10 **Abstract.** We present a new method for partitioning observed CO₂ enhancements (CO₂xs) into fossil and biospheric fractions (C_{ff} and C_{bio}) based on measurements of CO and δ¹³CO₂, complemented by flask-based Δ¹⁴CO₂ measurements. This method additionally partitions the fossil fraction into natural gas and petroleum fractions (when coal combustion is insignificant). Although here we apply the method only to discrete flask air measurements, the advantage of this
15 method (CO and δ¹³CO₂-based method) is that CO₂xs partitioning can be applied at high frequency when continuous measurements of CO and δ¹³CO₂ are available. High frequency partitioning of CO₂xs into C_{ff} and C_{bio} has already been demonstrated using continuous measurements of CO (CO-based method) and Δ¹⁴CO₂ measurements from flask air samples. We find that the uncertainty in C_{ff} estimated from the CO and δ¹³CO₂-based method averages 3.2 ppm (23 % of the mean C_{ff}
20 of 14.2 ppm estimated directly from Δ¹⁴CO₂) which is significantly less than the CO-based method which has an average uncertainty of 4.8 ppm (34 % of the mean C_{ff}). Using measurements of CO, δ¹³CO₂ and Δ¹⁴CO₂ from flask air samples at three sites in the greater Los Angeles region, we find large contributions of biogenic sources that vary by season. On a monthly average, the biogenic signal accounts for -14 to +25 % of CO₂xs with larger and positive contributions in winter and
25 smaller and negative contributions in summer due to net respiration and net photosynthesis, respectively. Partitioning C_{ff} into petroleum and natural gas combustion fractions reveals that the largest contribution of natural gas combustion generally occurs in summer, which is likely related to increased electricity generation in LA power plants for air-conditioning.

30

1 Introduction

The world's cities account for up to 70 % of global greenhouse gas (GHG) emissions, while covering less than 2 % of the Earth's surface (IPCC, 2014). Cities around the world have started implementing mitigation strategies to reduce carbon dioxide (CO₂) emissions and collaborate with each other in organizations such as the C40 Cities Climate Leadership Group (<https://www.c40.org/>) and the Global Covenant of Mayors for Climate and Energy (<https://www.globalcovenantofmayors.org/>). To support urban efforts, monitoring systems are necessary to evaluate and verify reductions attributable to specific mitigation strategies (Turnbull et al. 2022).

Current understanding of anthropogenic CO₂ emissions mainly derives from methods that estimate aggregate emissions in a domain using economic statistics such as total fuel sales or activity data such as total distance traveled for on-road vehicle emissions. These “bottom-up” methods provide specific location and process information that rely on mapping the source-specific emission factors and measurements of activities (e.g., McDonald et al. 2014; Gurney et al. 2019; Gately and Hutyra 2017; [Super et al. 2020](#)). In contrast, more recently “top-down” methods that quantify emissions from measurements of atmospheric CO₂ have been used to estimate emissions. These top-down approaches typically use either a mass balance technique where an initial estimate is not required (e.g. [Mays et al. 2009](#); [Cambaliza et al. 2014](#); Heimburger et al. 2017; Ahn et al. 2020) or an inverse/data assimilation approach where observations and a prior map of emissions are combined to generate a best estimate (e.g. [Bréon et al. 2015](#); [Staufer et al. 2016](#); Sargents et al. 2018; Turner et al. 2020; Lauvaux et al. 2016, 2020).

To estimate anthropogenic CO₂ emissions using top-down method, it is crucial to separate the fossil fuel signals from the biogenic signals, which can vary from negative (uptake) to positive (emission) across the annual cycle. Recent analyses of urban CO₂ suggest that biogenic emissions and uptake have significant magnitudes relative to fossil fuel fluxes, especially during the growing season (Sargent et al., 2018; Vogel et al., 2019; Miller et al., 2020). Previous top-down studies used biosphere models to estimate biogenic fluxes and then focused on determining the balance of emissions attributable to fossil fuel combustion assuming that the biogenic emissions are known (Sargent et al. 2018; Turner et al. 2020; Lauvaux et al. 2020). However, even with recent improvements in biosphere models (Wu et al. 2021; Gourджи et al. 2022) the actual magnitude and variability of these fluxes are still not well constrained (Hardiman et al., 2017; Winbourne et al.,

2022), potentially leading to unknown observational bias in the associated estimates of fossil fuel derived emissions.

