Abstract. The world's largest ice shelves are found in the Antarctic Weddell and Ross Seas where complex interactions between the atmosphere, sea ice, ice shelves and ocean transform shelf waters into High Salinity Shelf Water (HSSW) and Ice Shelf Water (ISW), the parent waters of Antarctic Bottom Water (AABW). This process feeds the lower limb of the global overturning circulation as AABW, the world's densest and deepest water-mass, spreads outwards from Antarctica. None of the coupled climate models contributing to CMIP6 directly simulated ocean-ice shelf interactions, thereby omitting a potentially critical piece of the climate puzzle. As a first step towards better representing these processes in a global ocean model, we run a 1° resolution forced configuration of NEMO (eORCA1) to explicitly simulate circulation beneath Filchner-Ronne (FRIS), Larsen C (LCIS), and Ross (RIS) ice shelves. These locations are thought to supply the majority of the source waters for AABW and so melt in all other cavities is provisionally prescribed. Results show that the grid resolution of 1° is sufficient to produce melt rate patterns and total melt fluxes of FRIS (117 ± 21 Gt/yr), LCIS (36 ± 7 Gt/yr) and RIS (112 ± 22 Gt/yr) that agree well with both high resolution models and satellite measurements. Most notably, allowing sub-ice shelf circulation reduces salinity biases (0.1 psu), produces the previously unresolved water mass ISW, and re-organises the shelf circulation to bring the regional model hydrography closer to observations. A change in AABW within the Weddell and Ross Seas towards colder, fresher values is identified but the magnitude is limited by the absence of a realistic overflow. This study presents a NEMO configuration that can be used for climate applications with improved realism of the Antarctic continental shelf circulation and a better representation of the precursors of AABW.

Plain language summary. Bottom Water constitutes the bottom half of the ocean's overturning system and is primarily formed in the Antarctic Weddell and Ross Seas due to interactions between the atmosphere, ocean, sea ice and ice shelves. Here we use a global ocean 1° resolution model with explicit representation of the three large ice shelves important for the formation of the parent waters of Bottom Water. We find doing so reduces salt biases, improves water mass realism, and gives realistic ice shelf melt rates.

31 **1 Introduction**

32 The Southern Ocean plays a vital role in global ocean circulation and in the storage of both heat and carbon (Marshall and
33 Speer, 2012; Frölicher et al., 2015; Rintoul, 2018). Within this backdrop, the processes taking place adjacent to and
34 underneath the Antarctic ice shelves are not only important for controlling regional ocean dynamics but also for facilitating
35 globally important water mass transformations (Schodlok et al., 2015). Sea ice formation on the continental shelf decreases
36 the buoyancy of the underlying waters through the process of brine rejection creating High Salinity Shelf Water (HSSW;
37 Jacobs et al., 1979). When this dense water mass is formed adjacent to an ice shelf, it can follow deep bathymetric pathways
38 into the neighbouring sub-ice shelf cavity and interact with the base of the ice to form Ice Shelf Water (ISW; Jenkins, 1991).
39 These dense waters then accumulate on the continental shelf and migrate towards the shelf break to cascade down the
40 continental slope as a gravity current (Gordon, 1986; Whitehead, 1987). As the waters descend towards the depths, they mix
41 with and entrain ambient water masses until they reach either a density neutral depth, or the sea floor, at which point they
42 spread outwards as Antarctic Bottom Water (AABW) (Bergamasco et al., 2003; Huthnance 1995). AABW plays a crucial
43 role in the global overturning circulation, in abyssal ventilation and in the cross-basin transport of heat, salt, carbon, nutrients
44 and numerous other tracers (Killworth, 1983; Johnson, 2008; Orsi, 2010). The principal locations for the formation of the
45 source waters of AABW are the Weddell and Ross Seas adjacent to the large ice shelves (Orsi et al., 1999; van Caspel et al.,
46 2015; Kerr et al., 2018; Bowen et al., 2021).

47
48 Filchner Ronne Ice Shelf (FRIS) is located at the southern boundary of the Weddell Sea and represents 28% of the total
49 Antarctic ice shelf area (Fig. 1a). Traditionally FRIS has been viewed as having the greatest contribution to AABW by
50 forming the coldest and most oxygen-rich dense waters in the Southern Ocean (Nicholls et al., 2009; Naveira Garabato et al.,
51 2002). Observations for the southern Weddell Sea continental shelf indicate that HSSW enters the FRIS cavity following the
52 Ronne Depression (Fig. 1a), circulates under the cavity causing melting at the base of the ice shelf at great water pressures
53 and then exits as colder and fresher ISW via the Filchner Trough (Nicholls et al., 2001; Nicholls et al., 2004; Janout et al.,
54 2021). This outflowing ISW mixes with HSSW formed on the shallow continental shelf adjacent to Berkner Island and
55 cascades down the continental slope, mixing with ambient modified Circumpolar Deep Water (CDW) to form AABW
56 (Fahrback et al., 1995; Nicholls et al., 2009).

57
58 While the main formation site of the source waters of AABW in the Weddell Sea is the FRIS continental shelf, Larsen-C Ice
59 Shelf (LCIS) is also thought to play an important role. Nestled into the arc of the Antarctic Peninsula (Fig. 1a), processes
60 adjacent to this ice shelf produce a fresher variety of dense water called Weddell Sea Deep Water (WSDW), which is lighter
61 than the Weddell Sea Bottom Water (WSBW) formed further south (Fahrback et al., 1995; Gordon et al., 2001). This water
62 mass is less hindered by bathymetric constraints so that it is more easily transported out of the gyre over the South Scotia
63 Ridge to make an important contribution to AABW (Abrahamsen et al., 2019; van Caspel et al., 2015).

64
65 The Ross Sea, the second largest site for AABW formation, is home to Antarctica's largest ice shelf representing 32 % of the
66 total Antarctic ice shelf area (Rignot et al., 2013). The Ross Ice Shelf (RIS) is located at the southern boundary of the Ross
67 Sea (Fig. 1b) where the continental shelf has very irregular topography with numerous troughs and depressions that act as
68 reservoirs for dense waters (Budillon et al., 2003). Just offshore, CDW flows largely un-modified within the Ross Gyre and
69 mixes with the local waters at the shelf break (Fig. 1b), providing a source of heat and making this a region of dynamic water
70 mass exchange (Bergamasco et al., 2003; Budillon et al., 2003). Two recurring ice-free zones are the principal formation
71 sites for HSSW in the area: one located at the south-western corner of the Ross Sea called the Terra Nova Bay polynya and
72 another in front of RIS called the Ross Sea Polynya. This HSSW then spreads both northwards towards the shelf break and

73 southwards under RIS (Fig. 1b). Similarly to FRIS, the HSSW flowing into the RIS cavity interacts with the base of the ice
74 shelf to form ISW (Jacobs et al., 1979).

75
76 While freshwater input to the ocean from ice shelf melt is (at present) relatively small in magnitude, it exerts a strong
77 modulating effect on dense water formation and Southern Ocean water mass transformation (Schodlok et al., 2015; Jeong et
78 al., 2020). The impacts of increased meltwater in a warming climate could, in addition to raising sea level, actually reduce
79 AABW formation with major consequences for global overturning (Silvano et al., 2018, Williams et al., 2016). One possible
80 series of events common to simulations by the E3SM, CSIRO Mk3L and LOVECLIM climate models describes how surface
81 freshening from ice shelf melt would increase stratification along the Antarctic coast, inhibit full depth convection and the
82 formation of dense shelf water, and simultaneously trap warm water at depth resulting in further ice shelf melting and a
83 horizontal propagation of the warming signal (Jeong et al., 2020; Phipps et al., 2016; Menviel et al., 2010).

