**Abstract.** New regulations from the International Maritime Organization (IMO) limiting sulfur emissions from the shipping industry are expected to have large benefits in terms of public health but come with an undesired side effect: an acceleration of global warming as the climate-cooling effects of ship pollution on marine clouds is diminished. Previous work has found a substantial decrease in the detection of ship tracks in clouds after the IMO 2020 regulations went into effect but changes in large-scale cloud properties have been more equivocal. Using a statistical technique that estimates counterfactual fields of what large-scale cloud and radiative properties within an isolated shipping corridor in the southeastern Atlantic would have been in the absence of shipping, we confidently detect a reduction in the magnitude of cloud droplet effective radius decreases within the shipping corridor and find evidence for a reduction in the magnitude of cloud brightening as well. The instantaneous radiative forcing due to aerosol–cloud interactions from the IMO 2020 regulations is estimated as  $O(1 \text{ W m}^{-2})$  within the shipping corridor, lending credence to global estimates of  $O(0.1 \text{ W m}^{-2})$ . In addition to their geophysical significance, our results also provide independent evidence for general compliance with the IMO 2020 regulations.

## 1 Introduction and approach

20 Since 1 January 2020, International Maritime Organization (IMO) Marine Environment Protection Committee (MEPC) regulations have limited sulfur in marine fuels from 3.5% by mass to 0.5%, or required exhaust gas cleaning systems (scrubbers) to achieve an equivalent reduction in sulfur oxide ( $\text{SO}_x$ ) pollution (IMO, 2019). These IMO 2020 fuel sulfur regulations and the resulting decrease in sulfate aerosol (airborne particulate) are expected to have large benefits to public health (Partanen et al., 2013; Sofiev et al., 2018; Zhang et al., 2021). They are also expected to have an undesired side effect, 25 however: as sulfate aerosol cools the climate by reflecting sunlight directly and indirectly via changing cloud properties, the IMO 2020  $\text{SO}_x$  reductions may accelerate global warming.

Shipping effects on clouds were first identified in in the mid-1960s in satellite imagery of ship tracks, or curvilinear cloud perturbations following individual ships (Conover, 1966; Twomey et al., 1968). For the same amount of liquid water

30 within a cloud, increasing aerosol increases the cloud droplet number concentration ( $N_d$ ) and decreases the effective radius  
( $r_e$ ), brightening the clouds (Twomey, 1974, 1977). Cloud macrophysical adjustments to this aforementioned Twomey effect  
have been observed within ship tracks as well, and can reinforce the microphysical brightening effect by suppressing drizzle  
(Albrecht, 1989; Goren and Rosenfeld, 2012) or counteract it by enhancing entrainment (Chen et al., 2012; Coakley and Walsh,  
2002; Toll et al., 2019). Challenges in understanding how much greenhouse gas warming is masked by these aerosol–cloud  
interactions from shipping and other forms of pollution are the largest source of uncertainty in quantifying present-day  
35 anthropogenic radiative forcing (Forster et al., 2021).

Although ship tracks have long served as “natural experiments” for testing hypotheses about aerosol–cloud  
interactions in cases of clear causality (Christensen et al., 2022), until recently, attempts to observationally assess regional-to-  
global-scale cloud perturbations and forcing from shipping have found negligible (Schreier et al., 2007) or null effects (Peters  
et al., 2011) due to the small fraction of ships that form easily identifiable tracks and the large background variability in cloud  
40 properties. New methods using machine learning have identified many times more ship tracks than has been possible with  
manual identification (Watson-Parris et al., 2022; Yuan et al., 2022; Yuan et al., 2019) and analyses tracking air masses from  
ship locations have shown that cloud adjustments differ systematically between easily-identifiable and “invisible” ship tracks  
(Manshausen et al., 2022). Using some of these newer methods, it has been shown that ship track occurrence decreased  
regionally after the introduction of emission control areas around North America and Europe and then globally after the IMO  
45 2020 regulations went into effect (Gryspeerd et al., 2019; Watson-Parris et al., 2022; Yuan et al., 2022). Large-scale changes  
in cloud microphysical and macrophysical properties have been more equivocal, however. Yuan et al. (2022) found  $N_d$   
decreases within ship tracks after the IMO 2020 regulations, as expected, but, paradoxically, greater  $r_e$  decreases than before  
and no difference in cloud brightness. Watson-Parris et al. (2022) did not find evidence for a change in global or regional  $N_d$   
after the IMO 2020 regulations despite the clear decrease in ship tracks, with a possible exception in the southeastern Atlantic.