65 Radiocarbon ($^{14}\text{CO}_2$) provides the ability to separate biogenic and anthropogenic CO_2 fluxes and mole fractions from an observational point of view (e.g. Levin, 2003; Turnbull 2006). Observational methods rely on the fact that fossil fuels and the resultant CO_2 produced during combustion are completely devoid of ^{14}C (i.e., $\Delta^{14}\text{C}_{\text{ff}} = -1000\text{‰}$ on the widely used Delta scale; **Stuiver and Polach, 1977**). Measurements of $\Delta^{14}\text{CO}_2$, acquired at time scales of weeks to months, allow quantification of seasonal variations in biogenic and fossil contributions to the atmospheric
70 CO_2 mole fraction (e.g., Djuricin et al. 2010; Miller et al. 2012; Turnbull et al. 2015). ^{14}C methods typically require air sample collection, preparation and analysis via accelerator mass spectrometry which limits the number of measurements, although a number of promising optical methods for in situ $^{14}\text{CO}_2$ measurement at natural abundance are currently being developed (Fleisher et al. 2017; Genoud et al. 2019; McCartt and Jiang 2022).

75 On the other hand, carbon monoxide (CO) is a widely used tracer that can be measured continuously in situ using high-precision optical analyzers (e.g. Vogel et al. 2010; Newman et al. 2013; Turnbull et al. 2015; **Lauvaux et al. 2020**). CO is often co-emitted with fossil fuel CO_2 ($\text{CO}_{2\text{ff}}$) during incomplete combustion. If the $\text{CO}_x\text{s}:\text{CO}_{2\text{ff}}$ ratio (R_{ff} , where CO_xs is the CO enhancement above background) is well constrained, continuous CO measurements combined
80 with R_{ff} can provide an estimate of continuous $\text{CO}_{2\text{ff}}$. A few studies have applied this method to estimate fossil fuel emissions for a moment in time during an airborne measurement campaign (Graven et al. 2009; Turnbull et al. 2011). However, this approach is challenging to identify interannual trends because R_{ff} at a site may vary significantly on timescales ranging from hours to years (Levin and Karstens, 2007; Vogel et al., 2010). $\text{CO}:\text{CO}_2$ emission ratio can vary by sources
85 depending on the carbon content of the fuel and combustion conditions. Due to the impacts of atmospheric transport at a given observation site and the variability in the source combination in time and space, R_{ff} also varies in time and space. Additionally, CO produced from oxidation of volatile organic compounds (VOCs) can have an effect (Vimont et al., 2019).

Vardag et al. (2015) proposed dividing fossil fuel emissions further into two groups that may
90 display less variability in $\text{CO}:\text{CO}_2$ emission ratio. If one group is well constrained by CO and the other by $^{13}\text{CO}_2$, each group can be identified by combining CO and $^{13}\text{CO}_2$ observations. Vardag et al. focused on separating traffic from non-traffic emissions, or biofuel emissions from the other

fossil fuel emissions. However, no significant benefit of combining CO and $^{13}\text{CO}_2$ was found because traffic and biofuel CO_2 do not produce distinct CO: CO_2 emission ratio or $^{13}\text{CO}_2$ isotopic signatures compared to the other CO_2 ff source terms.

