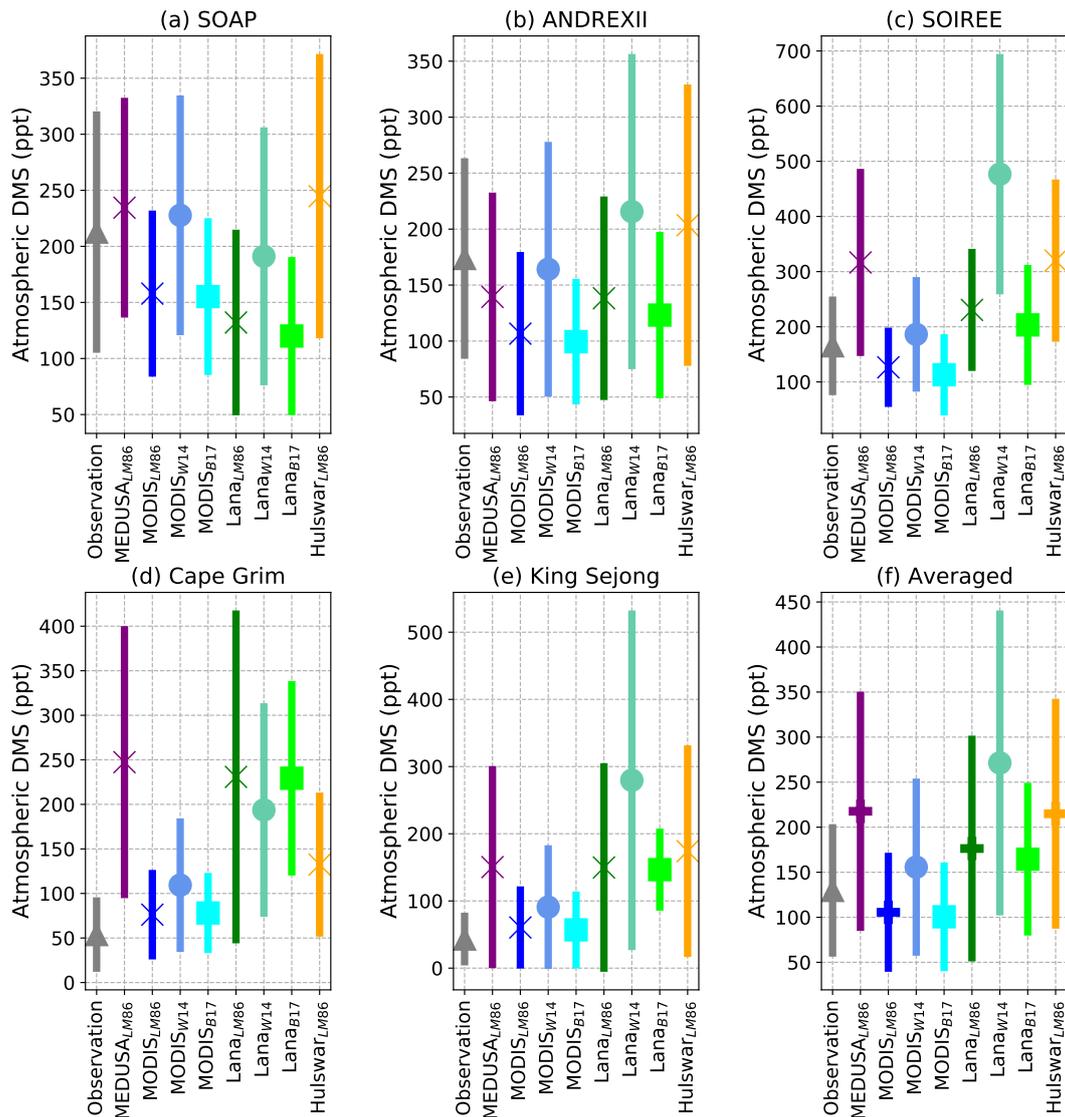

### 480 3.3 Atmospheric DMS

~~We now~~ We next evaluate atmospheric DMS in our sensitivity simulations. Figure 6 compares all simulated atmospheric DMS concentrations to observational data averaged across the Southern Ocean during austral summer. The observational data shown with observational datasets. Data in Figure 6 ~~was collated from three observational stations (Cape Grim, Amsterdam Island, and King Sejong Station) and three is from three~~ Southern Ocean voyages (SOAP, SOIREE, and ANDREXII), with an average and a standard deviation (spatial and temporal) summertime atmospheric DMS concentration of  $185 \pm$  ANDREXII; Figure 6a-c) and two stations (Cape Grim and King Sejong Station; Figure 6d-e). Figure 6f shows aggregate averaged DMS concentrations from all five observational sources, and has an average summertime concentration of 129 ppt (Smith et al., 2018; Wohl et al., 2020; Boyd and Law ~~.~~ The mean atmospheric DMS across all simulations is  $276 \pm 174$  ppt, and is within the range of the observations. In addition, when using the DMS source in best agreement with oceanic observations ( $74$  ppt (Smith et al., 2018; Wohl et al., 2020; Boyd and Law, 200 . The simulations using the MODIS-DMS ~~) combined with a linear DMS flux parameterisation oceanic source and linear DMS transfer models (LM86 and B17)~~ ), the atmospheric concentration mean is consistent show the closest agreement with the observational mean, averaging 164 of 106  $\pm 132$  ppt. Along the Peruvian coastline, Zhao et al. (2022) measured atmospheric

DMS concentrations at  $145 \pm 66$  ppt and  $100 \pm 95$  ppt, which also aligns well with the linear MODIS-DMS simulations. During the summer months, 60 ppt for MODIS<sub>LM86</sub> and MODIS<sub>B17</sub>, respectively. The mean total spread in summertime Southern Ocean atmospheric DMS across all simulations is 171%, compared with the spread of 153% in DMS emissions.