50 In this work, we assess the detectability of large-scale cloud perturbations from the IMO 2020 regulations by revisiting  
an alternate solution to the limitations of “bottom-up” methods tracking individual ship tracks: a “top-down” statistical  
approach developed by Diamond et al. (2020), hereafter D20, to identify regional-scale cloud perturbations within a shipping  
corridor in the southeastern Atlantic Ocean basin. Near-surface winds in that region blow parallel to the shipping corridor and  
keep the ships’ pollution constrained around the corridor, which also happens to intersect one of the world’s three major  
55 semipermanent subtropical stratocumulus cloud decks. D20 used a universal kriging method (Zimmerman and Stein, 2010) to  
estimate counterfactual fields of cloud properties and radiation in the absence of the shipping corridor using the observed  
spatial statistics of nearby, non-shipping-affected grid boxes. They found significant increases in  $N_d$  and cloud albedo (a  
measure of cloud reflectivity) and decreases in  $r_e$  within the stratocumulus deck but estimated that several years’ worth of data  
was needed to detect a clear signal. Thus, it is possible that the effect of the IMO 2020 regulations will have just become  
60 detectable using their method. Here, we apply an updated version of the D20 universal kriging algorithm to satellite retrievals  
of  $r_e$  and overcast albedo ( $A_{\text{cid}}$ ; top-of-atmosphere albedo when clouds are present) from the Clouds and the Earth’s Radiant  
Energy System (CERES) Single Scanner Footprint (SSF) product for the Terra satellite (Loeb et al., 2018; Minnis et al., 2011).

See Methods in Appendix A for details. Although Diamond et al. (2020) found a substantial decrease in cloud liquid water path within the corridor during the afternoon, no significant cloud macrophysical adjustments were found in the morning. We therefore interpret any changes in  $r_e$  and  $A_{\text{old}}$  using the Terra record (observations at  $\sim 10:30$  AM local time) as being dominated by the Twomey effect. We focus on both the austral spring season (SON; September–October–November), which features the strongest shipping signal, and the annual mean (ANN), which averages a greater number of observations and thus should minimize noise. For a variable  $X$ , the “factual” or observed value in the presence of the shipping corridor is referred to as “Ship” ( $X_{\text{Ship}}$ ), the counterfactual value in the absence of shipping obtained via kriging is referred to as “NoShip” ( $X_{\text{NoShip}}$ ), and the Ship-NoShip difference is signified as  $\Delta X$  and is interpreted as the effect due to the presence of the shipping corridor.

