Presto (apresto@andrew.cmu.edu) 11 12 **Abstract** 13 Cooking is an important but understudied source of urban anthropogenic fine particulate matter 14 (PM<sub>2.5</sub>). Using a mobile laboratory, we measured PM size and composition in urban restaurant 15 plumes. Size distribution measurements indicate that restaurants are a source of urban ultrafine 16 particles (UFPs, particles <100 nm mobility diameter), with a mode diameter <50 nm across Formatted: Font color: Red 17 sampled restaurants and particle number concentrations (PNC, a proxy for UFPs) that were 18 substantially elevated relative to the urban background. In our observations, PM mass emitted Formatted: Font color: Red 19 from restaurants was almost entirely organic aerosol (OA). Aerosol mass spectra show that while Deleted: The majority of observed PM was organic aerosol (OA) by mass. 20 emissions from most restaurants were similar, there were key mass spectral differences. All 21 restaurants emit OA at m/z 41, 43, and 55, though the composition (e.g., the ratio of oxygenated 22 to reduced ions at specific m/z) varied across locations. All restaurant emissions included 23 reduced nitrogen species detected as C<sub>x</sub>H<sub>y</sub>N<sup>+</sup> fragments, making up ~15% of OA mass measured

## Introduction

Concentrations of most air pollutants, including fine particulate matter (PM<sub>2.5</sub>) and ultrafine particles (UFPs; particles with diameter <100 nm), are typically higher in urban areas compared to rural or suburban areas (Cheng et al., 2019; Chow et al., 2006; Lenschow et al., 2001; Louie et al., 2005; Renzi et al., 2021; Wang et al., 2020). Elevated urban concentrations lead to higher human exposure, and in turn, contribute to the health impacts of air pollution. PM<sub>2.5</sub> exposures are associated with cardiovascular disease, lung cancer, and asthma and contribute to up to 100,000 deaths annually in the US (Castillo et al., 2021). Although health effects of UFP exposure are less extensively studied compared to PM<sub>2.5</sub> (Schraufnagel, 2020) and are an area of ongoing research, there is growing evidence that UFPs can enhance acute health effects because of their small size and high surface area (Ali et al., 2022; Ibald-Mulli et al., 2002; Kwon et al., 2020).

The PM<sub>2.5</sub> and UFP concentration enhancements in many urban areas are strongly influenced by anthropogenic emissions (Apte et al., 2017; Li et al., 2018; Mohr et al., 2011; Saha et al., 2019). Among a wide variety of contributing sources to air quality in the US, two notable

urban sources are mobile sources (e.g., motor vehicles) and cooking. These two sources contribute to urban enhancements relative to the non-urban areas and to intra-urban spatial variations in PM<sub>2.5</sub> and UFP concentrations (Klompmaker et al., 2015). In prior work, mobile sources and cooking emissions have led to neighborhood-scale enhancements of  $\sim$ 0.5-1  $\mu$ g m<sup>-3</sup> of

Deleted: Among a wide variety of contributing sources,

Formatted: Font color: Red

55 2020; Song et al., 2021b). Motor vehicle emissions are well studied and have seen dramatic reductions as a result of 56 57 effective regulations on PM emissions across Europe and the US (Font et al., 2019; Keuken et 58 al., 2012). In contrast, there has been less attention to cooking sources as contributors of PM and 59 UFP emissions. As such, there have been fewer direct measurements and regulations dedicated 60 to cooking-related emissions, including everyday sources such as restaurants and home kitchens. 61 For comparison, two studies conducted in Pasadena, California revealed that organic PM<sub>2.5</sub> 62 attributed to cooking decreased from approximately 2.4 µg/m<sup>3</sup> to 1.2 µg/m<sup>3</sup> between 1982 and 63 2010, while the contribution from traffic sources dropped from about 6.8 μg/m<sup>3</sup> to 0.82 μg/m<sup>3</sup> 64 (Hayes et al., 2013; Schauer et al., 1996). This means that while total PM<sub>2.5</sub> and vehicular-related primary PM<sub>2.5</sub> have decreased, the fraction of urban PM<sub>2.5</sub> attributed to cooking has increased. 65 Aerosol mass spectrometry (AMS) measurements worldwide further indicate the 66 67 importance of cooking PM. Factor analysis utilizing PMF (Positive Matrix Factorization) on 68 AMS data routinely identifies a Cooking Organic Aerosol (COA) factor that represents between 69 6 - 25% of the total organic aerosol (OA) within PM<sub>1</sub> in urban settings. Specifically, a study in 70 Athens and Patras, Greece, showed that the COA contribution increased to 75% of organic PM<sub>1</sub> 71 during mealtime in Patras (Florou et al., 2017). While the COA factor is routinely identified, 72 there can be significant variation in its composition from city to city (Bozzetti et al., 2017; Crippa, El Haddad, et al., 2013; R. Hu et al., 2021; X.-F. Huang et al., 2010; Lee et al., 2015; 73 74 N. Pandis et al., 2016; Sun et al., 2012)

PM<sub>2.5</sub> in North American cities and a factor of two enhancement in UFPs (Rose Eilenberg et al.,

**Deleted:** (Bozzetti et al., 2017; Crippa, El Haddad, et al., 2013; R. Hu et al., 2021; X.-F. Huang et al., 2010; Lee et al., 2015; N. Pandis et al., 2016; Rogge et al., 1991a; Sun et al., 2012).

of cooking PM. While the UFPs from cooking can contribute to ~ 80% of the total particle

Many potential factors could produce variability in the composition and size distribution

number concentrations indoors (Wan et al., 2011), there are a lot of factors—such as indooroutdoor air exchange rates (Wallace et al., 2004) and types of cooking oils used (Torkmahalleh et al., 2012)—that can determine the size distribution of particles as well as the PM<sub>2.5</sub> concentrations from cooking activities. There is some evidence that the chemical composition of cooking emissions may vary with the cooking style and the food cooked (Omelekhina et al., 2020; Reyes-Villegas et al., 2018a; Takhar et al., 2019). For example, the cooking temperature, ingredients, and methods used can alter chemical pathways that lead to the generation of nitrogen-containing functional groups, including amides, within COA (Ditto et al., 2022). Multiple studies found that nitrogen-containing composition has been observed while charbroiling (Rogge et al., 1991a) or deep-frying hamburgers (Reyes-Villegas et al., 2018b; Rogge et al., 1991a). Masoud et al., (2022) found that nitrogen-containing compounds contributed 12-19% of the signal measured by a chemical ionization mass spectrometer for emissions from typical in-home cooking. Overall, this variability across diverse cooking styles and conditions is relevant but poorly understood. This implies a significant need for real-world measurements to characterize and understand particle size and composition of cooking emissions in urban environments. This study aimed to characterize cooking emissions from real-world restaurant sources in

the US. We used a mobile laboratory to measure cooking emissions from nine restaurants in Pittsburgh, PA and Baltimore, MD. Four of these restaurants were visited twice, making for a total of thirteen cooking sites. Several analytical instruments, including an AMS and FMPS (Fast Mobility Particle Sizer), were used at each site for online measurements, with supplemental PM collection on Teflon filters for offline analysis. The measurements are used to examine variations in UFP concentrations and cooking OA composition measured outside of restaurants with a

focus on contributions from reduced nitrogen components across restaurant sites visited during the field campaign.