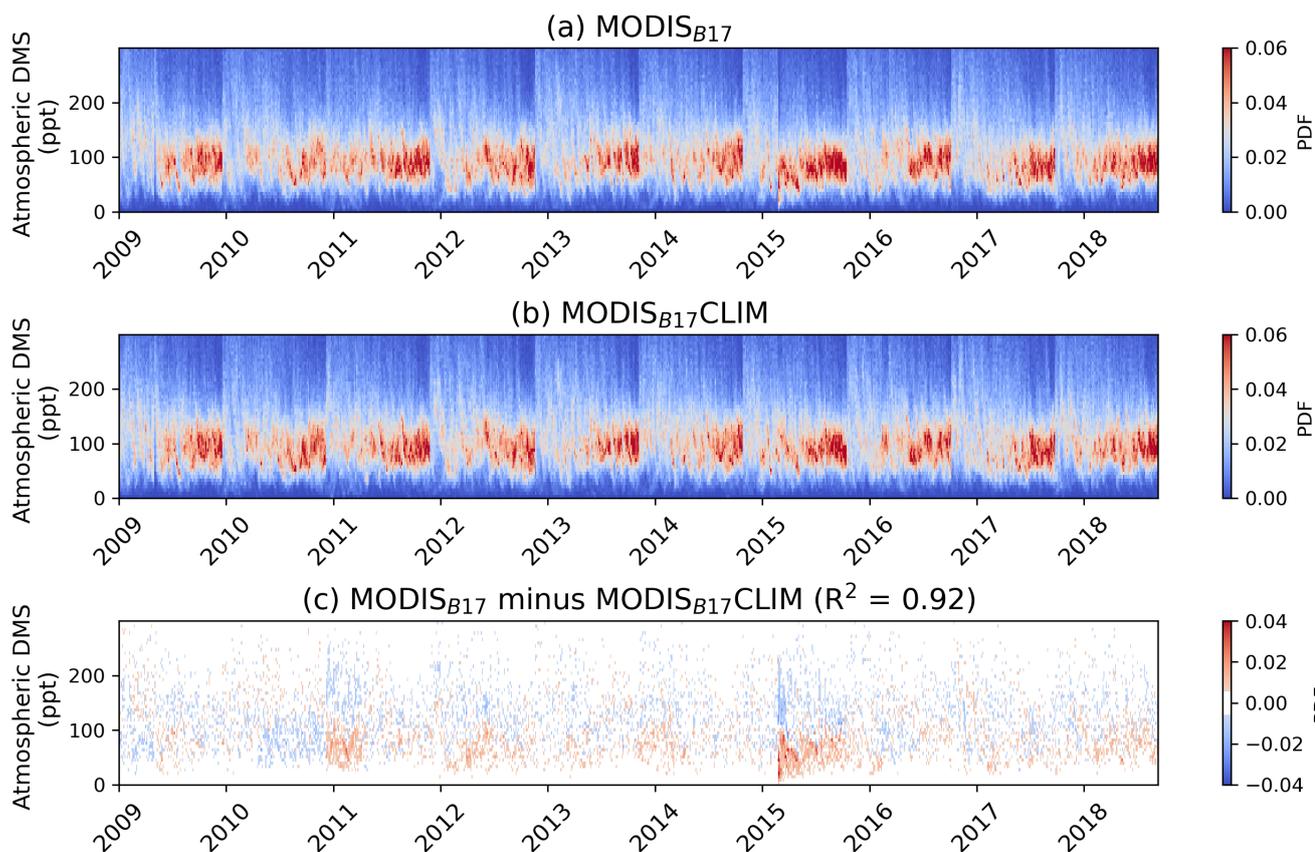

Our simulations, compared to coastal Antarctic measurements, offer insights into the performance of sea ice-influenced regions (Galí et al., 2021). In summer, Berresheim et al. (1998) recorded mean atmospheric DMS concentrations of 119 ppt (measured at 64.8 °S, 64 °W) by Berresheim et al. (1998) and 114 ppt (measured, closely matching MODIS<sub>B17</sub> at 121 ppt. All other DMS sources show concentrations which are more than twice as large as this measurement. Read et al. (2008) measured atmospheric DMS concentrations of  $45 \pm 50$  ppt at Halley Station, Antarctica (75.4 °S, 26.2 °W) by Read et al. (2008) align best with the MODIS-DMS simulations. Additionally, Lee et al. (2010) measured a mean of 61 ppt over the same high latitudes in February. However, there are also disagreements between observations and MODIS-DMS simulations with linear fluxes, as a voyage tracking along the Eastern South Pacific Ocean during January 2000 measured 340, best aligning with Lana<sub>B17</sub> at 42 ppt. It should be noted that all simulations fall within one standard deviation of the measurements reported at Halley Station. Preunkert et al. (2007) measured high interannual variation of atmospheric DMS at Dumont d'Urville (66.4 °S, 140 °E) during January, from 244 ppt in 2002 to only 60 ppt in 2003. The average January concentration over 13 years was  $170 \pm 370$  ppt (Marandino et al., 2009), which is consistent with Lana<sub>B17</sub> 180 ppt. Here, the Lana and Hulswar simulations are in closest