84
85 Despite the importance of ocean-ice shelf interactions for the climate system, none of the models contributing to the DECK
86 experiments of the Coupled Model Intercomparison Project Phase 6 (CMIP6, used to inform the Intergovernmental Panel on
87 Climate Change (IPCC) assessment report 6 (AR6)) explicitly represented circulation within sub-ice shelf cavities (Heuze et
88 al., 2021). This has lowered confidence in projected trends for the Southern Ocean and has limited our ability to incorporate
89 the impacts of global ocean warming on the Antarctic Ice Sheet (Meredith et al., 2019; Beadling et al., 2020; Comeau et al.,
90 2022). In most coupled climate models, the formation of dense water is poorly represented as AABW is formed via open
91 ocean convection, often with mixed layers that are too deep, and polynyas that are too large and too frequent (Heuze et al.,
92 2013; Mohrmann et al., 2021). In reality, deep open-ocean convection events able to produce AABW are rarely observed
93 (Goosse et al. 2021) and instead ocean–sea-ice–atmosphere interactions adjacent to the Antarctic ice shelves are responsible
94 for the creation of the majority of AABW source waters.

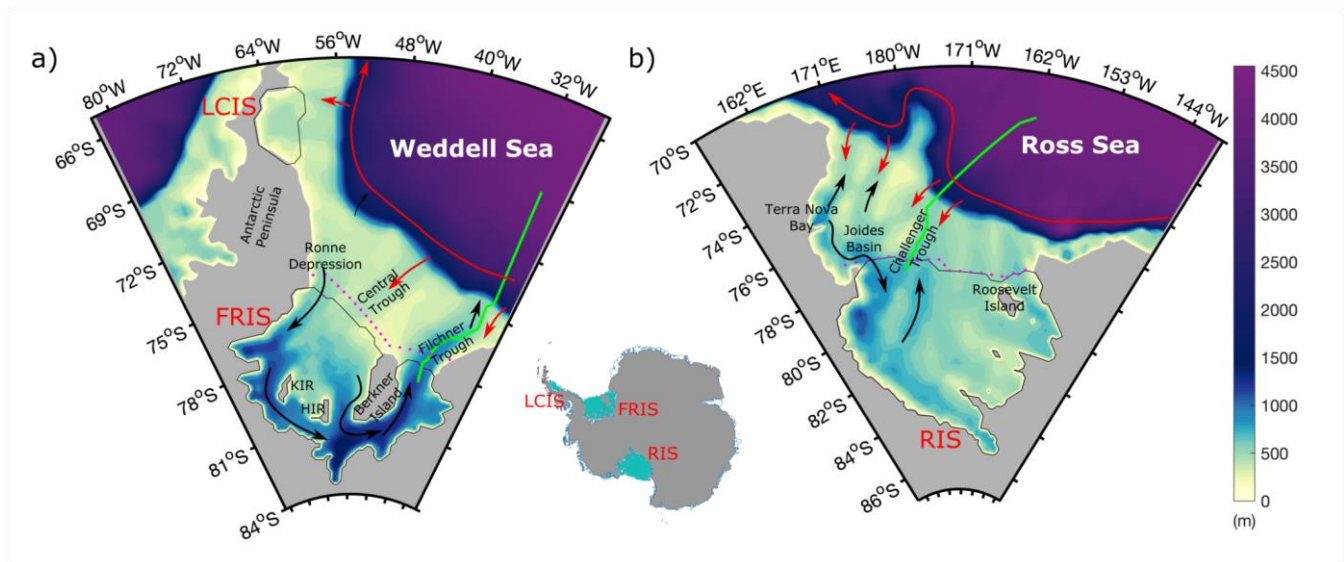

95
96 The authors propose that the path towards improving AABW realism in coupled climate models starts with a more accurate
97 simulation of the dense precursors on the Antarctic continental shelf. Then, work needs to be done on improving the
98 overflows so as to facilitate the downslope export of these waters, and on decreasing the strength of open ocean convection
99 (Heuze et al., 2021). The Nucleus for European Modelling of the Ocean (NEMO) model is used as the ocean component in
100 many climate models (Hazeleger et al., 2010; Scoccimarro et al., 2011; Hewitt et al., 2011, 2016; Dufresne et al., 2013;
101 Voldoire et al., 2013; Cao et al., 2018; Swart et al., 2019) and consequently the development of configurations with
102 improved realism of Antarctic shelf water circulation and AABW source water properties is of interest to a large community.

103
104 Ice shelf melt has previously been represented using NEMO in a variety of ways: prescribed using a freshwater flux at the
105 surface, a fixed flux distributed over the depth range of the mouth of the ice shelf front, a specified melt at the base of the ice
106 shelf, and an interactive melt with both fixed geometry and evolving coupled ice shelves (Mathiot et al., 2017; Storkey et al.,
107 2018; Smith et al., 2021). The simulations with a fixed freshwater flux parameterization at depth perform well in terms of
108 mimicking the vertical overturning and associated entrainment of ice shelf melt, but do not allow for interactive ice-ocean
109 exchange that evolves with ocean properties. Parameterizations of ice shelf melt using far field temperature (outside of the
110 cavities) exist and an extensive comparison was undertaken in Burgard et al. (2022). Here they found that none of the
111 available parameterizations yield a negligible error, and so parameterizing basal melt still remains a challenge. Furthermore,
112 these parameterizations do not solve the need to allow for circulation underneath the ice shelves in order to produce the
113 horizontal variability observed on the continental shelf. For this, it is necessary to open the sub-ice shelf cavities in the
114 simulation (Mathiot et al., 2017; Storkey et al., 2018; Comeau et al., 2022). Of all the previous studies using NEMO
115 configurations with explicit sub-ice shelf cavities, only one has been at a resolution that is compatible with long-term climate
116 projection applications, that developed by Smith et al. (2021) where a global ocean 1° NEMO (eORCA1) is coupled with

117 interactive ice sheets in the the U.K. Earth System model (UKESM). Previous studies have proven very useful in illustrating
118 the strengths and weaknesses of NEMO's representation of ocean-ice shelf interactions but the results apply to regional
119 configurations (e.g. Mathiot et al., 2017; Jourdain et al., 2017; Hausmann et al., 2020; Huot et al. 2021) or high resolution
120 global configurations (e.g. 1/4° and 1/12° in Storkey et al., 2018) and so do not fit the needs of typical CMIP models. The
121 results presented by Smith et al. (2021) for UKESM with NEMO eORCA1 coupled to an Antarctic ice sheet model highlight
122 the substantial advancement in model development, but do not show how this coupling affects the realism of Southern Ocean
123 water mass properties and dynamics. Evaluation of the initial state of the UKESM (NEMO coupled to BICYCLES ice sheet
124 model) was undertaken by Siahaan et al. (2021), but the investigation served to check for the absence of large biases and so
125 an in-depth comparison was not carried out.