Here, we differentiate CO_2 signals from biogenic, petroleum and natural gas sources by combining CO, $\delta^{13}\text{CO}_2$, and $\Delta^{14}\text{CO}_2$ measurements. The combination of $\Delta^{14}\text{CO}_2$ and $\delta^{13}\text{CO}_2$ has been used previously to distinguish biogenic, petroleum and natural gas signals for air sampling events (Lopez et al. 2013; Djuricin et al. 2010) and at seasonal scale (Newman et al., 2016). In contrast, the combination of CO and $\delta^{13}\text{CO}_2$, which can both be measured at high frequency, enables source partitioning at higher temporal resolution. We demonstrate the agreement between the existing $\Delta^{14}\text{CO}_2$, $\delta^{13}\text{CO}_2$ and newly proposed CO, $\delta^{13}\text{CO}_2$ methods. This establishes the utility of the CO and $\delta^{13}\text{CO}_2$ in partitioning CO_2 s into fossil fuel and biogenic components, with further partitioning of fossil fuel sources into petroleum and natural gas sources, in the Los Angeles megacity.

2 Methods

Here, we describe two methods for separating fossil fuel and biogenic components from atmospheric CO_2 measurements in the complex urban environment of the Los Angeles megacity (LA). Section 2.2 describes our application of the method already described by Newman et al. (2016) using $\Delta^{14}\text{CO}_2$ and $\delta^{13}\text{CO}_2$ observations. The details of the new method utilizing CO and $\delta^{13}\text{CO}_2$ measurements are described in section 2.3. Briefly, we take advantage of the fact that the combination of the CO: CO_2 emission ratio and the $^{13}\text{CO}_2$ isotopic signature reveal a very distinct pattern for biogenic, petroleum and natural gas sources. However, this approach requires knowledge of the CO: CO_2 emission ratio and the isotopic signature of each source. We apply isotopic signatures reported by previous studies, and CO: CO_2 emission ratios are determined for LA using measurements of CO, $\delta^{13}\text{CO}_2$ and $\Delta^{14}\text{CO}_2$ from flask samples. Flask measurements are described in section 2.1 and the source apportionment from $\Delta^{14}\text{CO}_2$ and $\delta^{13}\text{CO}_2$ observations, which is used to derive CO: CO_2 emission ratios for each source, is described in section 2.2.

2.1 Measurements

120 We use measurements from air samples collected at 2 p.m. local standard time at three existing
Los Angeles Megacity Carbon Project sites: University of Southern California (USC), California
State University, Fullerton (FUL), and Granada Hills (GRA) (Miller et al., 2020). Air samples
were collected from November 2014 to March 2016 using National Oceanic and Atmospheric
Administration (NOAA) programmable flask packages (PFPs) and programmable compressor
125 packages (Sweeney et al., 2015). The samples were sent back to the NOAA Global Monitoring
Laboratory where greenhouse gases including CO₂ as well as CO mole fractions were measured
using NOAA's high-precision/high-accuracy greenhouse gas measurement system (Sweeney et al.,
2015). After the measurement, residual air is extracted from PFP flasks and CO₂ is isolated for ¹⁴C
measurement using established cryogenic and mass spectrometric techniques (Lehman et al., 2013).
130 Samples are purified, graphitized and packed into individual targets at the University of Colorado,
Boulder, Institute of Arctic and Alpine Research (INSTAAR) and then sent to the University of
California, Irvine, Keck Accelerator Mass Spectrometry Facility for high- precision Δ¹⁴C
measurement. One-sigma measurement uncertainty is ~1.8 ‰, equivalent to ~1.2 parts per
million (ppm) of recently added fossil fuel-CO₂. δ¹³CO₂ in PFP samples is measured by dual inlet
135 isotope ratio mass spectrometry with a precision of approximately 0.02 ‰ at the INSTAAR Stable
Isotope Laboratory (Vaughn et al., 2004; Sweeney et al., 2015)
Enhancement of each species is defined relative to a time-dependent background level, which is
based on nighttime (2 AM local standard time) measurements made at Mount Wilson Observatory
(MWO; Fig. 1) located at 1,670 m above sea level. Nighttime air at MWO generally represents the
140 relatively clean, well-mixed free troposphere since polluted LA Basin boundary layer air has
typically descended back into the basin by this time. After an additional step of filtering obvious
outliers corresponding to pollution events indicated by anomalously elevated values were
interpolated to the time of observations within the LA Basin by fitting curves to the screened MWO
data (Fig. 2). A further analysis of associated CO measurements indicates that background
145 reconstructed using nighttime air samples from MWO is representative of clean background air
coming from either on- or off-shore (Miller et al., 2020).