agreement, and simulate average DMS concentrations between 92 and 141 ppt. Lastly, Lee et al. (2010) measured a 61 ppt average over the Pacific Southern Ocean in February, closest to MODIS<sub>B17</sub> and MODIS<sub>LM86</sub>, but not as high as Lana<sub>WT</sub>. The variability from Amsterdam Island measurements is much higher than that of the simulations. (64 and 53 ppt, respectively).

These measurements highlight the high variability of atmospheric DMS. Multi-annual studies emphasize high yearly variability (Read et al., 2008; Preunkert et al., 2007). Measurements during austral summer over the Southern Ocean show significant variability, especially in higher latitudes. The climatologies produce higher concentrations along the coastal regions of Antarctica, as illustrated in Figure 2a-d, but MODIS-DMS still captures much of the spatial variability (Figure ??). MEDUSA performs the worst over these higher latitude regions, where sea ice can have a large role in producing atmospheric DMS (Galí et al., 2021). Berresheim (1987) measured 106 ppt over the Drake passage during March and April, representing the lower end of our simulated DMS mixing ratio. All measurements during summer show very high variability, with lower values seen in higher latitudes. MODIS<sub>B17</sub> does a better job of representing atmospheric DMS compared to simulations from other represents atmospheric DMS more accurately than models like MEDUSA, Lana, and Hulswar when compared to observations based on observations over the Southern Ocean during summertime.