126
127 A gap therefore exists to take a step-by-step approach to represent ice shelf-ocean interactions in NEMO for climate
128 applications. Additionally, a well documented description of one possible method to simulate sub-ice shelf cavity circulation
129 in low resolution ocean models could be of use in the designing of the next phase of CMIP. In this study we present the first
130 proposed step in this journey by explicitly simulating circulation under only RIS, FRIS and LCIS. These ice shelves were
131 chosen due to their direct role in the formation of the parent waters of AABW (Kerr et al., 2018; Bowen et al., 2021), and
132 due to their large size and thus practicality of realistically simulating their sub-ice shelf cavities in a global ocean 1° setup.
133 We choose to keep all other ice shelf cavities closed with prescribed melt rates injected at the mouth of the front using the
134 method described by Mathiot et al. (2017). This includes the relatively large Amery Ice Shelf cavity, despite its role in
135 preconditioning bottom water formation in the Cape Darnley polynya (Williams et al., 2016), because this polynya is absent
136 in our configuration (due to the absence of icebergs and landfast sea ice). We choose to explore the changes in circulation,
137 melt rates, and water mass properties in the Weddell and Ross Seas in a forced scenario with fixed cavity geometry, as
138 coupling can introduce further biases and obscure the changes attributed to sub-ice shelf circulation. By taking this
139 circumspect approach it is possible to diagnose the impact of ocean-ice shelf interactions on the parent waters of AABW and
140 produce a validated configuration of NEMO that can either be used for the next generation of climate models or as an
141 interim step towards dynamic ice-sheet coupling.

142
143 The model setup, configurations used in this study, forcing, and methodology to establish initial conditions under the ice
144 shelves are described in Sect. 2. A validation of the reference configuration compared to ocean observations is presented in
145 Sect. 3. Sect. 4 then explores the results from the “Open” cavity simulation and compares melt rates and thermohaline
146 properties with other model estimates and observed values. Sect. 5 provides the reader with a summary discussion, and Sect.
147 6 presents a conclusion of the findings of this study. Additional information regarding model namelist nomenclature,
148 representation of tides, an investigation into sea ice production, and plots showing AABW volume and bottom density
149 changes are provided in Supplementary Material.

152 Figure 1: Model bathymetry for (a) the Weddell and (b) Ross Seas with main topographic features labeled (KIR: Korff Ice
 153 Rise; HIR: Henry Ice Rise). Red arrows show direction of flow of warm deep water and black arrows indicate dense shelf
 154 water circulation according to observational estimates. Circulation features depicted in this figure are adapted from
 155 information presented in Budillon et al. (2003), Bergamasco et al. (2003), Russo et al. (2011) and Janout et al. (2018).
 156 Magenta dotted lines indicate sections used for CTD comparisons and green lines show shelf cross sections used for analysis
 157 in Figs. 6 and 7.

158

2 Methods

159

2.1 Model setup

160

161 For this study, we use version 4.2 of NEMO (NEMO System Team, 2022). NEMO is a three-dimensional, free-surface,
 162 hydrostatic, primitive-equation global ocean general circulation model. Our configuration uses the eORCA1 global grid with
 163 nominal horizontal resolution of 1° at the equator and a reduction in meridional grid spacing towards higher latitudes to
 164 match the accompanying shrinking of the zonal dimension of the grid cells. In the Southern Hemisphere, the model grid has
 165 been extended to reach 85° S to allow for the representation of the sub-ice shelf seas according to the procedure described in
 166 Mathiot et al. (2017). The average horizontal resolution of the grid under RIS, FRIS, and LCIS is 20 km, 22 km and 42 km
 167 respectively. To account for the decrease in the horizontal size of grid cells at high latitudes, we decide to linearly scale the
 168 laplacian eddy viscosity south of 65° S according to grid cell size. In the vertical, the configuration possesses 75 levels, with
 169 thickness increasing from 1 m at the surface to 200 m at depth (Storkey et al., 2017). We use the z^* vertical coordinate
 170 adapted to the ice shelf so that all cells between the surface and the ice shelf base are masked at initialisation and the effect
 171 of the ice shelf on friction and pressure gradient is calculated (Madec and NEMO System Team, 2019; Mathiot et al., 2017).
 172 The bathymetry used is derived from the Earth TOPOgraphy version 2 data set (ETOPO2v2; NOAA, 2006) with information
 173 for the extension under the ice shelves based on the International Bathymetric Chart of the Southern Ocean (IBSCO; Arndt
 174 et al., 2013). For the calculation of the thermodynamic properties of seawater, NEMO uses the Thermodynamic Equation Of
 175 Seawater - 2010 (TEOS-10) giving results in conservative temperature and absolute salinity, which for the purposes of this
 study, were converted to potential temperature and practical salinity in order to facilitate comparison of the model results

176 with observations and known signatures of water masses. For more information regarding the choices of advection and
177 diffusion schemes, mixing coefficients, and eddy parameterizations, please refer to the copy of the namelists provided in the
178 accompanying data repository. A note explaining the nomenclature of the namelists and the differences between the “Open”
179 and “Closed” cavity simulations can be found in Supplementary Material Sect. S1.

180
181 The effect of tides on vertical mixing (through breaking of internal waves) is taken into account in NEMO using the energy
182 constrained parameterization of de Lavergne et al. (2020). This mixing parameterization does not, however, represent
183 trapped waves at high latitudes or any tide-induced internal-wave mixing below ice shelves, and does not include the effect
184 of tides on basal friction and thus melting of the ice shelves. To address this, by default there is a parameter (rn_ke0)
185 representing the background kinetic energy associated with tides which is set to a constant of $2.5 \times 10^{-3} \text{ m}^2 \text{ s}^{-2}$ everywhere.
186 We tested another methodology of parameterizing the impact of tides on melting according to Jourdain et al. (2019) using
187 CATS2008 two-dimensional tidal velocities; as summarised in Supplementary Material Sect. S2 and Fig. S1, this alternative
188 parameterization brings marginal changes in the simulated melt patterns and bulk melt rates ($< 10\%$). The explicit
189 representation of tides is not advisable in a configuration designed for climate applications due to the high levels of
190 numerical mixing induced.

191
192 The ocean dynamics component, NEMO OCE, is coupled with SI³, the dynamic and thermodynamic sea ice model of
193 NEMO (Rousset et al., 2015; Vancoppenolle et al., 2023). SI³ is directly resolved on the ocean grid, based on an energy- and
194 salt- conserving approach for sea ice thermodynamics (Vancoppenolle et al., 2023), multiple categories to resolve subgrid
195 scale variations in ice thickness (Bitz et al., 2001; Lipscomb, 2001), a second-order moment-conserving scheme for
196 horizontal advection (Prather, 1986), and the adaptive elastic-viscous-plastic formulation for the rheology term of the
197 momentum equation (Kimmritz et al., 2016).

199 **2.2 Open vs Closed Configurations**

200
201 Here, we present results from two configurations: first a “Closed” cavity reference configuration where ice shelf melt is
202 prescribed in a way that mimics the ice-shelf overturning, and secondly an “Open” cavity configuration. For the reference
203 “Closed” cavity configuration, a fixed freshwater flux corresponding to the volume of basal meltwater estimated by
204 Depoorter et al. (2013) for each ice shelf is added into the ocean evenly between the ocean floor and the base of the ice shelf,
205 horizontally uniform across the ice shelf front, and a vertical wall closes the cavity at this location (as in Mathiot et al.,
206 2017). The fixed freshwater flux is based on Depoorter et al. (2013) melt estimates as this is the same file used for the IPSL
207 climate model. Furthermore, the ice shelf area surveyed by Adusumilli et al. (2020) only extends to 81.5°S so that RIS and
208 FRIS are not fully covered and therefore don't have the full melt flux. For the “Open” cavity configuration, the majority of
209 ice shelves are kept closed using the same method as described above and only three of the largest cold water ice shelves are
210 opened. Circulation is simulated under RIS, FRIS and LCIS where the prescribed freshwater flux is turned off at the mouths
211 of these cavities and interactive melt is activated. Ice shelf melt and freeze are calculated using the 3-equation formulation
212 (Hellmer and Olbers, 1989; Holland and Jenkins, 1999; Asay-Davis et al., 2016) in which the temperature, salinity and
213 velocities are averaged over a fixed boundary layer thickness of 30 m chosen according to Losch (2008). The top drag
214 coefficient used is 10^{-3} and the temperature and salinity transfer coefficients used are 1.4×10^{-2} and 4×10^{-4} respectively.
215 Note that a fixed ice shelf geometry is maintained, thereby assuming a steady-state where all ice melted by the ocean is
216 replaced by the seaward advection of new ice (Schodlok et al., 2015; Mathiot et al., 2017).