Field samples were collected from 13 visits to 9 urban cooking sites in Pittsburgh and Baltimore during July and August 2019 (Table 1). Candidate restaurants were identified using Google maps. We first identified an initial list of candidate restaurants by searching Google maps for restaurants located adjacent to a public road that seemed to have a horizontal exhaust vent pointed towards the road (Figure S1). We then visited each candidate restaurant location in

Moved (insertion) [1] Deleted: ¶ City

Moved up [1]: ¶ City Deleted: ¶ City

person to determine whether our mobile laboratory could be parked near the restaurant exhaust for emissions sampling. Table 1 indicates the type of cuisine prepared at each restaurant. We tried to sample across a range of cuisines and price points. For example, one sampling location was a major fastfood chain that primarily serves hamburgers (Fast Food 1 and 2). Another location (Bar/Restaurant 1 and 2) was a more expensive restaurant where many entrees cost more than \$30. Lastly, we sampled twice outside of a large commercial bread bakery (Bakery 1 and 2). Our procedure for identifying candidate restaurants has two important implications for our results. First, it means that the set of sampled restaurants represents a convenience sample and may therefore not be completely representative of the types of restaurants found in Pittsburgh or Baltimore. Second, since we did not coordinate with restaurant owners or operators during our sampling, we do not have detailed information about cooking fuel (though we assume that most restaurants used either gas or electricity), the specific cooking methods used, or the volume of food cooked during our sampling periods. At each location, we parked a mobile laboratory near the restaurant's exhaust plume (SI Fig. 1). The selected restaurants represent a mix of accessible locations with visible emission plumes or exhaust vents. The sampling inlet on the mobile laboratory was typically within a few meters of the exhaust vent. However, this distance varied due to several uncontrollable external factors, such as the availability of parking and the height of the restaurants' exhaust vents. As a result, the measured emission plumes went through varying degrees of dilution before reaching our sampling inlet. At all locations we measured a mixture of fresh emissions and the ambient background air, though the fresh emissions were dominant. Nonetheless, it is important to

recognize that some of the variability we observe between restaurants could be the result of dilution-driven changes in UFP and OA concentrations.

**Deleted:** As a result, the measured emission plumes went through varying degrees of dilution before reaching our sampling inlet.

Several of the restaurants were sampled on multiple visits to examine day-to-day variations in emissions. These variations could be due to differences in activity (e.g., how many customers ordered food), the type of food ordered, and differences in dilution conditions. Each visit to a restaurant site lasted approximately 30-60 minutes. The sampling periods targeted expected times for lunch ( $\sim$ 11 am - 1 pm) and dinner ( $\sim$ 6 - 8 pm).

2.2 Mobile laboratory and measurements

Instruments were loaded into a gasoline-powered mobile laboratory. At each location, we oriented the mobile laboratory so that the vehicle exhaust was located downwind of the sample inlet to minimize self-contamination from the vehicle exhaust.

We use total particle number concentration (PNC) as our proxy for UFPs. Particle number counts were measured by a MAGIC<sup>TM</sup> water CPC (Moderated Aerosol Growth with Internal water Cycling Condensation Particle Counter, Aerosol Devices Inc, Model MAGIC200P). MAGIC CPC uses water condensation to enlarge particles through a 3-temperature stage growth tube. The enlarged particles are counted with a laser sensor up to 400,000 particles cm<sup>-3</sup> with a particle size range between 5 nm and 2.5 µm in diameter (Hering et al., 2019). Saha et al., (2019) previously observed that the MAGIC CPC undercounts relative to a butanol CPC. Thus, the raw CPC output was adjusted using a correction factor determined from the co-location of the MAGIC CPC with a TSI 3772 butanol CPC.

Particle size distributions and total number concentrations were measured with FMPS (Fast Mobility Particle Sizer, TSI Inc, Model 3091) for particles with diameters from 6.04 nm to

523.3 nm. The FMPS reported systematically lower particle counts than the MAGIC CPC (factor of 3.5, SI Section 2 and Fig. S2). FMPS data were utilized in lieu of the CPC data due to high particle number concentrations in restaurant plumes that exceeded the upper counting limit of the CPC (400,000 particles cm<sup>-3</sup>), resulting in error flags. To ensure consistency with the MAGIC CPC, all FMPS data were corrected by integrating the FMPS size distribution, which was scaled by the FMPS:CPC ratio. A High-Resolution AMS (HR-AMS, Aerodyne), which measures non-refractory particles with a diameter less than 1 µm (NR-PM<sub>1</sub>), was used to identify mass spectra of PM components (Organics, NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2</sup>-, and Cl<sup>-</sup>) in real-time. Squirrel (SeQUential Igor data RetTriEvaL) toolkit 1.62G and Pika (Peak Integration by Key Analysis) toolkit 1.22G in Igor Pro (Wavemetrics, Lake Oswego) were used for the HR-AMS data analysis. For the baseline and peak fitting correction procedures of the HR-AMS data, the high-resolution range of m/z (massto-charge ratios) 12 to 140 was selected. All AMS analysis presented here assumes a collection efficiency (CE) of one. An aethalometer (Magee Scientific, Model AE33), CO analyzer (Teledyne API T300), and CO<sub>2</sub> analyzer (LiCor LI-820, Biosciences) measured black carbon (BC), CO, and CO<sub>2</sub> concentration, respectively. PM<sub>2.5</sub> samples were collected at ~70 L/min on 47 mm PTFE membrane filters (47 mm, 2.0 µm pores, Tisch Scientific) through a separate inlet mounted close to the online instrumentation inlet outfitted with a cyclone (2.5 µm cut point with a flow rate of 92 LPM, URG-2000-30EH, URG cyclone). At each restaurant site where plumes were observed via AMS, a filter sample was collected for at least 30 minutes and Table S3 shows details for each filter

sample. Filter samples were transported on ice packs from the mobile lab and kept in sample

storage freezers. Additional filter collection details can be found in the Supporting Information. All samples were analyzed via liquid chromatography (LC) using an Agilent Infinity LC and an Agilent Poroshell 120 SB-Aq reverse-phase column (2.1×50 mm, 2.7 µm particle size). The LC was coupled to an electrospray ionization (ESI) source, operated in positive and negative modes for each sample, and connected to a high-resolution mass spectrometer (Agilent 6550 Q-TOF). These instruments were operated following previously described methods (Ditto et al., 2018, 2020).

Selected samples showing unique AMS spectra with nitrogen-containing compounds underwent further analysis via MS/MS (tandem mass spectrometry) with the objective of identifying the distribution of functional groups within the reduced nitrogen species that were observed via LC-TOF, similar to prior work (Ditto et al., 2020, 2022). LC-TOF mode data processing and QC/QA have previously been described (Ditto et al., 2018), and details of compound selection for MS/MS analysis in this study can be found in the Supporting Information (Section S3). MS/MS spectra analysis used SIRIUS with CSI:FingerID for molecular structure prediction (Dührkop et al., 2015, 2019), and the APRL Substructure Search Program was used for functional group identification from the predicted SMILES formula for atmospherically-relevant groups (Ruggeri & Takahama, 2016). Further details on LC-MS/MS analysis, processing, and associated limitations of ESI and MS/MS spectra analysis can be found in Ditto et al., (2020), with brief comments on relevant SIRIUS updates in the Supporting Information (Section S3).

### 3. Results and Discussion

3.1 Typical measurements of restaurant emission

Figure 1 demonstrates observations collected during a typical sampling day via the mobile lab in Baltimore. On this day, the mobile laboratory was initially (~15:36 – 16:49 EDT) parked in an urban park, here noted as background. Sampling was then conducted on-road, driving on various streets in urban Baltimore, from 16:49 to 18:20. At 18:20; the mobile laboratory was parked outside a restaurant (Bar/Restaurant 2).