**Figure 6.** Five observational datasets measuring atmospheric DMS concentrations (ppt) are directly compared with the eight simulations (a – e) at the same spatial and temporal resolution. In (a) SOAP and (b) ANDREXII, we follow both voyages using the nearest grid cell along each hour of the simulations, matching the timescales in 2012 and 2019. For comparing the simulations with the (c) SOIREE voyage, we also follow this voyage in an hourly timescale, but due to the voyage being outside our study period, we average this over all 10 years. The two observational stations used are (d) Cape Grim and (e) King Sejong Station. We calculate the nearest grid-cell for each simulation to the observational station and constructed an average over 10 years along with a temporal standard deviation. From this, we construct an overall average (f) and standard deviation for all observational measurements and simulations which can be compared directly to these observations.

### 3.4 Effects from Inter-annual and Spatial Variability

DJF-averaged

**Figure 7.** Time series of the atmospheric concentration-DMS probability density function between (ppt) for the nine simulations. The observations represent a summertime average across Cape Grim, Amsterdam Island, MODIS<sub>B17</sub> and King Sejong Station and three (b) MODIS<sub>B17</sub>CLIM from 2009 to 2018 summer over the entire Southern Ocean voyages (SOAP, SOIREE, and ANDREXIIc). The error bars represent the standard deviation through time difference between MODIS<sub>B17</sub> and space MODIS<sub>B17</sub>CLIM is also shown, with the R<sup>2</sup> shown between the two simulations.

So far we have focused on DMS, which is an important biogenic marine aerosol precursor. However, the development of To assess the impact of interannual variability in oceanic DMS on simulated atmospheric DMS, we compare the MODIS<sub>B17</sub> simulation with MODIS<sub>B17</sub>CLIM, which used a climatology of oceanic DMS calculated from the MODIS-DMS data set has implications for primary marine organic aerosol (PMOA), whose production is influenced by (Figure 7). Both simulations are similar (R<sup>2</sup> = 0.92) in terms of interannual variability across the Southern Ocean as a whole. (Figure 7c). Rolling means are presented in Figure ??b, c. While there are small differences in Southern Ocean atmospheric DMS between the simulations, the overwhelming similarities between Figure 7a and b suggest that an oceanic DMS climatology results in similar interannual