## 2 Results

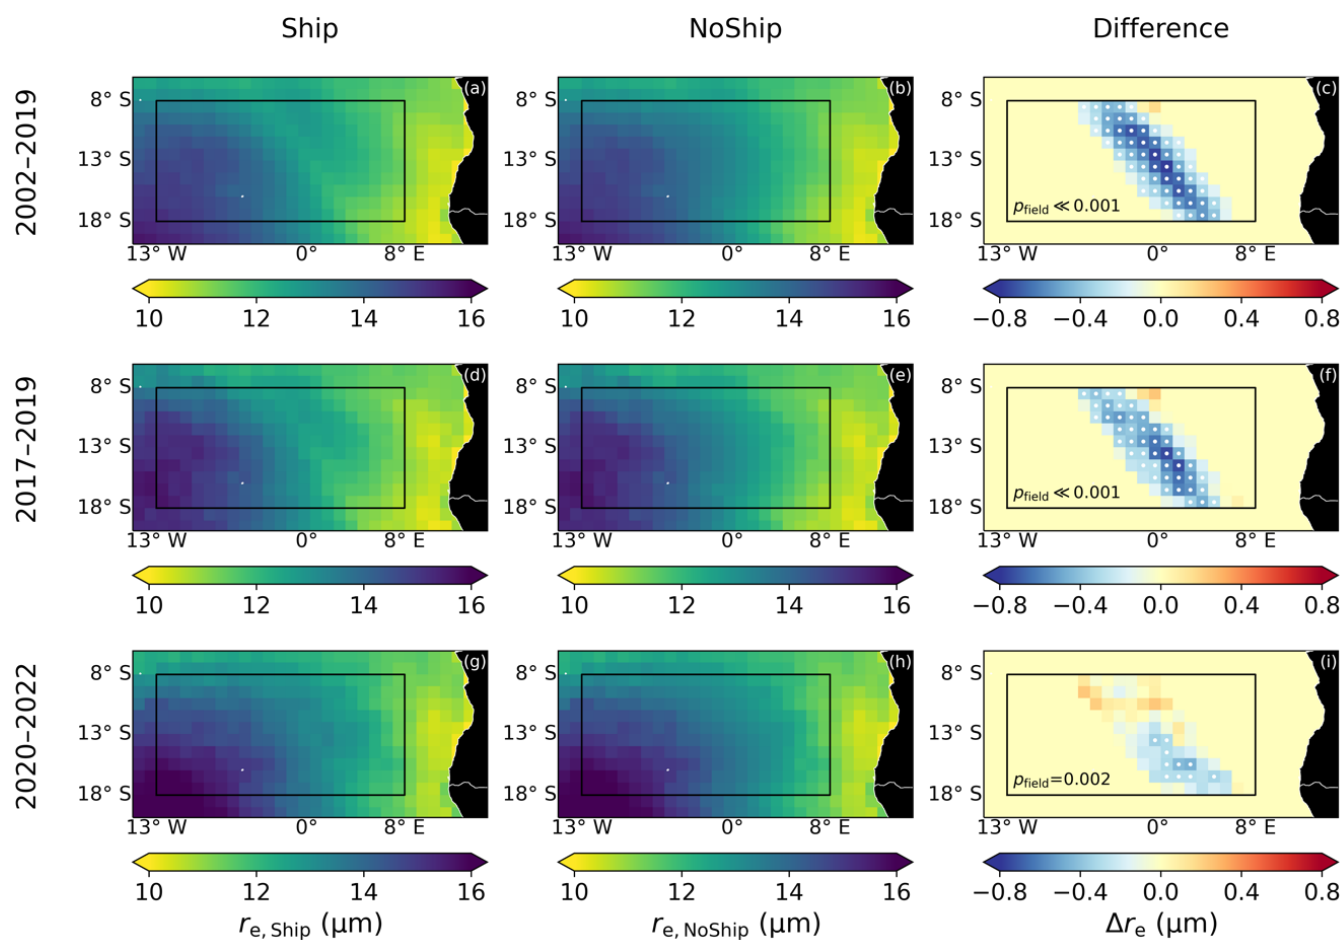

An unambiguous decrease in the magnitude of the  $r_e$  perturbation within the shipping corridor is evident in the 2020–2022 data as compared to the pre-2020 climatology (2002–2019) and the immediately preceding three-year period (2017–2019) during austral spring (Fig. 1). Although several significant grid boxes remain in the south of the domain (and thus some level of continued shipping influence is detected), the microphysical changes are smaller and less clearly tied to the corridor; the signal is completely lost further north. Similar results are found for the annual mean values (Fig. S1), albeit with a clearer continued effect of shipping in the 2020–2022 data.

The shipping perturbation in overcast albedo is less well defined than that in the cloud microphysics, but there is still a clear perturbation in the 2002–2019 climatology and 2017–2019 data that is diminished in the 2020–2022 data in austral spring (Fig. 2). Similar results are found in the annual mean, although the 2020–2022 change is more ambiguous from visual inspection alone (Fig. S2). Lower background  $A_{\text{old}}$  values in 2020–2022, particularly in the annual mean (Fig. S2g), may be related to unusually warm sea surface temperatures (Figs. S3–4).