2.2 Partitioning CO₂ signals using flask-based Δ¹⁴CO₂ and δ¹³CO₂ measurements

Our general approach to distinguishing CO₂ signals from biogenic, petroleum and natural gas sources using Δ¹⁴C×CO₂ and δ¹³C×CO₂ follows the procedure described by Newman et al. (2016).
 150 Following previous derivations (e.g., Turnbull et al, 2006; Miller et al. 2020), we start with the definition for CO₂ff which is based on mass balances for the atmospherically conserved quantities Δ¹⁴C×CO₂ and CO₂:

$$C_{ff} = \frac{C_{obs}(\Delta_{obs}-\Delta_{bkg})}{(\Delta_{ff}-\Delta_{bkg})} - \frac{C_r(\Delta_r-\Delta_{bkg})}{(\Delta_{ff}-\Delta_{bkg})} \quad (1)$$

Measured CO₂ mole fractions and Δ¹⁴C values are abbreviated as *C* and Δ. Subscripts ‘obs’, ‘bkg’,
 155 ‘ff’ and ‘r’ represent observations, background, fossil fuel, and respiration, respectively. Δ_{ff} is equal to −1000 ‰. As in the Miller et al. (2020) study focusing on LA, we estimate the value of the small respiratory term, $C_r(\Delta_r - \Delta_{bkg})/(\Delta_{ff} - \Delta_{bkg})$, as 0.25 ppm. The overall uncertainty of *C_{ff}* for LA measurements during 2015 is approximately 1.2 ppm, which includes 100% uncertainty assigned to the respiratory term. *C_{ff}* and *C_{bio}* ($C_{bio} = C_{xs} - C_{ff}$) are calculated for all
 160 available flask air samples during the 2014 – 2016 sampling period, a frequency of approximately three times per week at each of the three sites.

C_{ff} is then separated into signals from petroleum and natural gas combustion using ¹³C:¹²C ratios (δ¹³C as defined by standard isotopic definition; Craig, 1957) measured on the same air samples. First, the flux weighted-mean δ¹³C signature of all sources located in the observation footprints
 165 (δ_{src}) is determined on a sample-by-sample basis using the combined mass balances for δ¹³C×CO₂ and CO₂:

$$\delta_{src} = \frac{\delta_{obs} \times C_{obs} - \delta_{bkg} \times C_{bkg}}{C_{obs} - C_{bkg}} \quad (2)$$

where δ is short-hand for δ¹³C×CO₂. The uncertainties in *C_{obs}*, *C_{bkg}*, δ_{obs}, and δ_{bkg} are 0.1 ppm, 1.5 ppm, 0.02 ‰, and 0.08 ‰, respectively. The “obs” uncertainties are measurement uncertainties,
 170 while the “bkg” uncertainties are determined as the standard deviation of the difference between the observations and their smoothed curve representation at MWO. The median uncertainty in δ_{src} is 3.0 ‰ and is calculated by propagating the uncertainties listed above, including covariance between δ¹³C and δ¹³C×CO₂.

We combine *C_{ff}* (eq. 1) and δ_{src} (eq. 2) to determine the δ¹³C signature of fossil fuel emissions,
 175 δ_{ff}:

$$\delta_{src} = \delta_{ff} \times f_{ff} + \delta_{bio} \times (1 - f_{ff}) \quad (3)$$

Rearranging yields:

$$\delta_{ff} = \frac{\delta_{src} - \delta_{bio} \times (1 - f_{ff})}{f_{ff}} \quad (4)$$