The data in Figure 1 exemplify clear variations in pollutant concentrations between the background, on-road, and restaurant portions of sampling. In general, concentrations were the lowest and least variable in urban background locations and the highest and most variable for the restaurant sampling periods.

Nearby vehicles <u>significantly impacted</u> the measured concentrations during the on-road sampling period, thus differentiating it from the background period, where direct observations of on-road emissions were minimal. Concentrations of CO, CO<sub>2</sub> (Fig. 1a), organic aerosol (OA), black carbon (BC, Fig. 1b), and particle number (Fig. 1d) were all elevated in the on-road samples compared to the urban background.

In order to quantify concentrations differences between microenvironments (e.g., on-road versus background), we compute the enhancement of all species above the urban background (e.g., ΔΟΑ). We did this by defining the background concentration as the 5<sup>th</sup> percentile of measurements made in the background location on each sampling day. This background concentration is then subtracted from the measurements to determine local concentration enhancements. Background concentrations for BC and OA are listed in Table S1 of the SI, While many other background correction methods have been proposed in the literature (Actkinson et

Deleted: likely

Formatted: Font color: Red

Commented [AP2]: cite this paper: https://amt.copernicus.org/articles/14/5809/2021/

al., 2021), the overall results presented in Figure 1 are not sensitive to our specific choice of background correction method.

The mean organic aerosol concentrations are  $5.8 \,\mu g/m^3$  ( $\Delta OA$ :  $2.46 \,\mu g/m^3$ ) during onroad sampling versus  $4.2 \,\mu g/m^3$  ( $\Delta OA$ :  $0.85 \,\mu g/m^3$ ) in the urban background (Fig. 1b). Similarly, the BC concentration was  $0.5 \,\mu g/m^3$  higher on-road than in the urban background, and PNC was approximately a factor of three higher on-road than in the urban background. These enhancements in organic aerosol, black carbon, and PNC are broadly consistent with enhancements with those seen in high-traffic areas by our previous sampling in Pittsburgh and Oakland (Saha et al., 2020; Shah et al., 2018).

In addition to the overall increase in pollutant concentrations on-road, there are occasional, coincident spikes in CO, BC, OA, and PNC during the on-road sampling. The particle size distribution also changes during these spikes (Fig. 1c), with higher concentrations of particles in the 20-100 nm size range. These are likely plumes from <a href="mailto:nearby">nearby</a> high-emitting vehicles, potentially diesel trucks and buses (Dallmann et al., 2013; Tan et al., 2016).

The highest and most variable concentrations are observed in the restaurant plume. In this near-source environment, organic aerosol concentrations averaged  $146 \,\mu\text{g/m}^3$ . This is 35 times higher than the urban OA background. Particle number counts were also 35 times higher in concentration than background levels. CO, CO2, and BC enhancements were also observed when the mobile lab was parked near the restaurant. The enhancement of CO was 5.9 times the background, CO<sub>2</sub> and BC were 1.15 and 5.42 times higher, respectively.

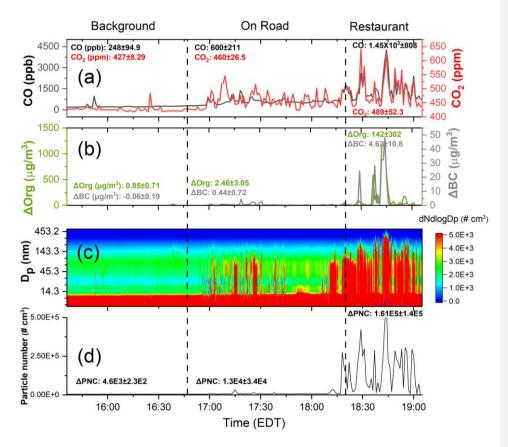

During the restaurant sampling period, there are several clear and concurrent spikes in OA (Fig. 1b) and particle number count (Fig. 1d). These seem to be associated with specific events, such as preparing a customer's new order (restaurant kitchens had varying activity levels

Formatted: Font color: Red

**Deleted:**  $\Delta OA$  and  $\Delta BC$  were calculated by subtracting the background concentration from the measured OA or BC mass concentration. The background concentration is defined as the  $5^{th}$  percentile of data collected on each sampling day (listed in Table S1).¶

during the sampling periods). The size distributions in Figure 1c show that these emissions span a wide range in particle size, from <10 nm up to a few hundred nm, demonstrating that restaurants may be a source of urban ultrafine particles.

**Figure 1.** Urban background, on-road, and restaurant plumes observed during a typical sampling day (Bar/Restaurant 2) in Baltimore, showing: (a) CO and  $CO_2$ , (b) background corrected organic aerosol (OA) and black carbon (BC) concentrations, (c) particle size distribution from FMPS, and (d) background-corrected total particle number concentrations. All concentrations were significantly higher and more variable in restaurant emissions plume than in the urban background or on-road period. Numbers in (a), (b), and (d) indicate the mean  $\pm$  standard deviation for each sampling period.

While average BC concentrations were about a factor of five higher than background during the restaurant sampling period, BC seems to be a relatively smaller component of PM emissions from the restaurant. The OA/BC ratio in the urban background and on-road sampling periods was ~4. In the restaurant plume, the mean OA/BC ratio was 28. Despite occasional periods of very high BC concentrations reaching up to  $58 \,\mu\text{g/m}^3$ , the OA/BC ratio during the spike was 230 (Fig. S3). Other PM components (e.g., sulfate and nitrate) show no discernable enhancement during the restaurant sampling period (Fig. S4). This indicates that the PM emissions from the restaurant were dominated by organic aerosol.

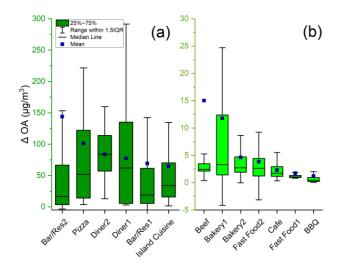

We also observed elevated concentrations of CO and CO<sub>2</sub> in the restaurant exhaust. We do not have information about each restaurant's cooking practices or fuels (i.e., whether the restaurants used natural gas or electricity). Jung & Su (2020) showed that food cooking emits CO, so the CO spikes observed here may also be from the food rather than fuel combustion. Other recent measurements in Pittsburgh by (Song et al., 2021a) also showed enhancements in CO during mealtimes in a restaurant-rich area.

3.2 Summary of organic aerosol enhancements at restaurant sites

Figure 1 shows the OA enhancement at a single restaurant. Enhancements in OA because of emissions from restaurants were similarly observed across all other sampling sites that we visited. Figure 2 is a box-plot visualization of the OA enhancement ( $\Delta$ OA) for each restaurant visit. The data are split into two main groups for visual clarity: high concentration (mean  $\Delta$ OA > 50  $\mu$ g m<sup>-3</sup>, Fig. 2a) and low concentration (mean  $\Delta$ OA < 30  $\mu$ g m<sup>-3</sup>, Fig. 2b). Because of the variation in distance from the exhaust of each restaurant and our sampling inlet, the

Formatted: Font color: Red

Deleted: as a result

**Figure 2.** Organic aerosol enhancement ( $\Delta OA$ ) at each restaurant site with (a) high (mean  $\Delta OA > 50~\mu g/m^3$ ) and (b) low (mean  $\Delta OA < 30~\mu g/m^3$ ) enhancements grouped in each for comparison. The sample names in (a) and (b) are ordered by decreasing mean concentration.