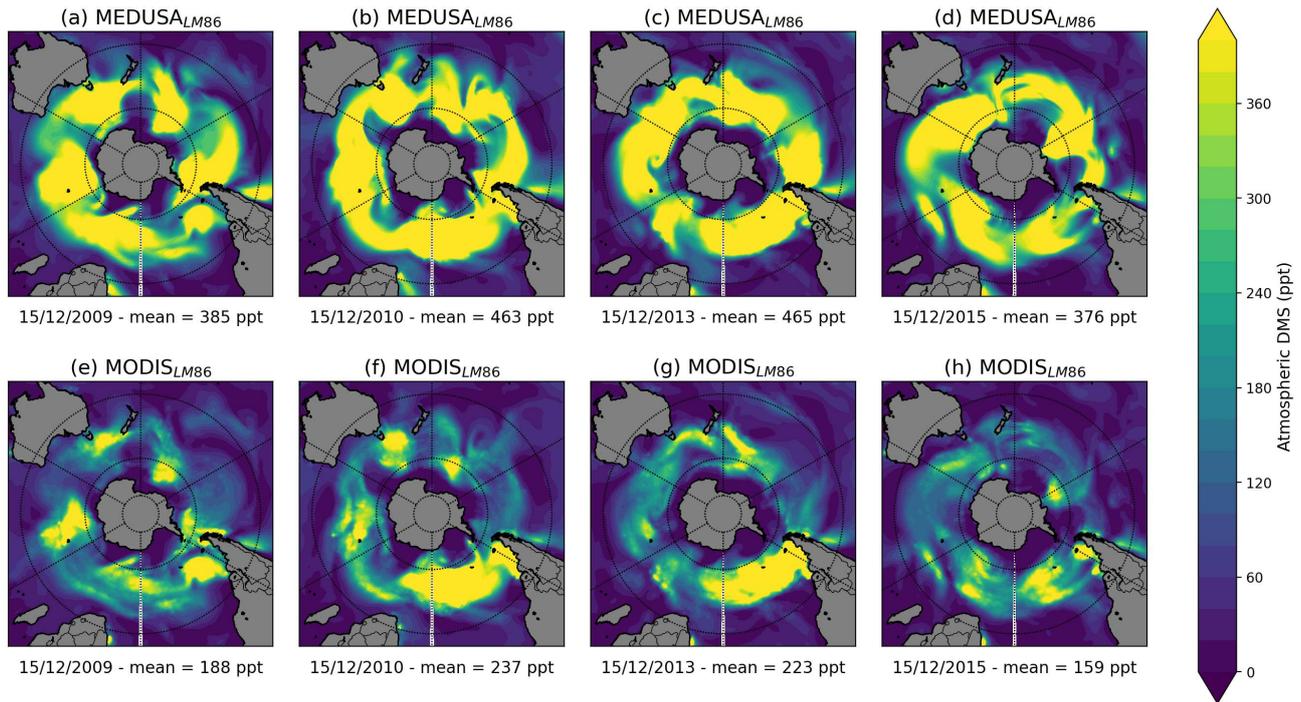

525

530 variability in the atmospheric DMS PDF suggesting that oceanic DMS is not a strong driver of interannual variability in atmospheric DMS. This result is in contrast to that of Galí et al. (2018) who used a different algorithm for producing oceanic DMS. This difference may be due to our use of the Anderson et al. (2001) algorithm, which is known to produce limited variability (Belviso et al., 2004; Bock et al., 2021).

535 To assess the impact of spatial variability in oceanic DMS on simulated atmospheric DMS, we compare simulations performed using the MEDUSA and MODIS-DMS data sets (with low and high spatial variability in oceanic DMS, respectively) in Figure 8. Larger variability in the MODIS-DMS oceanic DMS source leads to larger variability in simulated atmospheric DMS, compared with the MEDUSA simulations. The spatial CoV from MEDUSA<sub>LM86</sub> is 45% lower than MODIS<sub>LM86</sub>, showing greater spatial variability from MODIS-derived ~~chl-*a* concentration in UKESM1 (Mulcahy et al., 2020). PMOA are organic detritus or compounds that are emitted to the atmosphere when bubbles burst as waves break (Gantt et al., 2012, 2014)~~

540 ~~–A parametrisation of PMOA has been implemented in the UKESM1 in Mulcahy et al. (2020) based on the parametrisation developed by Gantt et al. (2011), where PMOA is a function of wind speed, sea salt dry diameter, and surface chl-*a*. As identified by Mulcahy et al. (2020), the MEDUSA chl-*a* bias is carried through to PMOA which results in a Southern Ocean distribution similar to that of oceanic DMS. The oceanic DMS signal in the atmosphere is strong but includes large fluctuations the wind.~~