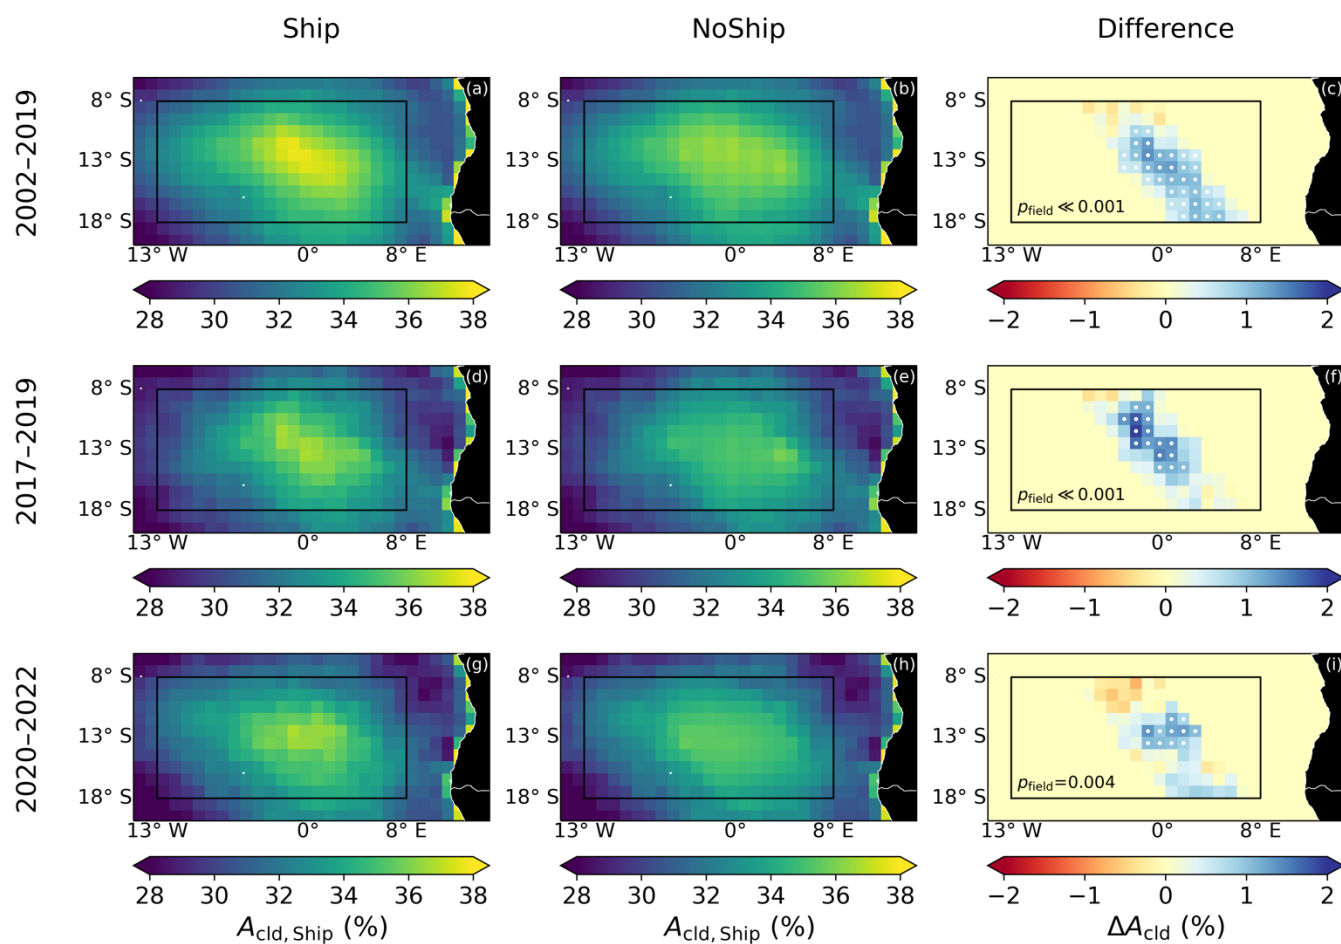

To assess how extreme the 2020–2022 shipping perturbation values are compared to prior three-year averages, we define a core shipping corridor region (see Methods in Appendix A) and average values over this area. To minimize effects from changing background conditions, perturbations are also calculated as relative differences ( $100\% \cdot \Delta X / X_{\text{Ship}}$ ). Full results are reported in Table S1 and summarized in Fig. 3. For the austral spring  $r_e$  perturbations, 2020–2022 is unprecedentedly weak (Fig. 3a) and does not overlap any prior period’s value within their 95% confidence intervals (Table S1). The separation between 2020–2022 and any other period’s values is not as clear for austral spring  $A_{\text{old}}$  (Fig. 3b), although the 2020–2022 perturbation values are the lowest on record and are the only period for which the effect is not distinguishable from zero at the 95% confidence level (Table S1). For the annual mean  $r_e$  perturbations, the 2020–2022 values are lower than any other period and the difference with the climatological value is much larger than for any other period, although the separation is not as clear as for austral spring (Fig. 3c). While the annual mean  $A_{\text{old}}$  values for 2020–2022 are also the lowest on record, the difference from climatology is not extreme compared to other periods (Fig. 3d).

To assess whether a reduction in the shipping effect after the IMO 2020 regulations went into effect is detected at various possible levels of confidence, Table S2 reports different percentiles of the ratio of the 2020–2022 relative differences over the climatology. A decrease in the  $r_c$  perturbation is detected at greater than 99% confidence in the austral spring and at greater than 95% confidence in the annual mean, whereas decreases in the  $A_{\text{cld}}$  perturbation are only significant at the 90% confidence level in the austral spring and within the interquartile range in the annual mean. We thus conclude that the effect of the IMO 2020 regulations has been clearly detected in the large-scale cloud microphysics and that there is strong evidence for a decrease in cloud brightness, although more years of data may be required for unequivocal detection of changes in overcast albedo.