217
218 By using this combination of explicit and parameterized ice shelf cavities, we provide an intermediate step between
219 prescribed melt and explicit cavities or even ice sheet coupling, and gain experience and a better understanding of the impact

on ocean dynamics in order to better inform future choices. The advantage of this approach is that it allows us to specify the melt for small cavities which remain unresolved or insufficiently resolved at a 1° resolution, and simultaneously utilize the model capability to resolve sub-ice shelf cavity circulation under the large cold ice shelves, which allows for more realistic formation of the source waters of AABW. In terms of computing cost, the “Open” cavity configuration costs 11% more than the “Closed” cavity simulation (mostly due to addition of cells as the model grid is extended further south; only 0.3% of this is associated with the cost of the ice shelf routines themselves). Figure 1 shows the extended bathymetry of eORCA1 for the Weddell and Ross seas with the three ice shelf cavities of interest un-masked and important features labelled.

2.3 Forcing

For both “Open” and “Closed” configurations, the model was run for 124 years using 2 cycles of interannual (1948-2009) CORE forcing (Coordinated Ocean - ice Reference Experiments version 2; Large & Yeager, 2004; Griffies et al., 2009). Sea surface salinity restoring is activated, but not under sea ice as we have low confidence in the sea surface salinity climatology in this area due to limited observations. Freshwater discharge from iceberg melt is parameterized using a prescribed surface flux with realistic distribution (Merino et al., 2016), based on calving estimates from Depoorter et al. (2013).

2.4 Initial conditions

For all simulations, global ocean properties were initialized using the 1981-2010 climatology of World Ocean Atlas 2013 (WOA2013; Locarnini et al., 2013; Zweng et al., 2013) as this dataset is used for the IPSL climate model and so was a convenient choice. This climatology does not, however, extend under the Antarctic ice shelves and so in order to provide somewhat realistic initial conditions underneath FRIS, LCIS, and RIS, we employed an idealized regional configuration of each ice shelf. For this we created a NEMO test case using a closed domain, with temperature and salinity restoring at the boundaries, 75 vertical layers and a resolution, timestep and bathymetry corresponding to that of eORCA1. The domain for each of the 3 configurations included just the ice shelf and adjacent continental shelf and slope and so were reasonably low-cost and fast to run in order to perform sensitivity experiments. The simulations were initialized with a constant and uniform temperature and salinity and restored at the boundaries using a mean profile from WOA2013 for that region. The choices for initial thermohaline properties inside the cavities were informed by calculating the mean values of detected ISW from CTD observations performed in the area adjacent to each ice shelf and converting these to conservative temperature and absolute salinity for input to the model [-2 °C and 34.76 for FRIS (Janout et al., 2021), -1.95 °C and 34.74 for LCIS (Nicholls et al., 2004; Hutchinson et al., 2020), and -1.94 °C and 34.76 for RIS (Bergamasco et al., 2003; Budillon et al., 2003)]. Each simulation was run for 10 years, which was found to be sufficiently long to spin-up the circulation within each cavity and reach a stable melt rate. The temperature-salinity distributions within the cavity were extracted and merged with WOA2013 data re-gridded to the NEMO eORCA1 grid, with a cubic spline used to smooth the data discontinuity across the ice shelf front. By following this method we have attempted to provide as realistic initial conditions for eORCA1 as possible with the simulation starting with CORE forcing from the 1st of January 1948.

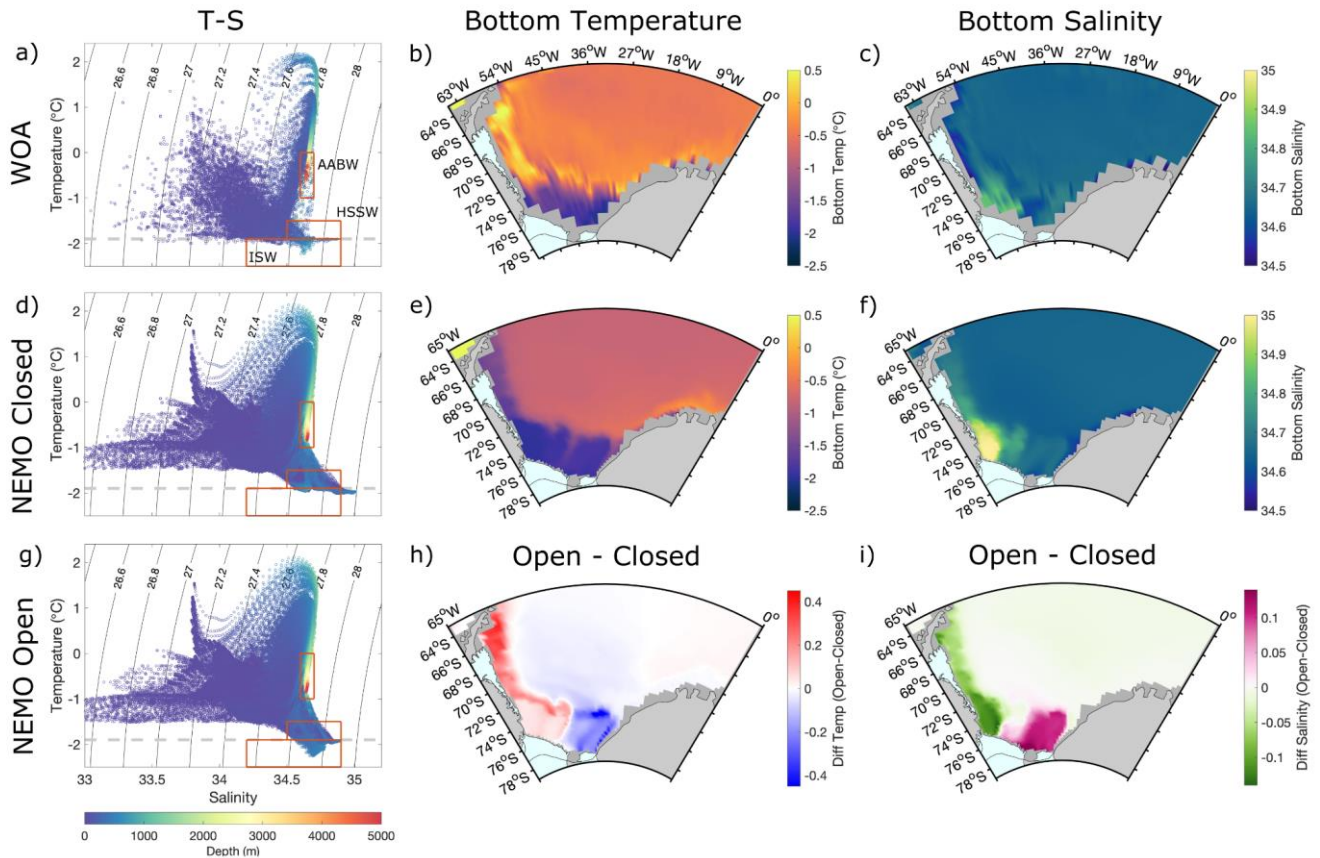

3 Water mass realism in NEMO without cavities

To assess the existing biases in the representation of dense water properties in NEMO v4.2 eORCA1 standard configuration (“Closed”), full depth temperature versus salinity plots along with bottom temperature and salinity are compared with World Ocean Atlas (WOA 2018) gridded observations from 1981-2010 (Locarnini et al., 2018; Zweng et al., 2019) in Figs. 2 and 3 for the Weddell and Ross Seas, respectively.