There is significant variability in measured  $\Delta OA$  between and within each restaurant (Fig. 2 and Fig. S4). For nearly every location sampled, the emissions varied over time, as shown in Figure 1, and this contributes to wide interquartile ranges (IQRs) in Figure 2. It also means that at nearly every restaurant, there were periods when the concentration was near the urban background level, as indicated by the whiskers reaching (or even going slightly below) zero.

The temporal variability of the concentrations measured at each restaurant contributed to an upward skew in  $\Delta$ OA, with a mean concentration greater than the 75th percentile at many locations. This suggests that the measurements were dominated by short, intense bursts of emissions rather than sustained high concentrations. Visualizations of this trend are noticeable in

Figure 1b, where there is a large spike in emissions so that OA goes above  $1000\,\mu\text{g/m}^3$  for several minutes. The temporal variability seems to be associated with the quantity of cooking that spikes amid busy mealtimes.

Four restaurants were sampled on multiple days (Bar/Restaurant, Fast Food, Bakery, and Diner). While there were day-to-day differences in the mean  $\Delta OA$  at each location, each of these locations fell into the same group (i.e.,  $\Delta OA < 30~\mu g~m^{-3}$  or  $\Delta OA > 50~\mu g~m^{-3}$ ) on both sampling days. This suggests that the day-to-day variations in emissions are smaller than within-day emissions for each location and that high-emitting restaurants are consistently high emitters. However, due to the limitation of a single visit to each sampling location during the campaign, it may be challenging to conclusively ascertain that the classification assigned to the sampled restaurants is not indicative of all similar cooking operations.

In this section, we compare the composition of cooking OA across the restaurants and to previous laboratory measurements and ambient factor analysis. Figure 3 shows the mean mass spectrum of OA measured at Bar/Restaurant 1 in Baltimore; mass spectra from three additional restaurants are shown in Figure S5. The mass spectrum contains a mixture of hydrocarbon (C<sub>x</sub>H<sub>y</sub>) and oxygenated (C<sub>x</sub>H<sub>y</sub>O) ions. This is consistent with the composition of cooking OA, which is often dominated by long-chain fatty acids from heated cooking oils and from meat cooking (Crippa, DeCarlo, et al., 2013; D. D. Huang et al., 2021a; Liu et al., 2017; Mohr et al., 2009; Takhar et al., 2019; Z. Zhang et al., 2021). Several lab experiments from seed oil cooking detected fatty acids or degradation fragments such as n-alkanoic acid, n-alkenoic acid, oleic acid, and carbonyls (Allan et al., 2010; Liu et al., 2018; Schauer et al., 2002). Unlike oils, which are entirely comprised of fats, meats contain proteins and fats, although the composition can vary depending on the type of meat. Cooking meat generally emits cholesterol and fatty acids like palmitic acid, stearic acid, and oleic acid (Rogge et al., 1991a; Schauer et al., 1996), which have all been used as chemical markers of meat cooking emissions. This mixture of hydrocarbon and oxygenated ions is also identified in PMF factor analysis of ambient datasets, as indicated by the mass spectrum from Crippa, DeCarlo, et al., (2013) shown in Figure 3. The most abundant peaks in the mass spectrum were at m/z 41 (mostly C<sub>3</sub>H<sub>5</sub><sup>+</sup>), 43

The most abundant peaks in the mass spectrum were at m/z 41 (mostly  $C_3H_5^+$ ), 43 ( $C_2H_3O^+$  and  $C_3H_7^+$ ), and 55 ( $C_3H_3O^+$  and  $C_4H_7^+$ ). These peaks have been used as COA markers for tracing cooking sources in previous studies (Allan et al., 2010; Dall'Osto et al., 2015; Kaltsonoudis et al., 2017; Mohr et al., 2009). Table 1 summarizes the mean contribution ( $f_{41}$ ,  $f_{43}$ , and  $f_{55}$ ) at these m/z to each restaurant's overall OA mass spectrum.

**Deleted:** Figure 3. Example mass spectrum from Bar/Restaurant 1 in this study and comparison with the COA mass spectrum from prior PMF work. High-resolution mass spectra are grouped into sticks of the unit mass resolution, and the coloring of each stick represents the mass fraction belonging to different chemical families.¶

**Figure 4.** Fraction of (a) m/z 41, (b) 43, and (c) 55 to the total organic aerosol mass concentrations and comparison to COA mass spectra from prior PMF studies (Äijälä et al., 2017; Crippa, DeCarlo, et al., 2013; Jeong et al., 2016; Lanz et al., 2007) and laboratory-generated cooking emissions (Kaltsonoudis et al., 2017; Liu et al., 2018; Z. Zhang et al., 2021). Only f<sub>43</sub> and f<sub>55</sub> were shown in (Jeong et al., 2016) (f<sub>41</sub> was not provided in the paper). Fast Food and Bakery samples are grouped in a box as they showed lower abundances of these common cooking marker fractions (f<sub>41</sub>, f<sub>43</sub>, and f<sub>55</sub>).

Figure 4 compares  $f_{41}$  (OA mass fraction at m/z 41),  $f_{43}$ , and  $f_{55}$  across the restaurants sampled here to previously published COA mass spectra. We compared two types of previous studies: COA mass spectra derived from factor analysis of ambient data using PMF and

laboratory measurements of cooking emissions. The laboratory measurements shown here include a combination of heating palm and olive oils (Liu et al., 2018) and various cooking experiments using meats (chicken and pork), vegetables, beans, and Asian cuisine (Kaltsonoudis et al., 2017; Z. Zhang et al., 2021).

For m/z 41, our data were dominated by the hydrocarbon ion ( $C_3H_5^+$ ), which was approximately 4-8% of OA mass for most of the restaurants. The exceptions were Fast Food 1 and the two samples collected at the Bakery location. These had lower  $f_{41}$  (1-5%) and are shown inside the dashed box.  $f_{41}$  fractions from our study were generally lower than from the PMF COA factors. Three of the four COA factors have  $f_{41}$  of ~9% (Äijälä et al., 2017; Crippa, DeCarlo, et al., 2013; Jeong et al., 2016). The COA factor from Lanz et al., 2007 is 4% and is lower than most of the restaurants we sampled here. There is a wide range in  $f_{41}$  from the laboratory experiments. The two oil heating experiments (palm and olive oil, Liu et al., 2018) generated higher  $f_{41}$  than most of our measurements (8-10%). There was a wider range in  $f_{41}$  for food cooking experiments (5-8%), and there is a strong overlap with our measurements.

For  $f_{43}$  and  $f_{55}$ , both oxidized (e.g.,  $C_2H_3O^+$  and  $C_3H_3O^+$ ) and hydrocarbon (e.g.,  $C_3H_7^+$  and  $C_4H_7^+$ ) ion fragments showed significant contributions across the urban cooking sites. There were also minor contributions from nitrogen-containing ions (e.g.,  $C_2H_5N^+$  and  $C_2HNO^+$ ). Except for Bakery 1,  $f_{43}$  was ~5-8% in our measurements. However, there was variation in the relative abundance of the hydrocarbon and oxygenated ions. For most sites, the contribution of the hydrocarbon ion ( $C_3H_7^+$ ) was larger than the oxygenated ion ( $C_2H_3O^+$ ). However, the sites with low  $f_{41}$ , Bakery and Fast Food 1, m/z 43 fragments were mostly oxygenated (mean = 3.5%).