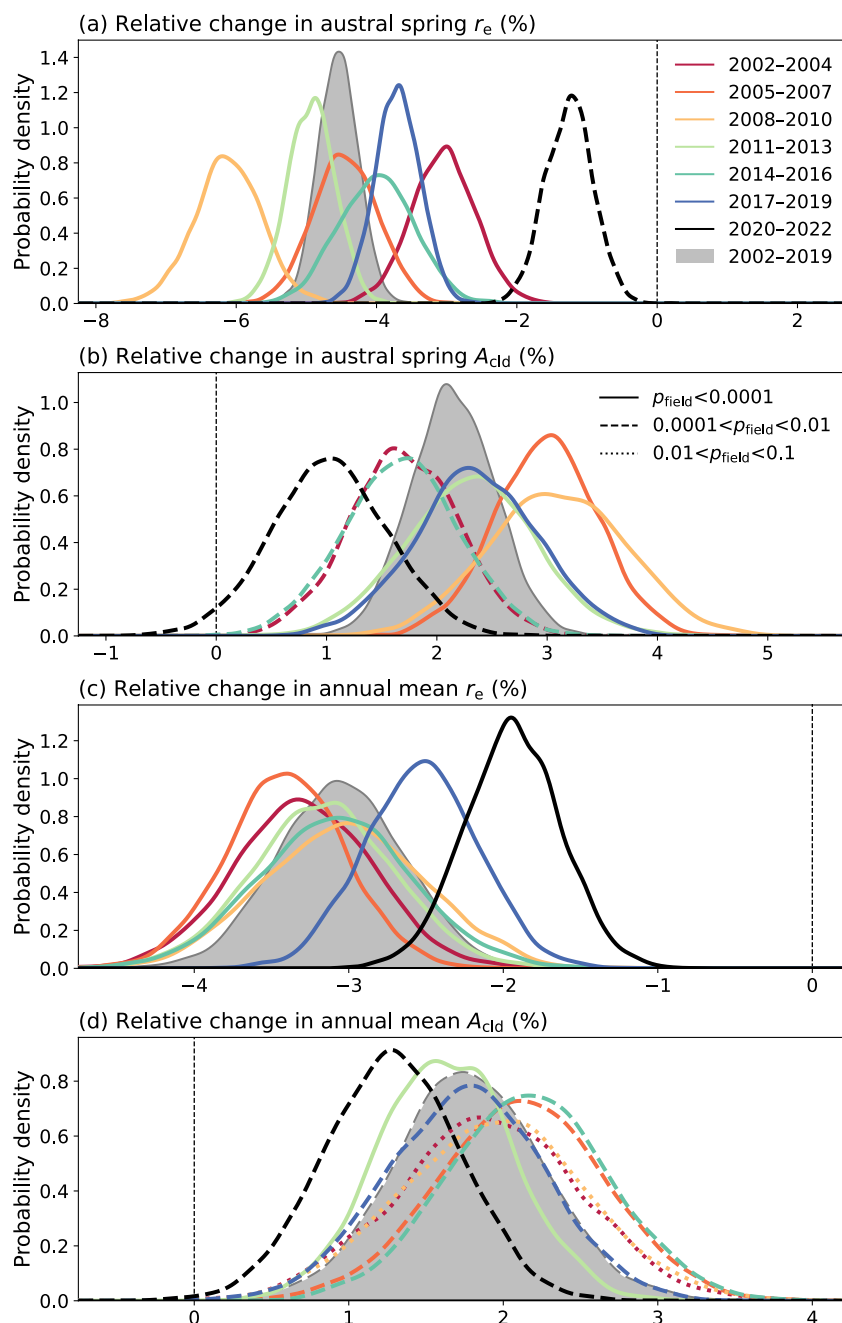

105 **Figure 1.** Maps of factual (Ship), counterfactual (NoShip), and difference (Ship-NoShip) values for austral spring liquid cloud droplet effective radius for the pre-2020 climatology (a–c), 2017–2019 (d–f), and 2020–2022 (g–i). The analysis domain of 18° S to 8° S, 13° W to 8° E is outlined in black. Grid points for which the observed values fall outside the 95% confidence interval obtained via kriging are indicated by white dots and the corresponding field significance values ( $p_{\text{field}}$ ) are reported in (c,f,i).

110

Figure 2. As in Fig. 1, but for austral spring overcast albedo.

115 **Figure 3.** Probability densities (via Gaussian kernel density estimation) for the Ship-NoShip relative differences within the core shipping corridor for austral spring  $r_e$  (a), austral spring  $A_{\text{clld}}$  (b), annual mean  $r_e$  (c), and annual mean  $A_{\text{clld}}$  (d). The 2002–2019 climatology values are shown as gray shading, the three-year periods prior to the IMO 2020 regulations as colored lines, and the 2020–2022 period as black lines. Solid, dashed, and dotted lines indicate decreasing degrees of field significance ( $p_{\text{field}}$ ).

### 3 Discussion

#### 3.1 Monitoring compliance with IMO regulations

120 Assessing (non)compliance with the IMO 2020 regulations is of critical importance for ensuring that the intended public health  
benefits are realized. One assessment method is to monitor the sulfur content of the global fuel oil supply. According to data  
supplied to the IMO MEPC, ~80% of the global fuel oil supply by mass consisted of fuels with sulfur mass contents exceeding  
0.5% prior to 2020, whereas only ~20% does since (IMO, 2020, 2021, 2022, 2023). This raw percentage understates  
compliance, as a “carriage ban” forbids ships from carrying the remaining noncompliant fuel oil unless they have scrubbers  
125 installed (IMO, 2018). Geophysical monitoring via cloud changes, as has been shown in Yuan et al. (2022) and Watson-Parris  
et al. (2022) for ship track occurrence and here for large-scale cloud microphysical properties, offers an independent check  
that can increase confidence that there has been substantial compliance with the IMO 2020 regulations. As our improving of  
the cloud effects from shipping aerosol improves, it may become possible to assess regional differences in compliance or even  
compliance for individual ships with geophysical monitoring.