264 WOA observations indicate the presence of HSSW on the south-western continental shelf of the Weddell Sea, possessing
265 salinities of up to 34.9 psu, likely sourced from the coastal polynya along the western flank of FRIS ice shelf front
266 (Supplementary Material Fig. S2a). On the eastern side of the FRIS ice shelf front, evidence of ISW can be seen with
267 temperatures below surface freezing point ($-1.9\text{ }^{\circ}\text{C}$) and fresher salinities of around 34.65 psu (Figs. 2b and 2c). Results from
268 CTD observations obtained on the continental shelf in front of FRIS propose a counter-clockwise circulation pattern with
269 HSSW entering the cavity via the Ronne Depression and ISW exiting via the Filchner Trough (Fig. 1a; Janout et al., 2021).
270 By comparison, the standard model configuration is overall too salty on the continental shelf with HSSW properties that are
271 out of the bounds of the observed range (HSSW box Fig. 2d). Most notably, there is a pool of HSSW that has built up in the
272 Ronne Depression resulting in overestimations of bottom salinity and exaggerated cool conditions on the southwestern
273 Weddell shelf (Figs. 2e and 2f). In terms of ISW, there is none detected in the model output (ISW box Fig. 2d), as in this
274 configuration there is no explicit ocean-ice shelf interaction. Offshore bottom temperature is overall colder than in WOA,
275 resulting in a core AABW signature that is at the lower limit of observed values (Fig. 2d). This is indicative of the effects of
276 strong open ocean deep convection (Heuze et al., 2021) which is discussed further in Sect. 4.4.

278 Due to the limited observations adjacent to LCIS, WOA bottom properties do not capture the cold water masses located on
279 the continental shelf detected by Hutchinson et al. (2020), where bottom temperatures of below $-2\text{ }^{\circ}\text{C}$ and salinities of 34.6
280 psu were reported. Instead Fig. 2b indicates very warm conditions (temperatures of around $0.5\text{ }^{\circ}\text{C}$) on the western flank of the
281 Weddell Sea. The authors explored the bottom properties in this area in the Southern Ocean State Estimate (SOSE; Mazloff
282 et al., 2010) atlas and found bottom temperatures on the shelf adjacent to LCIS in line with those reported from hydrographic
283 observations ($-2\text{ }^{\circ}\text{C}$) but the bottom salinities were found to be far too fresh (34.5 psu). A fair comparison can therefore not
284 be realistically made between NEMO and an atlas for the area adjacent to LCIS, but by comparing the model output with the
285 CTD results from Hutchinson et al. (2020; their Fig. 3b), we find the “Closed” configuration to be too saline with bottom
286 salinities (34.8 psu) greater than that observed. The overly saline conditions along the western flank of the Weddell Sea are
287 likely a spill-over effect from the HSSW buildup seen in the Ronne Depression further south (Fig. 2f).

288

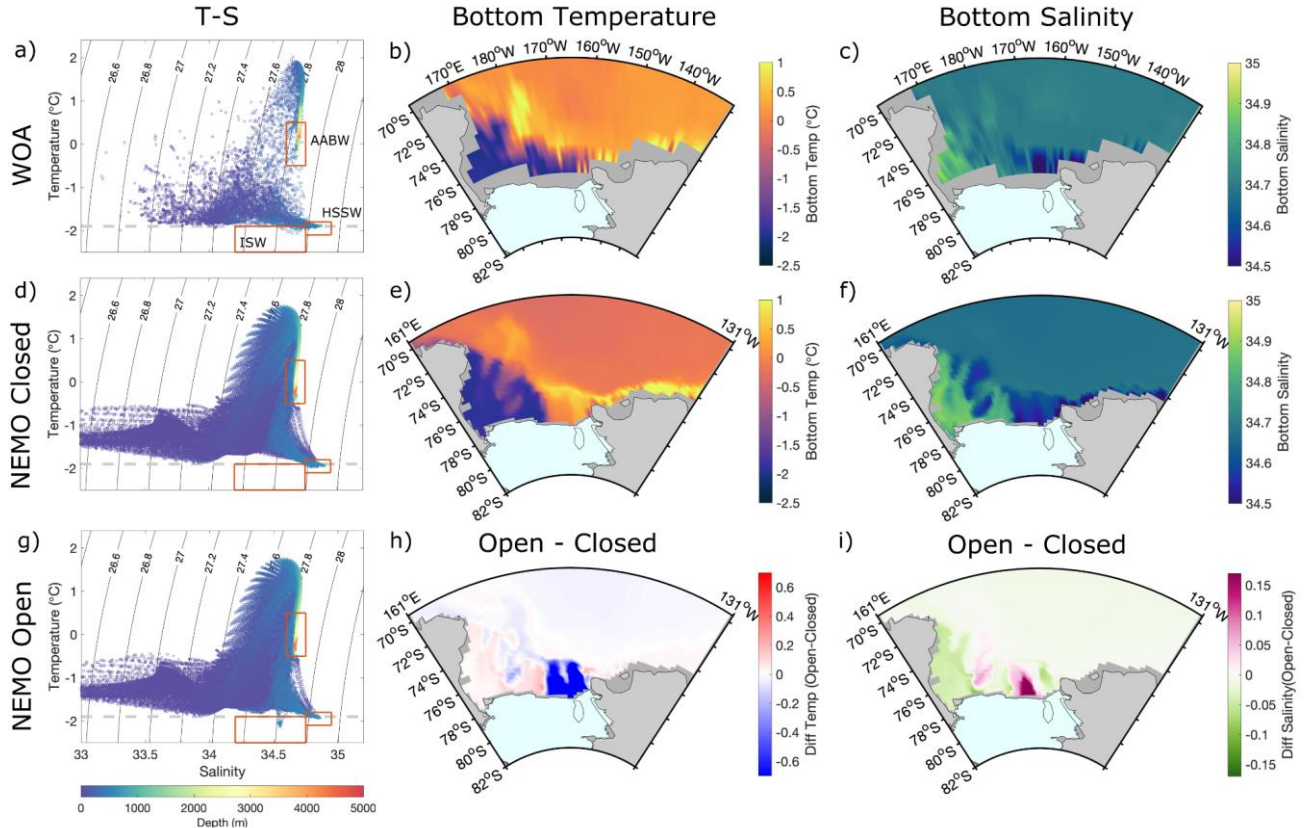

289
290

291 Figure 2: Weddell Sea comparison of NEMO v4.2 eORCA1 reference configuration (‘Closed’; subplots d-f) for equivalent
 292 years 1981-2009 to be compared with World Ocean Atlas (WOA; Locarnini et al., 2018; Zweng et al., 2019) observational
 293 dataset (subplots a-c). The temperature salinity-distributions in density space are shown in plots (a), (d) and (g) with the
 294 dashed gray line representing surface freezing point and labels in plot (a) indicating the observed ranges for properties
 295 corresponding to Antarctic Bottom Water (AABW), High Salinity Shelf Water (HSSW) and Ice Shelf Water (ISW)
 296 (Robertson et al., 2002; Hutchinson et al., 2020). Plots (b), (c), (e) and (f) show bottom temperature and salinity of WOA and
 297 ‘Closed’, and the difference in bottom properties between the ‘Open’ and ‘Closed’ cavity configurations (Open - Closed)
 298 are shown in subplots (h) and (i). Panels (a) and (g) exclude ice shelf cavity data matching the ‘Closed’ configuration of
 299 panel (d).