where f is the fraction. Following Newman et al. (2016), we take the isotopic signature of biospheric CO₂ fluxes (δ_{bio}) to be -26.6 ± 0.5 ‰ based on the analysis of Northern Hemisphere mid-latitude CO₂ and $\delta^{13}\text{C}$ observations (Bakwin et al., 1998b), which reflects the predominance of C₃ photosynthesis. However, because LA turfgrasses, which could account for a significant fraction of urban CO₂ fluxes [Miller, 2020], are often C₄ species (e.g., Bermuda and Buffalo grasses), we also conduct tests using $\delta_{bio} = -20$ ‰, representing a C3/C4 mix (Fig. S1). When we change δ_{bio} from -26.6 ‰ to -20 ‰, f_{pet} decreases by 0.04 and f_{ng} increases by 0.05 which is smaller than the median uncertainty in f_{pet} and f_{ng} which is 0.17 and 0.16, respectively. f_{ff} is the fraction of C_{ff} in C_{xs} , i.e., C_{ff}/C_{xs} , and $1 - f_{ff} = f_{bio}$. Lastly, the proportion of C_{ff} emitted by petroleum (pet) and natural gas (ng) combustion, f_{pet} and f_{ng} , are calculated from the values of δ_{ff} :

$$\delta_{ff} = \delta_{pet} \times f_{pet/ff} + \delta_{ng} \times (1 - f_{pet/ff}) \quad (5)$$

$$f_{pet/ff} = \frac{\delta_{ff} - \delta_{ng}}{\delta_{pet} - \delta_{ng}} \quad (6)$$

We use values of -25.5 ± 0.5 ‰ for δ_{pet} (Newman et al. 2016; measurements in 2014) and -40.2 ± 0.5 ‰ for δ_{ng} (Newman et al., 2008); $f_{pet} = f_{ff} \times f_{pet/ff}$, and $f_{ng} = f_{ff} \times f_{ng/ff}$, where $f_{ng/ff} = 1 - f_{pet/ff}$. We use temporally constant $\delta^{13}\text{C}$ signatures for petroleum, natural gas and biogenic sources (and sinks), although with additional processed-based information, this assumption could be relaxed in the future. Note that although pet, ng, and bio signatures are fixed, both δ_{src} and δ_{ff} vary with time, meaning that f_{bio} , f_{pet} and f_{ng} all vary at the frequency of the air sampling. Samples with calculated $f_{pet/ff}$ values outside the range of 0 and 1, corresponding to small CO₂xs and large uncertainty in δ_{src} , are excluded from the analysis.

200 2.3 Partitioning CO₂ signals using CO and $\delta^{13}\text{CO}_2$ measurements

Although we can determine f_{bio} , f_{pet} and f_{ng} at the frequency of discrete flask sampling events using the method described in Section 2.2, here we describe how comparable CO₂xs fractions can in theory be determined at high frequency using continuous measurements of CO and $\delta^{13}\text{CO}_2$. To evaluate the method, we compute the relative contributions of biogenic, petroleum and natural gas sources to CO₂xs using flask air CO and $\delta^{13}\text{CO}_2$ measurements and compare these to values obtained using the $\Delta^{14}\text{CO}_2$ -guided approach for the same samples by applying the following system of equations:

$$R_{src} = R_{bio} \times f_{bio} + R_{pet} \times f_{pet} + R_{ng} \times f_{ng} \quad (7)$$

$$\delta_{src} = \delta_{bio} \times f_{bio} + \delta_{pet} \times f_{pet} + \delta_{ng} \times f_{ng} \quad (8)$$

$$1 = f_{bio} + f_{pet} + f_{ng} \quad (9)$$

R_{src} represents the CO/CO₂ ratio of the total source, which is the observed CO_xs/CO₂xs ratio, and we use R to refer to the CO/CO₂ emission ratios of individual CO₂xs components (bio, pet, and ng). For now, we assume that R of each source are constant over a year-long period and over the greater LA region (discussed in Section 3.2); especially with high frequency CO and $\delta^{13}\text{CO}_2$ measurements, this assumption could easily be relaxed (discussed in Section 3.3).

R values and $\delta^{13}\text{C}$ signatures for bio, pet, and ng are needed to solve Eqs. 7-9. $\delta^{13}\text{C}$ signatures are specified in section 2.2; R values are obtained via multiple linear regression of Eq. 7 using observed R_{src} and f values determined using $\Delta^{14}\text{C}$ and $\delta^{13}\text{C}$ of CO₂ measurements as described in Section 2.2. Then we solve Eqs. 7-9 for new f values, f' . This new CO₂xs partitioning (i.e., f'_{bio} , f'_{pet} , f'_{ng}) based on CO and $\delta^{13}\text{CO}_2$ observations is used to calculate new values of C_{ff} and C_{bio} (i.e., C'_{ff} and C'_{bio}).