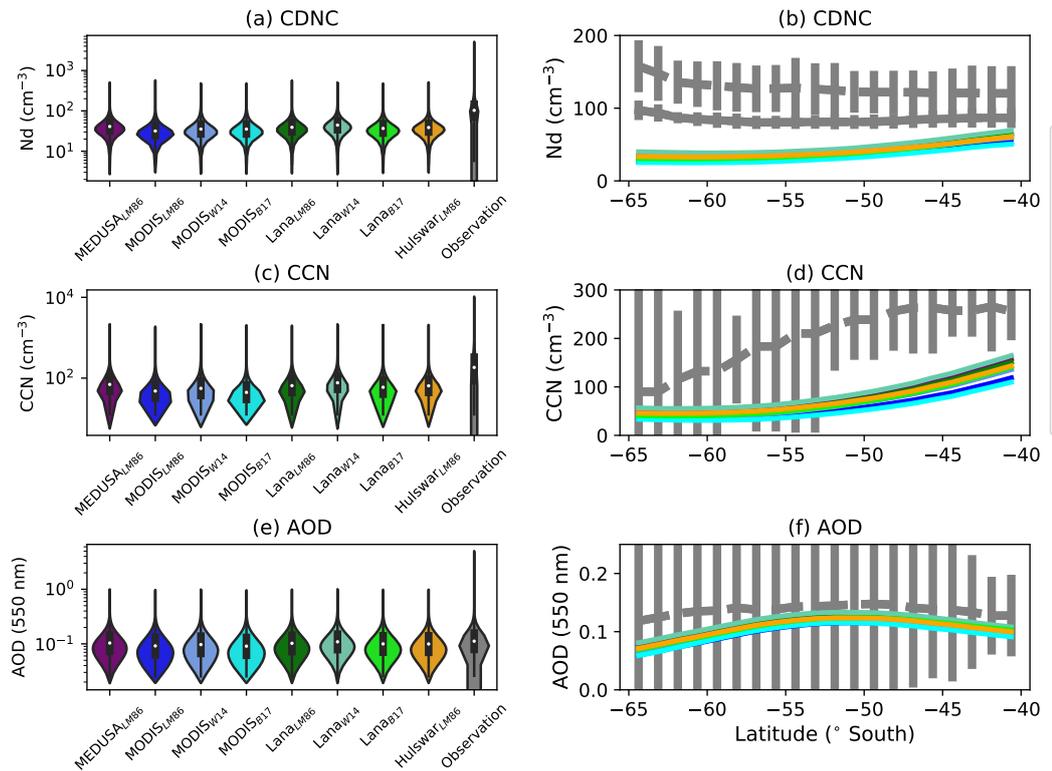

545 ~~PMOA is the dominant source of ice nucleating particles over the Southern Ocean (Vergara-Temprado et al., 2018; Zhao et al., 2021) which may reduce the downwelling shortwave radiation bias (Schuddeboom and McDonald, 2021; Fan et al., 2011; Fiddes et al., 2022) –This shortwave bias may have links to a deficit in supercooled liquid~~

**Figure 8.** Atmospheric DMS concentrations comparing (a - d) MEDUSA<sub>LM86</sub> with (e - h) MODIS<sub>LM86</sub> across four of the same summertime days (15<sup>th</sup> December) in (a, e) 2009, (b, f) 2010, (c, g) 2013, (d, h) 2015. The area-weighted Southern Ocean mean is shown below each plot.

### 3.5 Aerosol and cloud response

Figure 9 shows the effect on cloud and aerosol properties of changing the atmospheric DMS distribution. Changing the atmospheric DMS concentration yields little change to CCN, CDNC or AOD. This suggests that these variables are significantly influenced by factors such as sea spray aerosol and the atmospheric oxidation pathways that convert DMS to sulfate aerosol (Revell et al., 2021; Fossum et al., 2020). Changes to the DMS source increase the spread in simulated CCN and CDNC over the Southern Ocean within CMIP6 (Fan et al., 2011). Our analysis shows that upon implementing chl-*a* measurements derived into the parametrisation (Figure ??), PMOA rather than changing the mean DMS emissions, which is consistent with our findings for atmospheric DMS concentrations. Altering the DMS source affects AOD by 73% more than DMS emissions over the Southern Ocean increase substantially during summer (81%). Although PMOA is in the preliminary stages of development within the UKESM1, our results increase in ice nucleating particles which could improve PMOA-driven cloud formation processes, emphasizing the role of the ocean in producing atmospheric DMS. Box plots of AOD, CCN, and CDNC (Figure 9e, a, c) show that the simulations do not capture the maxima in CDNC, CCN or AOD over the Southern Ocean. This will be investigated in future work.

### Emissions of primary marine organic

**Figure 9.** Summertime climatology between  $60^{\circ}$  S to  $40^{\circ}$  S showing the (a,b) cloud droplet number concentrations, (c,d) cloud conversation nuclei (800 m in altitude), and (d,e) aerosol for optical depth at 550 nm. The violin plots (a,c,e) MEDUSA represent all spatial and for temporal data points across the 10 years over the Southern Ocean in DJF. The lowest 1% of values are excluded from the violin plots. In (b,d,f) MODIS-DMS simulation integrated over the summer period grey lines represent observational datasets where (DJFb) Grosvenor et al. (2018) (dashed) and Bennartz and Rausch (2017) (solid) are shown for CDNC, (d) Choudhury and Tesche (2023) is shown at 818m, and (f) AOD climatology by the MODIS satellite-retrieval is shown (Platnick et al., 2017). The mean value is area weighted across error bars represent one standard deviation either side of the Southern Ocean DJF observational mean.