300

301 WOA bottom temperatures and salinities for the Ross Sea indicate a strong east-west gradient in properties across the
 302 continental shelf (Figs. 3b and 3c). Conditions in the south west reveal the cold and salty signature of HSSW likely formed
 303 in the Terra Nova Bay polynya and the Ross Polynya. Intrusions of CDW at the eastern portion of the RIS front can be seen
 304 by warm signatures of up to 1 °C (Fig. 3b) and fresher bottom salinities (Fig. 3c). Hydrological and current meter data
 305 presented by Budillon et al. (2003) reported that HSSW dominates bottom properties within the troughs connected to the
 306 Joides Basin, and ISW dominates in the Challenger Trough (see locations of bathymetric features in Fig. 1b), thus indicating
 307 a western intensified anticlockwise circulation cell under RIS. In terms of HSSW properties, the model is within the
 308 observed range (Fig. 3d), yet the proportion and salinity of HSSW in Terra Nova Bay and Joides Basin appear to be

309 overestimated (Fig. 3f). The bottom temperatures from NEMO indicate the presence of very warm waters, likely of
 310 circumpolar origin right on the eastern continental shelf (Fig. 3e) whereas in observations this shelf is found to be cold and
 311 the warm water confined offshore of the shelf break with only occasional intrusions (Bergamasco et al., 2003; Fig. 3b).
 312 Again, there is no ISW in this standard configuration, as there is no explicit model representation of ice shelf-ocean
 313 interactions. Offshore bottom properties are slightly cooler than WOA in the model, but the AABW signature (AABW box
 314 Fig. 3d) falls within the range reported from observations (Bergamasco et al., 2002; Bouillon et al., 2011; Silvano et al.,
 315 2016).
 316

317
 318
 319 Figure 3: Same as Fig. 2 but for the Ross Sea.

320
 321

322 4 Impact of explicit sub-ice shelf circulation

323

324 The following sections present results pertaining to the “Open” cavity run where the eORCA1 grid is extended under FRIS,
 325 LCIS and RIS to allow for circulation within the cavities and explicit interaction with the base of these ice shelves.

326

327 4.1 Melt rates

328

329 The average ice shelf melt rate pattern for FRIS, LCIS and RIS is shown in Fig. 4 for the model simulation equivalent years
330 1995 to 2009, where orange indicates melt and purple shows refreezing. The average total melt flux for this time period is
331 shown in Table 1 and compared to Depoorter et al. (2013) from which the volumes for the prescribed melt were taken for the
332 reference configuration (“Closed”). Opening the cavities results in at least double the melt reported from Depoorter et al.
333 (2013). This discrepancy reflects both a warm bias on the continental shelf in NEMO (Sect. 4.4) and a possible bias in
334 Depoorter’s estimates which are lower than all other satellite estimates (Table 1). The total melt fluxes of each ice shelf from
335 various other observational and model studies are also listed in the table showing the wide spread in basal melt estimates
336 both within values calculated from observations and between observations and models (Table 1). The model studies of
337 Mathiot et al. (2017) and Bull et al. (2021), which are both regional NEMO 1/4° configurations, and the NEMO 1/12°
338 configuration of the southwestern Weddell Sea of Haussmann et al. (2020), are particularly relevant to compare eORCA1
339 with, as here we see the possible impact of lowering the resolution in NEMO. For the Weddell Sea, our global 1° (eORCA1)
340 compares well with these regional high resolution studies producing a net basal melt within 12 Gt/yr of the other estimates
341 for FRIS and LCIS. The eORCA1 melt rate for RIS, while higher than observational studies, is in the middle of other model
342 estimates, and is especially well aligned with that of NEMO 1/4° from Mathiot et al. (2017). Overall, eORCA1’s total melt
343 fluxes correspond well with the average from all other estimates and are well within the standard deviations (last line of
344 Table 1).
345

	<i>Values in Gt/yr</i>	FRIS	LCIS	RIS
	NEMO 4.2 eORCA1 (1995-2009)	117 ± 21	36 ± 7	112 ± 22
Obs	Depoorter et al., 2013 (1995-2009)	50 ± 40	18 ± 8	34 ± 25
	Adusumilli et al., 2020 (1994-2018)	81 ± 123	78 ± 99	80 ± 82
	Rignot et al., 2013 (2003-2008)	155 ± 36	21 ± 67	48 ± 24
	Moholdt et al., 2014 (2003-2009)	124		50
Models	Mathiot et al., 2017 (1988)	123	46	111
	Timmermann et al., 2012(1980-1999)	138	48	260
	Hellmer et al., 2004 (1978-1997)	119	38	180

	Haussmann et al., 2020 (1993-1997)	105	24	
	Bull et al., 2021 (1986-2017)	124		
	Average from all the above excluding present study	111 ± 33	37 ± 21	118 ± 87

346
347 Table 1: Comparison of mean total melt flux (Gigatons per year) for Filchner-Ronne (FRIS), Larsen C (LCIS) and Ross Ice
348 Shelves (RIS) for observational and model studies. The mean and standard deviation of all the estimates depicted in the table
349 excluding the current study are shown at the bottom.
350

351 The patterns of melt shown in Fig. 4 also compare well with those of observational estimates like Rignot et al. (2013; their
 352 Figure 1) and high resolution model results like Haussmann et al. (2020; their Figure 3) whose color bar we replicated for
 353 ease of cross-comparison. If we look at the melt pattern of FRIS and compare it with these two aforementioned studies, we
 354 see that eORCA1 captures the high melt rates at the western portion of the ice shelf front, at the southern edge of Berkner
 355 Island and along the grounding line at the back of the cavity. The model also correctly simulates the region of refreezing
 356 along the western boundary of the circulation cell within the cavity, in both the Ronne and Filchner depressions and the re-
 357 freezing in the shallow region between the Korff and Henry Ice Rises (Fig. 4a, see bathymetry location in Fig. 1a). For LCIS,
 358 the entire shelf shows a positive melt (Fig. 4b). Observations from Rignot et al. (2013) and simulations from Harrison et al.
 359 (2022) indicate some re-freezing under this ice shelf but the regional high resolution model studies of Mathiot et al. (2017)
 360 and Haussmann et al. (2020) similarly show melting only. The pattern for RIS generally compares well with that reported
 361 from observations but the magnitude of melt at the ice shelf front, especially to the east, is elevated (Fig. 4c).

362
 363 Figure 4: Melt rates in meters per year for (a) Filchner-Ronne Ice Shelf, (b) Larsen C Ice Shelf and (c) Ross Ice Shelf where
 364 orange indicates melt and purple re-freezing. The results are mean values for the model equivalent period 1995-2009.