130 Given the clear detection of cloud microphysical changes in austral spring after the IMO 2020 regulations went into  
effect, it is reasonable to ask whether advanced statistical methods are necessary for evaluating (some level of) compliance or  
if simple time series [e.g., Fig. S5 of Watson-Parris et al. (2022)] would suffice. From the time series of austral spring Ship  
and NoShip  $r_e$  values averaged over the southeastern Atlantic (Fig. 4), it is evident that the shipping effect before 2020–2022  
is of similar magnitude to interannual variability in the background values and that the 2020–2022  $r_e$  values are estimated to  
135 be the highest on record even before any IMO 2020 effect is considered. As an estimate of what the 2020–2022 observed value  
would have been under a scenario of complete noncompliance with the sulfur regulations, the average Ship-NoShip difference  
from the 2002–2019 climatology is applied to the 2020–2022 NoShip value (Noncompliance in Fig. 4). The +0.1  $\mu\text{m}$  difference  
between the observed (Ship) value and this noncompliance hypothetical is due to compliance with the IMO 2020 regulations.  
If we had rather based our noncompliance scenario on a persistence forecast of the 2017–2019 value and then observed the  
140 value from the “true” noncompliance estimate calculated above, we would erroneously conclude that the IMO 2020 regulations  
were successfully implemented and led to a +0.3  $\mu\text{m}$  increase in regional  $r_e$ . Of course, in this latter scenario, the true value of  
the difference due to IMO 2020 would have been zero and the apparent effect only an artifact of the changing background.  
Caution is therefore advised in attempting to interpret time series of large-scale cloud properties without applying a method  
(like track identification or kriging) that plausibly establishes causality.

145

150 **Figure 4.** Time series of observed Ship (black circles) and mean NoShip (blue diamonds) values averaged the southeastern Atlantic analysis  
 domain (18° S to 8° S, 13° W to 8° E). A Noncompliance scenario in which the IMO 2020 regulations were not enforced and the Ship-  
 NoShip difference in 2020–2022 were the same as for the 2002–2019 climatology is donated as a black “x”. The red dotted line denotes the  
 155 estimated effect from compliance with the IMO 2020 regulations, calculated as the difference between the observed Ship and hypothetical  
 Noncompliance value expected for no change in 2020–2022. The orange dotted line denotes the mistakenly determined effect that would  
 have resulted if the Noncompliance scenario were true and observed but a persistence forecast of 2017–2019 were used as the expectation  
 value for no change in 2020–2022.

### 3.2 Radiative forcing implications

Assuming that the Terra-based  $r_e$  and  $A_{\text{clid}}$  perturbations are dominated by the Twomey effect as in D20, it is possible to estimate the instantaneous radiative forcing due to aerosol–cloud interactions ( $\text{IRF}_{\text{ACI}}$ ; Forster et al., 2021) from the IMO 2020 regulations within the shipping corridor (see Methods in Appendix A). Results are shown in Fig. 5 for the 2002–2019 climatology, 2020–2022, and their difference (interpreted as the effect of the IMO 2020 regulations). The Twomey effect estimates are much better constrained for the calculations using  $r_e$ , but those using  $A_{\text{clid}}$  show consistent results. The IMO 2020 regulations led to an  $\sim 2 \text{ W m}^{-2}$   $\text{IRF}_{\text{ACI}}$  within the shipping corridor during austral spring and an  $\sim 0.5 \text{ W m}^{-2}$   $\text{IRF}_{\text{ACI}}$  in the annual mean. Taking the  $\sim 70\%$  decline in  $\text{IRF}_{\text{ACI}}$  from the austral spring  $r_e$  values as an upper bound and applying it to the  $-0.1$  to  $-0.6 \text{ W m}^{-2}$  range of forcing due to shipping emissions from global models (Capaldo et al., 1999; Lauer et al., 2007; Peters et al., 2013; Righi et al., 2011; Sofiev et al., 2018), global forcing values of  $O(0.1 \text{ W m}^{-2})$  and up to  $+0.4 \text{ W m}^{-2}$  due to the IMO 2020 regulations are plausible.

170

175 **Figure 5.** Probability densities (via Gaussian kernel density estimation) of  $IRF_{ACI}$  for austral spring (a) and the annual mean (b) over the core shipping corridor calculated using the changes in  $r_e$  (shading) and  $A_{cld}$  (lines) for the 2002–2019 climatology (blue) and 2020–2022 period (black) due to the presence of the shipping corridor and as the 2020–2022 minus climatology difference as an estimate of the effect due to implementation of the IMO 2020 regulations (red).