The mean  $f_{43}$  in the PMF profiles was 6.3% with a range of 4-8.7%, which is similar to the mean and range observed in our dataset. Similarly, the laboratory emissions data cluster

Formatted: Font color: Red

around  $f_{43}$  of 8%, with slightly lower  $f_{43}$  in the heated oil experiments. This is slightly higher than the  $f_{43}$  measured in the restaurant emissions.

The pattern in  $f_{55}$  is similar to  $f_{43}$ ; contributions are dominated by the hydrocarbon and oxygenated ion, with minor contributions from N-containing ions. For most sites, including the Bakery and Fast Food sites, the contributions of hydrocarbon and oxygenated ions at m/z 55 are similar. The largest difference is that the Bakery and Fast Food sites have significantly lower  $f_{55}$  (1-6%) than the other sites (4-12%). Additionally, for many of the sites,  $f_{55}$  is larger than the PMF factors and the laboratory experiments.

The variations in  $f_{41}$ ,  $f_{43}$ , and  $f_{55}$ , as well as variations in the ratios between these m/zs, may indicate the food cooked at the different restaurants. For example,  $f_{41}$  appears to be larger than  $f_{43}$  for cooking emissions from oil, as observed in the oil heating experiments by Liu et al. (2018) and in laboratory oil cooking emissions by Allan et al. (2010). Meat cooking emissions seem to have the opposite relationship, with  $f_{43} > f_{41}$ . Both oil cooking and meat cooking have high  $f_{55}$ , and meat cooking may have  $f_{55} > f_{43}$  (Mohr et al., 2009).

For most restaurants sampled here (except for both Bakery and Fast Food), m/z 55 is the most abundant signal in the aerosol mass spectrum. Additionally,  $f_{41}$  is slightly higher than  $f_{43}$  for these sites. This suggests a mixture of meat and oil cooking at these locations. For Bakery and Fast Food,  $f_{43}$  is typically the most abundant ion, with  $f_{41}$  exceeding  $f_{55}$ . This may suggest a different mix of food being cooked, or a difference in the cooking style, however, there is insufficient evidence in the mass spectra to conclusively explain the differences.

**Deleted:** For example,  $f_{41}$  seems to be larger than  $f_{43}$  for cooking emissions dominated by oil; this is the case in the oil heating experiments from Liu et al. 2018 as well as from laboratory oil cooking emissions measured by Allan et al. (Allan et al., 2010).

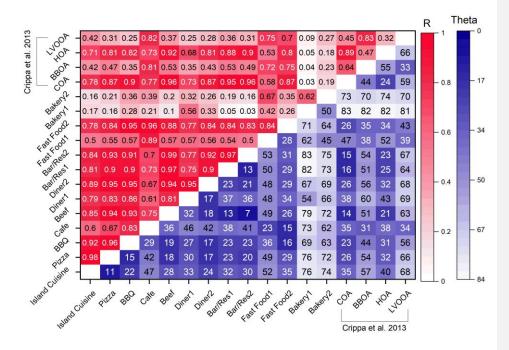

Figure 5. Comparison of the AMS UMR (unit mass resolution spectra) in two urban areas using correlation coefficients (R) and cosine similarity ( $\theta$ , in degrees). R values close to 1 and  $\theta$  values close to 0 mean strong correlations of mass spectra. Both R and  $\theta$  values are presented such that darker colors correspond to higher similarity.

Figure 4 compares the cooking OA mass spectra for specific marker ions. Figure 5 compares the full cooking OA mass spectra. We use two metrics: the Pearson correlation (R) and cosine similarity. The statistical approach, correlation coefficient R, has been widely used in many studies, such as the analysis of air quality, to show an association between any two variables (Devarakonda et al., 2013; Giorio et al., 2012; Kiendler-Scharr et al., 2009; Raatikainen et al., 2010). Cosine similarity treats pairs of mass spectra as vectors and computes the angle ( $\theta$ ) between them (Kaltsonoudis et al., 2017; Kostenidou et al., 2009).  $\theta$  is a measure of the similarities between two mass spectra, with a value of  $\theta$ , meaning that both spectra are

identical and  $\theta$ >30° indicating considerable differences between the spectra. Cosine similarity is more sensitive to smaller differences in mass spectra than R, as the correlation coefficient can be dominated by ions with large abundance (Kaltsonoudis et al., 2017). Figure 5 also compares the cooking emissions to PMF factors retrieved from Paris during winter (Crippa, DeCarlo, et al., 2013) for biomass burning (BBOA), combustion emissions (HOA), and secondary OA (LVOOA) obtained from the Jimenez Research Group website. (http://cires1.colorado.edu/jimenez-group/AMSsd/). Overall, the COA measured from most of the restaurants is similar. Of the 78 restaurantrestaurant pairs, 33 have R > 0.8 and 49 have  $\theta$  < 30°. These metrics underscore a notable similarity in mass spectra across a significant proportion of the sampling sites. The exceptions **Deleted:** For most restaurants, the R between mass spectra are the Bakery samples and, to a lesser extent, the Fast Food samples. These sites contribute the majority of the cases where R < 0.8 and  $\theta > 30^{\circ}$ . Formatted: Font color: Red Formatted: Font color: Red Bakery samples had R < 0.3 and  $\theta > 50^{\circ}$  when compared to most of the other restaurants. This suggests that the emissions from the bakery site were fundamentally different than emissions from the other restaurants. While we do not have details on the specific activities at the bakery on the two days when we sampled, the bakery clearly prepares different food than many of the restaurants. For example, the bakery does not cook meat. The following section

is larger than 0.8 and  $\theta$  is less than 27°, suggesting that the mass spectra are similar. Figures 3 and 4 show that the dominant ions in these mass spectra are at m/z 41, 43, and

Deleted: There were day-to-day differences in the Fast Food mass spectrum, with one day (Fast Food 1) being similar to other restaurants (R = 0.7-0.8,  $\theta$  < 30°), and the other day (Fast Food 2) having lower R and higher  $\theta$ .

Formatted: Font color: Red

Formatted: Font color: Red

The other location where the mass spectrum was different from other restaurants was Fast

Food, There were day-to-day differences in the Fast Food mass spectrum, with one day (Fast

Food 1) being similar to other restaurants (R = 0.7-0.8,  $\theta$  < 30°), and the other day (Fast Food 2)

discusses key mass spectral differences in more detail.

having lower R and higher  $\theta$ .