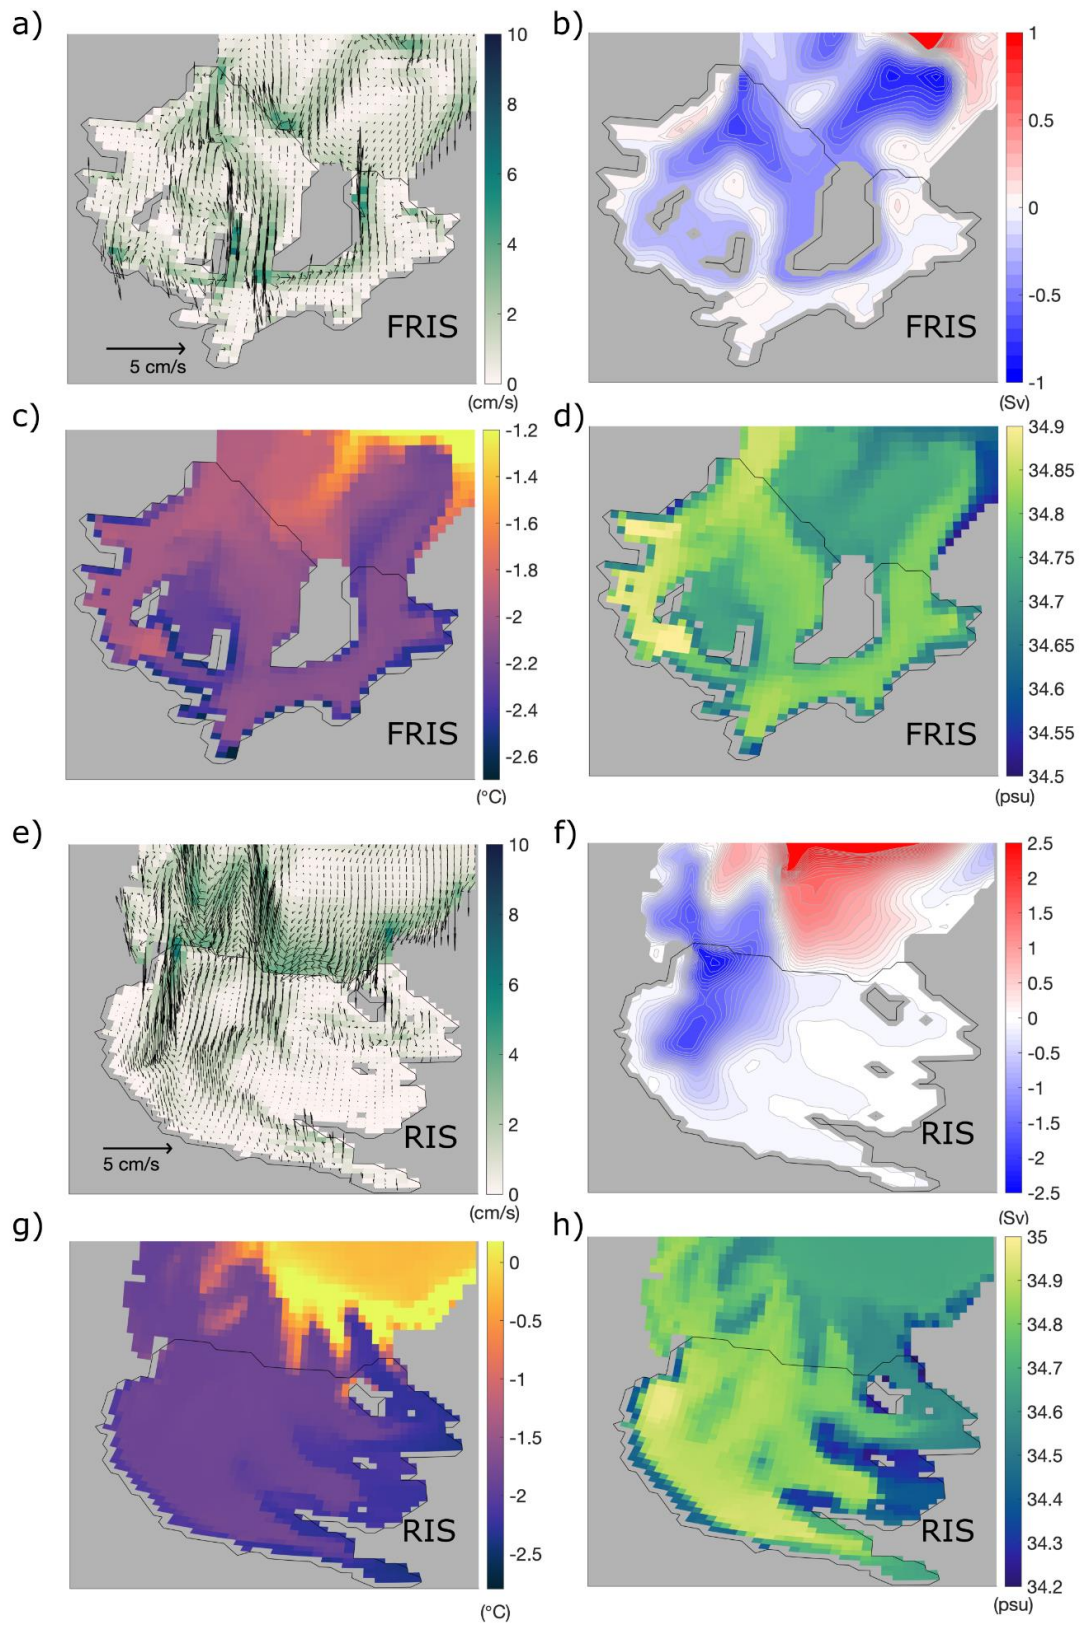

367 4.2 Circulation and properties

368
 369 Opening the sub-ice shelf cavities in eORCA1 allows for the establishment of a horizontal gyre circulation within the cavity
 370 and on the continental shelf of the Weddell and Ross Seas, in line with previous studies (Losch et al., 2008; Mathiot et al.,
 371 2017).

372
 373 The mean state of circulation from the last 10 years of simulation within the FRIS cavity, along with the associated bottom
 374 thermohaline properties can be seen in Figs. 5a-5d. The circulation patterns shown here are in good agreement with Bull et
 375 al. (2021) at $1/4^\circ$ and with Hausmann et al. (2020) at $1/12^\circ$ with the exception of higher bottom salinities in eORCA1 and a
 376 slightly weaker barotropic circulation strength. Note that here we use potential temperature and practical salinity so as to be
 377 in line with the other figures of this paper, so approximately 0.17 psu must be added when juxtaposing with absolute salinity
 378 plots. The depth averaged velocity and barotropic circulation pattern in Figs. 5a and 5b both indicate an anticlockwise
 379 circulation under the ice shelf. Comparatively warm and salty HSSW enters via the Ronne Depression, circulates from west
 380 to east, melts the base of the ice shelf mostly along the grounding line (cold, fresh signatures in Figs. 5c and 5d), and exits
 381 via the Filchner Trough as ISW. This pattern is consistent with observations (Nicholls et al., 2001; Janout et al., 2021). Two
 382 pathways of Modified Circumpolar Deep Water (MCDW) towards the ice shelf front can be seen, both in the circulation
 383 pattern (Fig. 5a) and via the bottom temperature (Fig. 5c): one located in the middle of the continental shelf (Central Trough)

384 and the other on the shelf to the east of Filchner Trough. These pathways provide a conduit for heat towards the ice shelf and
385 facilitate the mixing of shelf water masses with MCDW. It is therefore encouraging that eORCA1 (with an effective
386 horizontal resolution under FRIS of 22 km) captures these, as they could play an important role in the evolution of shelf
387 circulation in future climate scenarios (Naughten et al., 2021).