## 4 Conclusions

There is a detectable change in large-scale cloud microphysical properties and evidence supporting a decrease in cloud brightness within the major southeastern Atlantic shipping corridor after implementation of the IMO 2020 fuel sulfur regulations, resulting in a positive  $IRF_{ACI}$  within the corridor of  $O(1 \text{ W m}^{-2})$ . Although this study did not address potential changes in cloud adjustments from the IMO 2020 regulations, this will be an important area of future work, especially as the fuel regulations are expected not only to decrease overall aerosol numbers but also shift them toward smaller sizes and sootier composition (Ault et al., 2010; Lack et al., 2011; Seppälä et al., 2021).

## Appendix A: Methods

### Data

All cloud, radiation, and meteorological data in this work come from the CERES SSF regional  $1^\circ \times 1^\circ$  (SSF1deg) monthly product based on the CERES instrument from the Terra satellite (CERES Science Team, 2021, 2023; Loeb et al., 2018; Wielicki et al., 1996). Radiative fluxes are temporally interpolated over the diurnal cycle assuming constant cloud and meteorological properties but varying the solar zenith angle (Doelling et al., 2013). Overcast albedo values are calculated as in Diamond et al. (2020) but with the clear-sky albedo assumed to be 0.1 to avoid issues with missing clear-sky data in the SSF1deg product. The overcast albedo (albedo as seen from space when clouds are present) differs from the cloud albedo (cloud reflectivity) due to the scattering and absorption of sunlight from above-cloud aerosols and gases.

Cloud properties are retrieved from Moderate Resolution Imaging Spectroradiometer (MODIS) measurements using CERES algorithms (CERES Science Team, 2016; Minnis et al., 2011), which have some differences from the standard MODIS products (Platnick et al., 2017). Only daytime cloud retrievals utilizing  $3.7 \mu\text{m}$  channel radiances are used in this work. Low cloud fraction is defined for clouds with cloud top effective pressure values greater than 700 hPa.

Meteorological variables including surface skin temperature (over oceans, the Reynold's sea surface temperature), estimated inversion strength (Wood and Bretherton, 2006), and wind speed are from the NASA Goddard Space Flight Center Global Modeling and Assimilation Office (GMAO) Goddard Earth Observing System (GEOS) version 5.4.1 (CERES Science Team, 2021).

Sulfur dioxide ( $\text{SO}_2$ ) emissions data from 2010 are from the Emissions Database for Global Atmospheric Research (EDGAR) version 4 (Crippa et al., 2018) and are identical to those used in Diamond et al. (2020). The EDGAR  $\text{SO}_2$  values are only used for identification of the shipping corridor location.

### Shipping corridor identification

For each latitude between  $8^\circ \text{ S}$  and  $18^\circ \text{ S}$ , shipping-affected grid boxes are identified as those with the maximum EDGAR  $\text{SO}_2$  emission values between  $13^\circ \text{ W}$  and  $8^\circ \text{ E}$  as well as the four grid boxes to the west and two to the east. This represents a

northward and westward expansion of the shipping corridor definition used in Diamond et al. (2020) for their subtropical domain that is intended to better center the microphysical effects. Ship tracking via the automatic identification system (AIS) identifies substantial traffic slightly west of where EDGAR places the maximum SO<sub>2</sub> emissions and there are indications of an additional westward shift in traffic during 2020 (March et al., 2021). As a sensitivity test, the analysis in Fig. 1 was repeated  
215 using a shipping corridor mask shifted further west by two degrees, but no notable differences were found. The core shipping corridor area used in Figs. 3 and 5 and Tables S1-2 is defined as the central three grid boxes of the shipping mask for each latitude.

### Universal kriging

The universal kriging algorithm mostly follows the implementation of Diamond et al. (2020). Universal kriging is a classic  
220 geostatistical method in which estimates of unknown values at some location are informed by nearby observations of the same variable under the assumption that errors around a mean function are spatially correlated as a function of the distance between locations only (stationarity). In our case, counterfactual values for the shipping-affected grid boxes identified are estimated using the values of nearby, non-shipping-affected grid boxes between 8° S and 18° S and 13° W and 8° E. Our mean function takes the form of a multiple linear regression model using as regressors some combination of the surface skin temperature  
225 (SST), estimated inversion strength (EIS), and wind speed (WS) from the SSF1deg auxiliary data and latitude (lat), longitude (lon), and their squares (lat<sup>2</sup>, lon<sup>2</sup>) and product (lat\*lon), as determined by whichever combination minimizes the Bayesian information criterion (BIC) to avoid overfitting. Table S1 reports the selected combination of regressors (based on BIC minimization) for each combination of variable ( $r_e$  and  $A_{\text{cld}}$ ) and time period. A logit transform is applied to the  $A_{\text{cld}}$  values before kriging, which was previously found to produce more normally distributed errors around the mean function for bounded  
230 fields like albedo and cloud fraction (Diamond et al., 2020). The stationary error term is then estimated by using weighted least squares to fit a parametric (exponential) covariance model to an empirical variogram (a plot of the squared difference between pairs of variables versus their distance). Figures S5-8 show the binned empirical variograms and fitted variograms for austral spring  $r_e$  and  $\text{logit}(A_{\text{cld}})$  and annual mean  $r_e$  and  $\text{logit}(A_{\text{cld}})$ , respectively. Using the statistical model provided by the kriging process above, we simulate 5,000 realizations of the NoShip counterfactual for each variable/time period combination.