486 There is also a high correlation of most restaurants with the COA PMF factor from 487 Crippa et al., (2013) (R >  $\sim$ 0.75,  $\theta$  <  $\sim$ 30°). This suggests that PMF analysis of ambient datasets 488 yields a COA factor that is similar to fresh cooking emissions from many restaurants. There is a 489 high R between our COA and the PMF HOA (hydrocarbon-like OA) factor, which is 490 representative of primary combustion-related emissions. Even though m/z 41, 43, and 55 are 491 useful COA markers to resolve cooking-related factors, there are diverse sources of m/z 41, 43, 492 and 55. In general, there is a high correlation between HOA and COA because the major HOA 493 peaks like m/z 55 and 57 are prominent in both factors (Milic et al., 2016; Sun et al., 2013; D. 494 Yao et al., 2021). 495 One key difference between HOA and COA is that the HOA mass spectrum is dominated 496 by hydrocarbon (C<sub>x</sub>H<sub>y</sub>), whereas the cooking OA has a mixture of hydrocarbon and oxygenated 497 ions, as shown in Figure 4. For example, m/z 43 in HOA is almost entirely due to C<sub>3</sub>H<sub>7</sub><sup>+</sup> (Ng et 498 al., 2010), whereas cooking OA contains both C<sub>3</sub>H<sub>7</sub><sup>+</sup> and C<sub>2</sub>H<sub>3</sub>O<sup>+</sup> (Fig. 4). Similarly, for m/z 55, 499 COA has contributions from both hydrocarbon (C<sub>4</sub>H<sub>7</sub><sup>+</sup>) and oxidized (C<sub>3</sub>H<sub>3</sub>O<sup>+</sup>) fragments 500 (Canonaco et al., 2013; Lalchandani et al., 2021), whereas the reduced ion dominates HOA. 501 Lastly, while m/z 55 and 57 are important signals for both COA and HOA, COA typically has f<sub>55</sub> 502 > f<sub>57</sub>, whereas HOA has the reverse (W. Hu et al., 2016; D. D. Huang et al., 2021a; Mohr et al., 503 2009; Shah et al., 2018; Y. Zhang et al., 2015; Zhu et al., 2018). 504 Figure 5 also compares our cooking emissions measurements to PMF factors for biomass 505 burning (BBOA) and secondary organic aerosol (LVOOA). The majority of restaurant sites 506 exhibited weak correlations with BBOA and LVOOA. BBOA has prominent peaks at m/z 60 and 507 73, and the largest peak in the LVOOA mass spectrum is m/z 44; none of these peaks are

Formatted: Font color: Red

Formatted: Font color: Red

**Deleted:** Correlations with BBOA and LVOOA are weaker as these factors are characterized by dominant peaks at m/z 60 and 73 for BBOA and m/z 44 and 43 for LVOOA. There is a high R between our COA and the PMF HOA factor, which is representative of primary combustion-related emissions.

particularly large in the cooking mass spectra from the restaurant sites sampled here.

# 3.4 Cooking as a source of urban reduced nitrogen

Cooking OA from all of the restaurant sites had a significant contribution from AMS ions containing reduced nitrogen. The mean contribution of nitrogen-containing fragments to the total cooking OA mass was 15.8% (median = 10.7%; Table S2). The bulk of these N-containing ions (95% by mass) did not contain oxygen (Fig. S6), though oxygen could still be present on the parent molecule prior to fragmentation. These CxHyN+ fragments include  $C_2H_5N+ (m/z 43)$  and  $C_3H_5N+ (m/z 55)$ , shown in Figure 4. For example, in the mass spectrum presented for Bar/Restaurant 1 (Figure 3), the collective contribution of the CHN family peaks is 9.2% of the total signal mass. The nitrogen-containing fragment at m/z 41, denoted as  $C_3H_5N+ C_5H_5N+ C_5H_5N$ 

We took several steps to verify the presence of these reduced nitrogen peaks in our mass spectra. These quality assurance checks, including examples of peak fitting, are shown in section 3 of the SI. For example, Figuire S8 shows the fitting of C<sub>3</sub>H<sub>8</sub>N<sup>+</sup> for the Bakery samples. Figure S8 shows that the CHN family peaks are not present when the AMS chopper is closed. This indicates that these signals arise from particles, and are not instrument artifacts. One potential source of reduced-N peaks is surface ionization, where atoms are ejected from a heated surface and subsequently ionized. Figure S9 shows that our peak shapes remain Gaussian, and are therefore unlikely to be influenced by surface ionization.

Previous studies have reported the existence of nitrogen compounds or fragments from cooking experiments. These nitrogen-containing compounds can originate from the food itself or reactions with the types of gas used during cooking (Abdullahi et al., 2013). Reyes-Villegas et

Commented [AP3]: C+H+N does not equal 41. What is the ion?

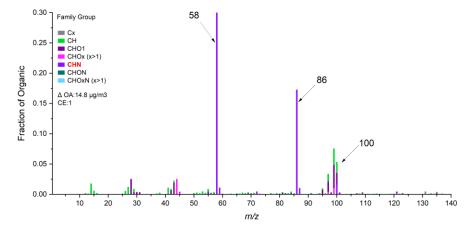

Formatted: Font color: Red

Formatted: Font color: Red

**Deleted:** For example, the mass spectrum from Bar/Restaurant 1 in Figure 2 has 9% CHN family peaks by mass, with significant contributions at m/z 41 and 43. For nearly all restaurants sampled here, the most abundant CHN group ion was C<sub>3</sub>H<sub>8</sub>N<sup>+</sup>, with fc<sub>3H8N</sub> typically > 196.¶

al., 2018 measured gas- and particle-phase emissions and found 14 different nitrogen-containing compounds using chemical ionization mass spectrometry. Rogge et al., 1991 measured amides in cooking emissions, including palmitamide and steramide. Amides were also identified from both Chinese cooking (Y. Zhao et al., 2007a) and Western-style cooking (Y. Zhao et al., 2007b) using GC-MS. Ditto et al., (2022) recently demonstrated that amides can be formed from the reaction of ammonia formed by amino acid thermal degradation with triglyceride ester linkages. In contrast to the reduced nitrogen in our samples, these nitrogen-containing compounds, including amides, have at least one oxygen in their formula.

The Bakery 1 and Bakery 2 samples had the largest contributions from reduced N. Figure 6 shows the aerosol mass spectrum from Bakery 1. The two most abundant ions in the mass spectrum are  $C_3H_8N^+$  (m/z 58) and  $C_5H_{12}N^+$  (m/z 86); together these two ions make up ~48% of the AMS-measured OA mass spectra. There is also a large contribution from  $C_6H_{14}N^+$  at m/z 100. The large abundance of these reduced N-containing peaks contributes to the low correlation between the Bakery samples and other sites in Figure 5.

**Figure 6.** The aerosol mass spectrum from <u>Bakery 1</u> with prominent peaks at m/z 58, 86, and 100 that are in the CHN family.

Deleted: Barkery 1

Formatted: Font color: Red

Though fast food sites have a lower correlation with other cooking sites in Figure 5, it is not primarily due to higher CHN levels like bakery samples. The most abundant signals of Fast Food 1 and Fast Food 2 were in the category of CHO and CH groups, where their sum accounts for 73.3 % and 82.0 % of the total mass, respectively. Two samples from Fast Food sites show moderate to slightly large proportions of CHN family peaks (14% and 7%) and  $f_{C3H8N+}$  (2.15 and 2.33).

While the  $C_3H_8N^+$  fragment has been observed in all of our cooking site data, there is almost no contribution of m/z 86 ( $C_5H_{12}N^+$ ) and 100 ( $C_6H_{14}N^+$ ) in our samples except for the two bakery visits (Table S2), which were collected adjacent to a large commercial bread bakery. It is thus possible that m/z 86 and 100 are more associated with commercial bakeries than restaurant cooking. The underlying source of the reduced nitrogen ions, especially m/z 86 and 100 observed at the bakery, is unknown. One potential source could be the use of azodicarbonamide ( $C_2H_4N_4O_2$ , ADA), which is used as an aging and bleaching ingredient in bread baking. To test whether ADA contributed to nitrogen-containing emissions from bread baking, we baked bread with and without ADA addition. We used the AMS to measure the composition of PM emissions during fermentation (i.e., while the bread dough rose) and baking. While we observed OA emissions during baking, none of our experiments showed the CHN signals with  $C_3H_8N^+$ ,  $C_5H_{12}N^+$ , and  $C_6H_{14}N^+$ . As a result, we cannot conclude that the presence of ADA leads to high proportions of CHN ions (SI Fig. 7).