3 Results and Discussion

3.1 Contribution of biogenic, petroleum and natural gas sources in CO₂ excess

We calculated the fractional contribution of petroleum, natural gas, and biospheric fluxes to total CO₂xs each month from April 2015 to March 2016 using $\Delta^{14}\text{CO}_2$ and $\delta^{13}\text{CO}_2$ observations recorded at FUL, USC and GRA. The results are given in Table S1 and presented in Figure 3. Figure 4 presents the results in terms of the relative CO₂xs contribution from each source at each

230 site. We observe seasonal variation in CO₂xs from each source. Fossil fuel is the dominant CO₂ emissions source at each site which agrees with the findings of Newman et al. (2016) and Miller et al. (2020). Annually averaged across all three sites, biogenic emissions account for 6 % of CO₂xs. Biogenic emissions are larger and positive in winter and smaller and negative in summer, indicating winter respiration and uptake in summertime, generally consistent with the results of Miller et al. (2020). Note that in this study, we do not partition C_{bio} into an urban biosphere component and other components related to the oxidation of biogenic carbon including ethanol
235 added to gasoline, and human and other animal food and waste (which can only be positive and are unlikely to vary much seasonally). If, as in Miller et al. (2020), we accounted for the always positive ethanol, food, and waste signals, we would likely observe similarly large seasonal drawdown associated with urban vegetation.

We also observe spatial differences: The USC site exhibits a smaller contribution of the biosphere
240 (3 % of annual average CO₂ excess) compared to FUL and GRA (9 % and 5 % of total CO₂ excess, respectively). However, these modest annual average biospheric contributions mask significant seasonal activity. On a monthly basis, maximum positive biogenic contribution is observed in November at 25 %, 26 %, and 22 % at USC, FUL, and GRA (percentage of total CO₂ excess, respectively). And the maximum negative contribution, driven by net photosynthesis, is observed
245 in July with values of -22 %, -13 %, and -12 % at USC, FUL, and GRA (percentage of total CO₂ excess, respectively).

Network average C_{ff} is 11.0 ± 14.5 ppm in winter (November-February; median and standard deviation) and 12.2 ± 6.6 ppm in summer (May-August). No significant difference is observed in winter and summer C_{ff}. This corresponds to the seasonality in Hestia-LA emissions, which
250 indicates C_{ff} inputs are only 3 % higher in winter. High variability observed in wintertime C_{ff} agrees with Miller et al. (2020) which is likely caused by increased temperature inversion trapping as the cold ground surface in winter cools the air layer right above the ground. While Hestia-LA estimated relative contribution of petroleum and natural gas to fossil fuel emissions as 75 % and 25 %, we observe lower contribution of petroleum, 67 %, and larger contribution of natural gas,
255 33 %. Furthermore, the top-down seasonality of petroleum and natural gas (Fig. 4), which as fractions of C_{ff} should be largely independent of mixing, are clearly evident. The proportion of natural gas in fossil fuel signals are 40 % and 36 % in summer and 34 % and 30% in winter at FUL and USC (Fig. 3). The increase in the natural gas contribution observed in summer can be

explained by the increase in natural gas generated electricity in LA power plants to provide for air conditioning in summer (Newman et al., 2016; He et al., 2019). GRA, located northwest of USC by ~35 km without an electricity generation facility nearby, shows the opposite pattern (24 % in summer and 40 % in winter). This suggests the local influence of increased natural gas usage for heating in the winter.