## 4 Conclusions

The concentration and distribution of atmospheric DMS is highly uncertain. Modelled atmospheric DMS over the Southern Ocean, in part due to the lack of observational data and lack of understanding of oceanic DMS and DMS is sensitive to both oceanic sources and sea-to-air emissions. We examine the key processes and relationships involved in the emissions of DMS and the production of atmospheric DMS. We also provide an overview of different oceanic DMS climatologies and calculate an oceanic DMS time series using chl-*a* satellite data. We then used three different oceanic DMS climatologies (MEDUSA, Lana, and Hulswar) in examined the sensitivity of atmospheric DMS to different oceanic source data sets and sea-to-air transfer velocity parameterizations using the UKESM1-AMIP model. We also constructed a competing oceanic DMS

570 ~~spatially distributed time series, using satellite chl-a demonstrate the effectiveness of using a 'MODIS-DMS' oceanic DMS data set and climatology calculated from satellite chlorophyll-a data from 2009 to 2018. By using nudged simulations, we can more accurately examine the drivers of the change between oceanic DMS and atmospheric DMS via closer comparisons with observations. Across all four oceanic DMS datasets, we used the sea-to-air parameterization proposed by Liss and Merlivat (1986). We incorporated a quadratic parameterization from Wanninkhof (2014) in the observations. MODIS-DMS and Lana oceanic DMS source to align with current flux estimations in the literature and other Earth System Models. Moreover, we tested a formula based on DMS observations from Blomquist et al. (2017) within the MODIS-DMS and Lana simulations.~~

MODIS-DMS suggests that large areas of open water simulations indicate that large open water areas in the Southern Ocean have lower oceanic DMS concentrations compared with to the other three oceanic DMS data sets tested (MEDUSA, Lana, and Hulswar. Our study finds that climatologies based on observations show). Climatologies compiled from in-situ observations (Lana and Hulswar) depict fewer distinct features in oceanic DMS concentrations. On average, all four oceanic DMS datasets have a summertime mean of  $3.7 \pm 1.2$  nM within the Southern Ocean (40 °S to 60 °S). MODIS-DMS oceanic DMS shows significant differences in the Southern Ocean between coastal areas and the open ocean, where coastal regions contain enhanced oceanic DMS. By incorporating a time series based on proxies of real-world biological data, we demonstrate that annual than MODIS-DMS. Coastal regions have enhanced chlorophyll-a and DMS, and we demonstrate the influence of spatiotemporal chl-a fluctuations can influence oceanic DMS and impact emissions. This highlights the importance of capturing high levels of biological activity within oceanic DMS over time fluctuations on oceanic and atmospheric DMS. Atmospheric DMS in the MODIS-DMS time series simulation shows similar interannual variability to the MODIS-DMS-CLIM simulation, indicating that capturing realistic spatial variability is more important than capturing realistic interannual variability.

Current oceanic DMS climatologies in climate models lack realistic spatial distributions for Southern Ocean summer, evident from voyage comparisons and atmospheric DMS spatial distribution. We show how using chl-a data from the MODIS-aqua satellites offers a good spatial representation of oceanic DMS. Approaches such as this and that of Gali et al offer promising avenues for realistically capturing spatial variability in oceanic DMS associated with marine biogenic activity. The current approach to calculating oceanic DMS within UKESM1 (MEDUSA) shows little spatial variability and high average biases in the Southern Ocean region, emphasizing the need for further refinement (e.g. Bock et al., 2021; Mulcahy et al., 2020; Yool et al., 2021)