### 235 Statistical significance testing

Four distinct tests of statistical significance are used in this work, the first three following Diamond et al. (2020). Statistical significance for individual shipping-affected grid boxes is assessed as whether the observed Ship value exceeds the 97.5<sup>th</sup> percentile or falls below the 2.5<sup>th</sup> percentile of the distribution obtained via kriging for the counterfactual NoShip value for that grid box.

240 Field significance is assessed by determining whether the number of individually significant grid boxes calculated above is extreme as compared to that which could occur by chance; p-values are calculated as the fraction of the 5,000 NoShip simulations that would have a number of individually significant grid boxes greater than or equal to the factual case and are

adjusted for multiple testing using a Benjamini-Hochberg adjustment to control the false discovery rate (Benjamini and Hochberg, 1995; Ventura et al., 2004). If none of the 5,000 NoShip simulations would produce a number of individually significant grid boxes as or more extreme than the Ship field, the p-value is reported as <0.0001 instead of zero in Table S1.

The range of Ship-NoShip values generated from the 5,000 simulated NoShip fields is used to assess if the magnitude of effects within the core shipping corridor area are statistically distinct from zero at 95% confidence (Table S1).

Finally, a new test for “detectability” at different confidence interval thresholds is presented in Table S2 and based on the range of possible ratios of 2020–2022 over climatological relative Ship-NoShip values from the 5,000 simulated NoShip fields. We adopt significance at 95% confidence or greater as distinguishing between “detection” for the  $r_e$  changes versus “evidence” short of detection for the  $A_{\text{cld}}$  changes.

### Twomey effect calculations

For the  $r_e$  perturbations,  $\text{IRF}_{\text{ACI}}$  is estimated as:  $-F_{\odot} C_{\text{low}} \phi_{\text{atm}} \alpha_{\text{cld}} (1 - \alpha_{\text{cld}}) (-\Delta r_e / r_{e,\text{Ship}})$ , where  $F_{\odot}$  is the insolation,  $C_{\text{low}}$  is the low cloud fraction,  $\phi_{\text{atm}}$  is a transfer function between changes in overcast and cloud albedo (Diamond et al., 2020; Wood, 2021), and  $\alpha_{\text{cld}}$  is the cloud albedo. Based on the values in D20,  $\phi_{\text{atm}}$  is estimated as 0.6 and  $\alpha_{\text{cld}}$  as 0.5. For the  $A_{\text{cld}}$  perturbations,  $\text{IRF}_{\text{ACI}}$  is estimated as:  $-F_{\odot} C_{\text{low}} \Delta A_{\text{cld}}$ .

### Code availability

Code for processing the data and recreating the analyses in this work is available from GitHub (<https://github.com/michael-s-diamond/IMO2020>, last accessed 10 May 2023). The universal kriging algorithm is implemented in R (R Core Team, 2014) using the geoR package (Ribeiro and Diggle, 2018). Other analyses are performed in Python using the numpy (Harris et al., 2020), cartopy (Met Office, 2010–2015), matplotlib (Hunter, 2007), scipy (Virtanen et al., 2020), statsmodels (<https://github.com/statsmodels/statsmodels>, last accessed 10 May 2023) and xarray (Hoyer and Hamman, 2017) packages.

### Data availability

SSF1deg data (CERES Science Team, 2023) are available from the NASA Langley Research Center CERES ordering tool (<https://ceres.larc.nasa.gov/data/>, last accessed 14 April 2023). EDGAR data (European Commission Joint Research Centre, 2018) are available from the European Commission Joint Research Centre Data Catalogue ([https://doi.org/10.2904/JRC\\_DATASET\\_EDGAR](https://doi.org/10.2904/JRC_DATASET_EDGAR), last accessed 10 May 2023). Processed data used in this work (Diamond, 2023) are available in a Zenodo repository (<https://doi.org/10.5281/zenodo.7864530>, last accessed 10 May 2023).

### Competing interests

The author declares that they have no conflict of interest.

## Acknowledgements

This work was supported with startup funds from Florida State University. Hannah M. Director merits continued gratitude for her contributions to the original code base and analysis methods. Discussion with Leon Simons provided the impetus for attempting to detect a signal with only three years of post-2020 data.