3.2 CO:CO₂ emission ratio (*R*) values of biogenic, petroleum and natural gas sources

Monthly, site-based R_{src} varies between 5.5 – 11.4 ppb ppm⁻¹ (Fig. 5), with a mean and standard deviation of 8.2 ± 1.6 ppb/ppm (relative s.d. = 19 %). Greater variability is seen in R_{ff} (lower panel): mean and s.d. of 9.6 ± 2.1 ppm (relative s.d. = 22 %). To understand and predict the variation in R_{ff} , we further divide the fossil fuel emissions into petroleum and natural gas emissions. Applying the calculated f values from $\Delta^{14}\text{CO}_2$ and $\delta^{13}\text{CO}_2$ observations (Section 2.2., Fig. 3), we solve Eq. 7 for each source's CO/CO₂ emission ratio, R (Table 2). Note that we exclude negative flask-based values of CO_xs (and corresponding R_{src} values) and CO_{2ff} (and corresponding f_{ff} values) as non-physical. Likewise, positive δ_{src} values and $f_{pet/ff}$ values (and corresponding f_{pet} and f_{ng} values) outside the range of 0-1 are also excluded. A bootstrapping method is used to calculate the mean and uncertainty of possible CO/CO₂ ratios. The CO/CO₂ ratios of petroleum (R_{pet}) and natural gas (R_{ng}) combustion emissions are 12.2 ± 0.6 ppb ppm⁻¹ and 2.3 ± 1.2 ppb ppm⁻¹, respectively. As discussed above, the proportion of natural gas in fossil fuel emissions is bigger in summer resulting in smaller R_{ff} in summer at FUL and USC. We find the value of 1.8 ± 0.8 ppb ppm⁻¹ for R_{bio} which is non-zero because biofuel (mainly corn-based ethanol) in the gasoline in California with large CO/CO₂ ratio signal is included in the biogenic sources while respiratory CO/CO₂ ratios approach 0. A larger contribution of the biosphere with a low CO/CO₂ ratio in winter offsets the large R_{ff} lowering the variability in R_{src} at each site. We compare our model-determined CO/CO₂ ratios of each source (Table 2) to bottom-up inventory-based estimates (Table 1). CO/CO₂ ratios of each source constrained from our model and observational data approach agree well with the bottom-up inventory-based estimates. Sources contributing a high percentage of CO₂ emissions strongly influence the total CO/CO₂ ratio. The CO/CO₂ ratio of petroleum combustion is greatly affected by on-road emissions and industrial emissions (contributing 60 % and 28 % of total petroleum CO₂ emissions). Natural gas is mostly

dominated by non-mobile emissions (Electricity production, residential, commercial, and industrial, sequentially) resulting in low CO/CO₂ ratio.

290 3.3 Estimation of CO₂ff based on CO and ¹³CO₂ observations

Table 2 shows the CO/CO₂ ratio and δ¹³C signature of each source. The combination of the R and δ signals reveal a distinct pattern for each source: the biosphere has low near-zero R , petroleum has high R , and natural gas has low R . Petroleum and biosphere CO₂ have similar δ values, whereas natural gas has a very low δ . By substituting these values into Eqs. 7-9, f' values are
295 calculated, and then we calculate C'_{ff} by multiplying the sum of f'_{pet} and f'_{ng} by CO₂xs measured every few days. We compare f'_{ff} and C'_{ff} to f_{ff} and C_{ff} (determined using ¹⁴C observations) in Fig. 6. Assessment for each source is shown in Figure S2 and S3. The R² values are 0.63 and 0.90 for f'_{ff} and C'_{ff} , respectively.

If R values are allowed to vary in time, it is likely to improve the precision of the method. We
300 calculate the uncertainty in C'_{ff} for varying temporal resolutions of R (black solid line in Fig. 7). We find that the uncertainty increases when the size of the window increases from 1-week to 10-week; in other words, allowing temporal variation in R improves the precision of the method. However, the uncertainty slightly decreases beyond the 10-week window. This is likely caused by the reduction in the error of R values (not shown) as the number of observations used to find R (by
305 solving Eq. 7) increases. In summary, the ideal flask sampling frequency for this method would be higher than every 2 weeks. In cases where this is impossible, it is better to assume constant R values.