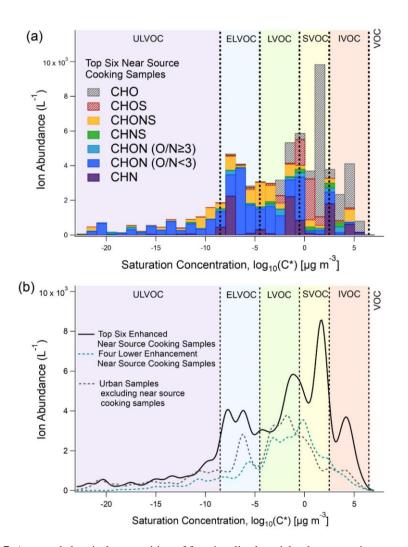

Abundant reduced nitrogen was also observed in the particle phase via LC-TOF and LC-MS/MS measurements. To supplement the online measurements of functionalized aerosol-phase compounds, especially those containing nitrogen, offline analysis using LC-TOF was employed

for organic compound speciation for each restaurant site with sufficient mass loading, with soft ionization allowing for the molecular formula-level speciation of observed organic species. Based on the online AMS data showing differences in OA enhancement (Fig. 2), the samples were split into three sample groups, the six high-emitting restaurants (Bar/Res 1, Diner 2, Pizza, Bar/Res 2, Diner 1, Island Cuisine), the lower enhancement near-source cooking samples (Bakery 1, Bakery 2, Fast Food 1, Fast Food 2, Cafe), and urban samples excluding near-source cooking samples (i.e., samples taken in different neighborhoods and parks), though this likely includes cooking-related contributions to the urban background.

Figure 7a shows the ion abundance volatility distribution of the different functionalized compound classes in the 6 samples with the highest PM concentrations (Fig. 2, see Fig. S10 for other samples). Compound volatilities were estimated from the generated formulas, assuming all species were at 300 K (Y. Li et al., 2016) from each sample, and all ion abundances were normalized by the sample volume for comparison across samples. Figure 7b shows the volatility distributions of ion abundances from the three sample groups, with the six more enhanced near-source cooking samples demonstrating high ion abundance consistent with the higher mass concentrations of PM<sub>2.5</sub> sampled. The six enhanced cooking samples in Figure 7a show a greater abundance of I/SVOCs compared to the other two sample groups, suggestive of fresh emissions. The observed mixtures are highly functionalized, with observed species containing nitrogen, oxygen, and sulfur, but we note that the LC-TOF employed here has poor ionization efficiencies for CH and CHS compounds, which are thus not considered for this analysis of functionalized compounds.

While urban particulate matter has been shown to contain many functionalized species (Ditto et al., 2018; Ye et al., 2021), recent work has also shown cooking to be a source of

nitrogen and sulfur-containing species, which can be emitted in the gas-phase from foods such as vegetables (Marcinkowska & Jeleń, 2022) or formed through cooking (Ditto et al., 2022; Takhar et al., 2019). The urban background samples excluding cooking samples and the five lower enhanced near-source cooking samples have similar volatility distributions with nitrogen-containing compounds (Fig. 7b, S11), which suggests a role for cooking emissions in the background functionalized OA composition in urban areas.

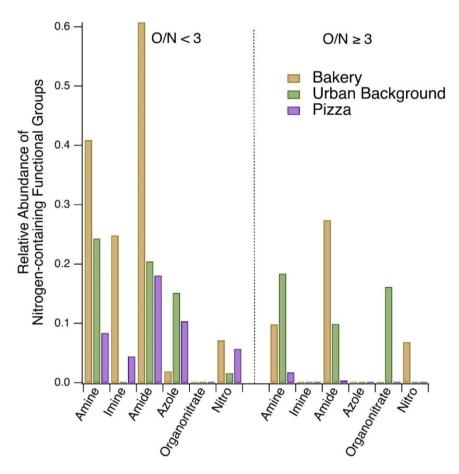

**Figure 7.** Averaged chemical composition of functionalized particle-phase organic compounds from (a) filters collected from the top six near-source cooking samples showing the highest enhancement in OA from the AMS measurements and (b) average ion abundance volatility distributions for the three sample groups, top six enhanced cooking samples, lower five near-source cooking samples, and the urban samples excluding near source cooking samples. Volatility bins were defined for the same reference temperature in (a) and (b) (i.e., 300 K, as all samples were collected during summertime).

While all samples contained nitrogen-containing compounds, LC-MS/MS was used on select samples (Bakery 1, Pizza, background sample 5) from each sample group to compare the functionalities of observed nitrogen. After compounds observed via LC-TOF (i.e., Fig. 7a) underwent QC/QA, those compounds were selected for MS/MS analysis in a targeted mode similar to prior work (Ditto et al., 2020).

Most nitrogen-containing compounds observed had an oxygen to nitrogen ratio (O/N) of less than 3, but other nitrogen-containing compound classes were present (Fig. 7, S11). Figure 8 shows the observed nitrogen-containing functional groups for the three samples run on MS/MS, split by O/N ratio less than 3 or greater than or equal to 3. Here, the Bakery 1 compounds analyzed by MS/MS were dominated by reduced nitrogen features, with prominent amine and amide functional groups, especially for compounds with O/N ratios lower than 3, which in itself is indicative of the presence of reduced nitrogen structural features.

Deleted: O/N

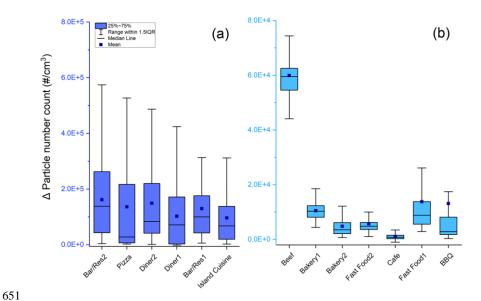

Formatted: Font color: Red

**Figure 8.** The relative abundance of nitrogen-containing functionalities in the Bakery 1, background sample 5, and Pizza MS/MS compounds are shown, separated by O/N ratio <3 on the left and  $\ge$  3 on the right, with prominently reduced nitrogen functionalities in the bakery sample. See Figure S13 for the complete range of functional groups and structural features observed in these samples. Enamine, nitrophenol, and nitrile functionalities were also searched for but were not detected in these three samples.

# 3.5. Particle size distributions and UFP enhancements in restaurant plumes

To expand upon Figure 1's observations of UFPs in an example restaurant plume, we examined UFP enhancements across the sampled restaurants and the size distribution of those emissions.

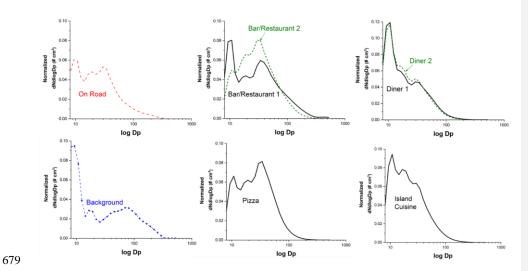

**Figure 9.** Particle number enhancement ( $\Delta PNC$ ) at each restaurant site (with IQR). The sample names in (a) and (b) are placed in the same order as in Figure 2.

Figure 9 summarizes the particle number concentrations above the background ( $\Delta PNC$ ) measured by the FMPS and scaled to the CPC. Similar to our  $\Delta OA$  distribution in Figure 2, there are notable site-to-site differences in particle number concentrations with the sites breaking down into the higher and lower-emitting groups (high  $\Delta PNC$  group mean  $\Delta PNC > 10^5$  #/cm³, low  $\Delta PNC$  group mean  $\Delta PNC < 10^5$  #/cm³).