595 ~~We find that atmospheric DMS is more sensitive to changes in oceanic DMS than the range of flux parameterizations used in this study. Using different sensitivity to oceanic DMS changes surpasses the sensitivity to flux parameterizations in our study. Different oceanic DMS concentrations with, using the same sea-to-air parameterization results in, lead to a 112% spread across the means within the DMS emissions. In contrast, changing just the DMS flux parameterization alone results in a spread of 50-60%. Additionally, atmospheric DMS concentrations are more sensitive to changes in oceanic DMS concentrations than DMS emissions. The mean emissions between all eight simulations have a spread of spread. The total spread in average Southern Ocean DMS emissions across all simulations is 153%, smaller than the spread across the atmospheric concentration of while the atmospheric DMS concentration spread is 171%. Changing either the oceanic DMS or Both oceanic DMS and DMS flux parameterization has considerable effects on atmospheric DMS concentrations and emissions, thus requiring careful~~

605 ~~thought about implementation in future simulations~~changes significantly influence atmospheric DMS, emphasizing the need for careful consideration in future research.

~~We recommend moving away from the commonly used W14 quadratic sea-to-air flux parameterization in CMIP6 models for DMS and instead consider more up-to-date relationships developed specifically for DMS. The Wanninkhof (2014) quadratic DMS parameterization has a leads to 33% larger influence on more DMS emissions than that of Liss and Merlivat (1986) and Blomquist et al. (2017). Additionally, all simulations have a summertime Southern Ocean flux of  $22.2 \pm 5 \mu\text{mol m}^{-2} \text{d}^{-1}$ , with linear flux parameterizations aligning Linear transfer velocity parameterizations align better with observations than the quadratic flux. Furthermore, we found that using for DMS emissions, particularly for the MODIS-DMS simulations. Using a linear flux parameterization ,B17, and LM86, within MODIS-DMS aligned the brought atmospheric DMS ( $164.88 \pm 132$  ppt) much closer to the observations ( $185.55$  ppt) closer to observations ( $108 \pm 129.61$  ppt). All simulations have a Southern Ocean DJF mean of  $276 \pm 174$  ppt, within one standard deviation.~~

610

~~The use of climatologies within climate models to represent oceanic DMS does not represent realistic distributions within the Southern Ocean as shown by comparisons to voyages. Climatologies should be replaced by spatially distributed time series to represent inter-annual variability of oceanic DMS. The time series would benefit from using a wide-spread readily available dataset that best represents a realistic spatial distribution of oceanic DMS. Given the current data availability, using chl-*a* data from the MODIS-aqua satellite is a viable option. The oceanic DMS within the UKESM1 (MEDUSA) is positively biased (e.g. Bock et al., 2021; Muleahy et al., 2020; Yool et al., 2021), and is in need of further development. In futurework, when developing sulfate chemistry, we recommend using the LM86 or In future, we recommend that models use up-to-date DMS-specific relationships such as B17 flux parameterization along with either Lana or MODIS-DMS oceanic DMS concentrations, to capture a more realistic DMS cycle in the Southern Ocean.~~

955 ~~Timeseries of each oceanic DMS dataset input into the simulations during DJF in the Southern Ocean. chl-a is shown with a black line. The MODIS-DMS error bars represent the standard deviation across the Southern Ocean.~~

~~DMS emissions for each simulation tracking the SOAP voyage across each hour, through time and space as a violin plot. The  $r^2$  value compares the monthly DMS flux vs the respective oceanic DMS. Spearman's rank compares the rankings of hourly flux simulation with the rankings of hourly TAN1802 data. Each simulation overlays the corresponding SOAP voyage flux, whereby both emissions are calculated with the same sea-to-air flux, winds, and Schmidt number.~~

960 ~~Same as Figure ??, but for TAN 2018~~

~~Scatter plot representing how DMS flux and atmospheric DMS mixing ratio respond to increasing oceanic DMS concentrations. (a-i) Each simulation presents 97920 data points within the DJF Southern Ocean. (j,k) The relationship between observational voyages during 2012 (SOAP using the Wanninkhof (2014) flux parameterization), 2019 (ANDREXH), and 2008 (SOExchange) is also presented. The  $r^2$  value is shown on each plot to represent the coefficient of determination between the oceanic DMS and DMS emissions for each simulation and voyage.~~