The uncertainty in C'_{ff} estimated using the CO-based method is also shown in Figure 7 (black dashed line). The CO-based method also provides improved precision of the method when flask
310 sampling is available at higher frequency. However, the CO and δ¹³CO₂-based method shows greater confidence than the CO-based method for the whole range of adjusted temporal resolution in R . When using constant R values (temporal resolution of 50 weeks), the uncertainty is 3.2 ppm (the 1σ standard deviation of differences between C_{ff} and C'_{ff}) for the CO and δ¹³CO₂-based method, while it is 4.8 ppm for CO-based method. This improvement is likely associated with the
315 additional information provided by δ¹³CO₂ that constrains the effective R_{ff} and further separates fossil fuel sources into sub-categories (petroleum and natural gas sources).

4 Conclusions

We present a CO and $\delta^{13}\text{CO}_2$ -based method to estimate CO_2ff which is based on flask-based $\Delta^{14}\text{CO}_2$ measurements. We have applied the method to measurements from flask samples collected in the LA basin, every few days in the afternoon for more than one year (2015-16). The proposed method was assessed by comparing it to a more traditional $\Delta^{14}\text{CO}_2$ -based method. CO and $\delta^{13}\text{CO}_2$ approach can be applied to continuous measurements of CO_2 , CO and $\delta^{13}\text{CO}_2$ which can provide CO_2ff estimates at higher temporal resolution and with greater accuracy than previously applied CO-based methods.

We have analyzed three locations in the Los Angeles megacity, partitioning observed CO_2 enhancements (CO_2xs) into biogenic, petroleum and natural gas sources. We observed a substantial biogenic signal that varies from -14% to +25% of CO_2xs over the course of the year, with positive contributions in winter and negative contributions in summer due to net respiration and net photosynthesis, respectively. Furthermore, partitioning CO_2ff into petroleum and natural gas combustion fractions revealed that natural gas combustion has the largest contribution in summer, potentially due to an increase in electricity generation at LA power plants for air conditioning.

Data availability. The data that support the findings of this study are available from JBM (john.b.miller@noaa.gov) upon request.

Author contributions. JK designed and executed the study. JBM, SJL, and SEM provided the data. JK prepared the manuscript with contributions from all co-authors

Competing interests. The authors declare that they have no conflict of interest.

545 **Figure 3.** Monthly mean fractional contributions (f) of biosphere (green), petroleum (red), and natural gas (yellow) to CO₂xs at each site, as determined from $\Delta^{14}\text{C}$ and $\delta^{13}\text{C}$ observations (Section 2.2). The sum of the fractions is one in each month. Dates are labeled in month/year.

550

Figure 4. Monthly mean CO₂xs partitioned into biosphere (green), petroleum (red), and natural gas (yellow) signals, as determined from $\Delta^{14}\text{C}$ and $\delta^{13}\text{C}$ observations, at each site. The black marker indicates CO₂xs. Dates are labeled in month/year.

555

Figure 5. Monthly variations in COxs/CO₂xs (Rsrc) and COxs/CO₂ff (Rff) at each site. COxs/CO₂ff is calculated using ¹⁴C observations. Dates are labeled in month/year.

560

565

Figure 6. Comparison of f_{ff} and f'_{ff} (left) and C_{ff} and C'_{ff} (right). Black lines represent 1:1 relationships and different colors indicate different sites.

570

Figure 7. Uncertainty in C'_{ff} for varying temporal resolution of R (N weeks). R is determined for each data point solving Eq. 7 using CO, $^{13}\text{CO}_2$ and $^{14}\text{CO}_2$ observations within a moving window of $2N$ weeks. For CO-based method, R_{ff} is smoothed using a $2N$ weeks moving window.

575

Table 1. Bottom-up CO₂ emission, CO emission, and R (CO/CO₂ ratio) estimates for each source sector and fuel type for LA basin based on the Vulcan 3.0 and the U.S. Environmental Protection Agency (EPA) National Emission Inventory for 2011 (NEI 2011) product. NEI 2011 is scaled by the emissions with fuel consumption dataset from the U.S. Energy Information Administration (EIA) State Energy Data System (SEDS) to estimate 2015 CO emissions.