All of the high  $\Delta$ PNC sites were also high  $\Delta$ OA sites, but most sites do not have a strong correlation between mean  $\Delta$ OA and mean  $\Delta$ PNC (Fig. S8). A moderate positive correlation was observed in the time series of PNC and OA at Diner 1 ( $R^2 = 0.64$ ), Beef (0.63), Bar/Restaurant 2 (0.60), and Bakery 1 (0.57); most other sites had poor correlations between  $\Delta$ OA and  $\Delta$ PNC ( $R^2 < 0.4$ ). This poor correlation may indicate that the emissions of OA and PNC are decoupled during cooking so that different activities boost emissions of OA mass versus particle number. For example, the PNC time series in Figure 1 has several spikes that do not have associated spikes in OA.

The PNC enhancements are less skewed than the OA enhancements. For  $\Delta$ PNC, the mean is always inside the IQR except for the BBQ sample, unlike several sites that had mean  $\Delta$ OA > 75<sup>th</sup> percentile. This implies that PNC emissions are less dominated by intense spikes than OA emissions. Figure 2 and Figure S4 show that OA concentrations often fell close to the background between spikes. PNC, on the other hand, was consistently elevated during the restaurant sampling. One possible explanation is that OA spikes are associated with cooking, whereas the consistently high PNC is associated with the heating of the cooking surface by either a natural gas flame or electricity (Amouei Torkmahalleh et al., 2018; Dennekamp et al., 2001; Wu et al., 2012).

**Figure 10.** Mean particle size distribution comparison of on-road, background, and high ΔPNC restaurants observed at Bar/Restaurant, Diner, Pizza, and Island cuisine measured from the FMPS (Fast Mobility Particle Sizer). To fit the size distributions onto the same scale, all are normalized to the total particle number of each sampling period. Thus the integral over each of the normalized size distributions is 1.

Figure 10 shows the mean particle size distributions for the "high  $\Delta PNC$ " restaurants from Figure 7a and the mean on-road and background particle size distributions from the period shown in Figure 1. All the restaurants emitted UFPs. The mode particle diameter from all sampled restaurants was less than 50 nm (Table 1), and the size distributions in Figure 10 clearly peak in the ultrafine size range. However, there is variability across the restaurants as some sites had bimodal size distributions, while others are closer to unimodal. For example, Bar/Restaurant 1 has distinct modes at ~10 and 40 nm, whereas Island Cuisine has a single broad mode centered around 20 nm. There is also variability within sites. For example, Bar/Restaurant 2 has a unimodal distribution with a mode around 40 nm, and the size distribution differs from the other

Formatted: Font color: Red

**Deleted:** To fit the size distributions onto the same scale, all are normalized to the total particle number (dN/dlogDp) of each sampling period over each size bin and make the sum of all normalized size distributions to be 1.

sample at the same location, while the two samples at the Diner have nearly identical size distributions.

In addition to being enhanced in terms of concentrations, the size distributions in the restaurant plumes are distinct from the average background size distributions, which have a bimodal distribution with a nucleation mode peak around 10 nm and an accumulation mode peak around 100 nm. Emissions from nearby vehicles dominate the on-road periods, with a bimodal size distribution around 10 nm and 20-40 nm, which is similarly observed in previous studies (Sturm et al., 2003; Wang et al., 2008; X. Yao et al., 2005).

## 4. Conclusions and Atmospheric Relevance

Using mobile measurements across a range of commercial cooking operations in two cities, our real-world sampling of cooking plumes from restaurants demonstrates substantial cooking-associated aerosol emissions with variability in the concentrations, chemical composition, and size distribution of PM and UFP emissions. Overall, emissions from most restaurants had similar mass spectra both to each other and to COA factors determined from factor analysis of ambient datasets. Aerosol mass spectra of cooking emissions were generally dominated by a mix of reduced  $(C_xH_y^+)$  and oxygenated  $(C_xH_yO^+)$  ions.

There were significant site-to-site differences in the OA enhancement attributable to restaurant emissions. This variability is due to a combination of differences in the emission rate from each restaurant and in dilution between the restaurant exhaust and our sampling inlet, though we cannot quantify the importance of each process. Since at all locations our inlet was only a few meters from the restaurant exhaust, it is likely that differences in the emission rate dominate site-to-site variability. Previous research by Louvaris et al., 2017 investigated meat

charbroiling emissions diluted within a chamber and reported that approximately 80% of the

COA persisted following isothermal dilution at ambient temperature (25 °C) by a factor of 10.

This is consistent with much of the cooking OA being in the LVOC or ELVOC volatility range.

Reduced nitrogen (N) was prevalent across all restaurant samples, contributing approximately 15% of the cooking organic aerosol (OA) mass at the sampled sites, with a diversity of reduced N functional groups observed. The presence of these reduced nitrogen species is confirmed with offline analysis of filter samples, which identified multiple Ncontaining species with O/N < 3, indicating that these nitrogen containing species were unlikely to be organic nitrates. A notable finding of this study was the distinct composition of emissions collected from a commercial bakery, marked by the elevated presence of reduced nitrogen. Numerous studies have investigated cooking aerosol compositions, demonstrating that different cooking techniques and ingredients can elevate nitrogen content levels in cooking PM (Ditto et al., 2022; Masoud et al., 2022; Reyes-Villegas et al., 2018b; Rogge et al., 1991b). Nitrogen found in cooking emissions has diverse origins, including from the food itself with both natural (e.g., protein-rich and plant-based products) (Bak et al., 2019; Han et al., 2020) and anthropogenic sources (e.g., fertilizers and food additives like nitrates and nitrites) (Dimkpa et al., 2020; Karwowska & Kononiuk, 2020). Nitrogen in cooking PM can also be formed from heterogenous reactions with thermal degradation products formed during cooking (Ditto et al., 2022),

To further examine potential sources of the nitrogen features identified from the bakery emissions, we conducted an experiment with the AMS measuring bread baking emissions both with and without the dough stabilizer azodicarbonamide (C<sub>2</sub>H<sub>4</sub>N<sub>4</sub>O<sub>2</sub>) as a potential source of N-containing peaks. While the reduced nitrogen peaks were not observed, this result implies the

This study also highlights that cooking emissions are substantial contributors to urban UFPs. Variability between sites was observed, with some sites displaying unimodal and others displaying bimodal size distributions. However, there are uncertainties in identifying the characteristics of UFPs from cooking emissions, such as their origin from cooking processes or natural gas usage, and potential changes in particle size distributions during dilution due to the evaporation of semi-volatile components. Uncontrolled dilution in this study may have contributed to differences in UFP concentration and size distribution (Lipsky & Robinson, 2006).

In order to gain a deeper understanding of the factors influencing UFP size distribution from real-world cooking sources, further investigation is warranted, taking into account aspects such as restaurant proximity, food type, and order frequency. Consequently, subsequent research can identify the prevalent molecular features of reduced nitrogen in cooking emissions by setting constraints on specific parameters, providing a more comprehensive analysis.

Overall, this study underscores the importance of comprehensively understanding cooking emissions, including their contribution to the PM<sub>2.5</sub> mass, composition, and exposure variability across urban areas, in order to develop effective strategies for mitigating their impact on air quality and human health. Specifically, further research is needed to better understand the role of reduced nitrogen in atmospheric emissions from cooking activities.