388
389 Moving now to the Ross Sea, the time mean circulation pattern under RIS along with the bottom temperature and salinity
390 can be seen in Figs. 5e-5h. Here, we notice a strong anticlockwise circulation concentrated at the western boundary with
391 reduced magnitude currents towards the back and east of the cavity. The west of the cavity is overall warmer and saltier and
392 the east shows signatures of ISW. Bottom temperature indicates the presence of a cold ISW plume exiting the cavity to the
393 far east (Fig. 5g), which is not seen in the time averaged velocities or barotropic streamfunction, likely because the
394 associated speeds are slow. Instead, the simulated circulation indicates an offshore advection of sub-ice shelf water following
395 the Challenger Trough (see location marked in Fig. 1b). This water mass is likely recirculated HSSW as its temperature
396 remains at surface freezing point (-1.9 °C). A strong clockwise circulation cell offshore of RIS (red in Fig. 5f) brings warm
397 CDW into contact with the ice shelf front to the east, mixing out the signature of ISW further offshore (Fig. 5g). While this
398 simulated circulation pattern agrees well with that described by observations (Fig. 1; Bergamasco et al., 2003; Budillon et
399 al., 2003), it is likely too strong, resulting in an exaggerated net melt flux compared to the observational estimates (Table 1;
400 anomalously high melt at the eastern portion of the ice shelf front in Fig. 4c).

402 Figure 5: Circulation pattern and characteristics of properties under Filchner Ronne (a-d) and Ross (e-h) ice shelves for the
403 last 10 years of the open cavity experiment. Subplots (a) and (e) show depth averaged velocity, (b) and (f) barotropic stream
404 function, (c) and (g) bottom potential temperature and (d) and (h) bottom practical salinity (as opposed to conservative and
405 absolute shown in Bull et al., 2021).

406 407 408 **4.3 Impact on offshore properties**

409
410 To highlight the impact of opening the FRIS, LCIS and RIS sub-ice shelf cavities on the offshore properties, Figs. 2g and 3g
411 show the temperature versus salinity distribution excluding the data under the ice shelves. The differences in bottom
412 temperature and salinity can be seen in Figs. 2h and 2i for the Weddell Sea and 3h and 3i for the Ross Sea.

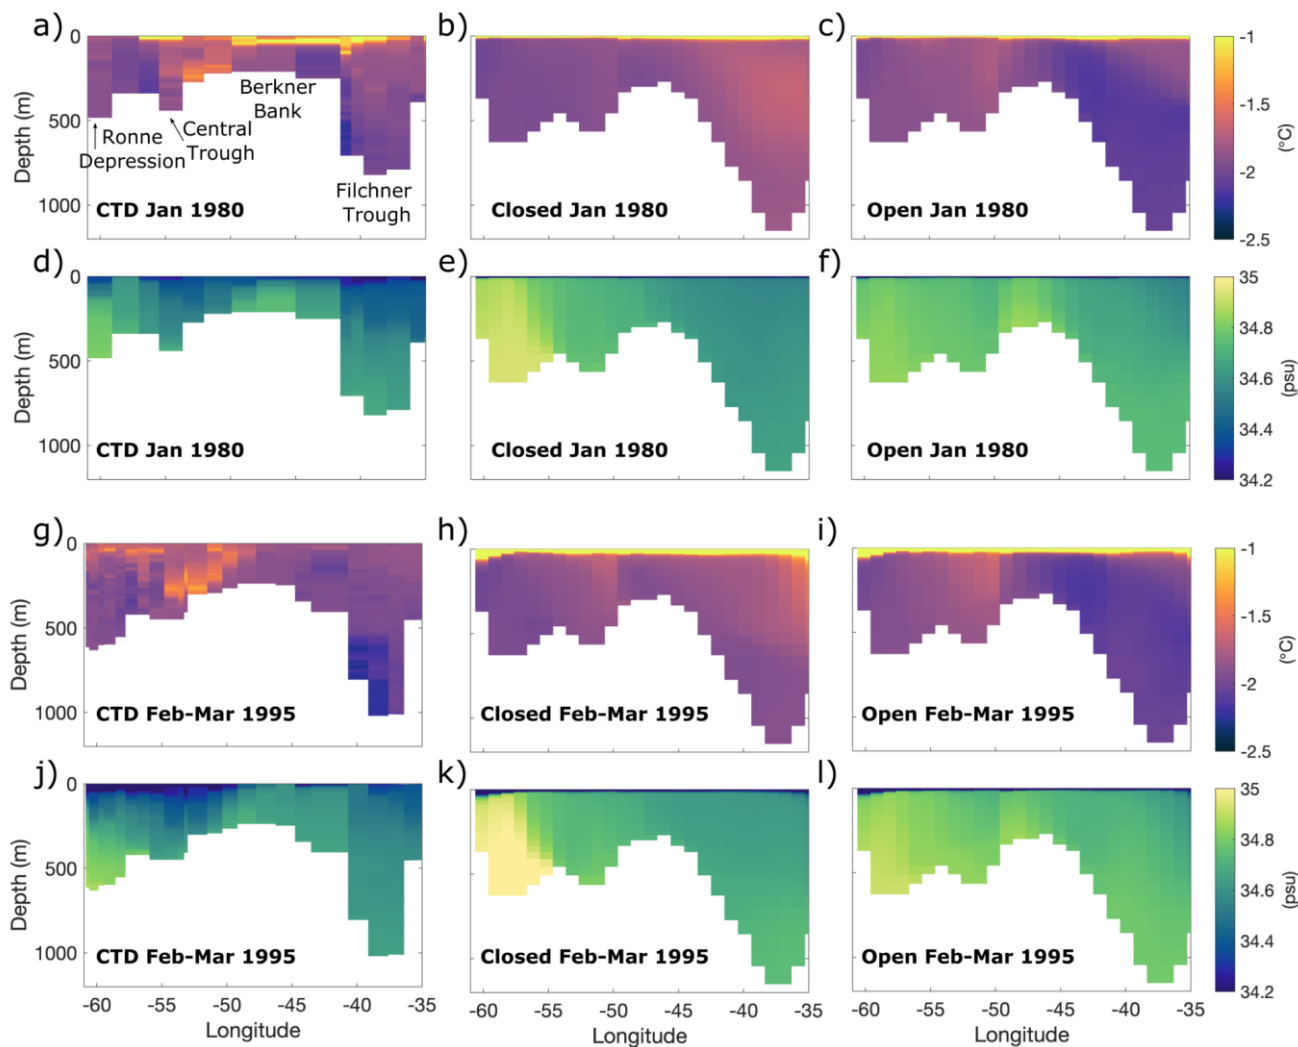

413
414 A significant improvement in the representation of Weddell shelf water properties is evident as now HSSW is within the
415 observed range and ISW is detected on the continental shelf (see HSSW and ISW red boxes in Fig. 2g). Opening the sub-ice-
416 shelf cavity of FRIS has allowed the HSSW that previously built up in the Ronne Depression to advect under the ice shelf,
417 become modified through basal interactions and exit the cavity as colder and fresher ISW. Consequently, the temperature
418 and salinity differences are polarized west and east with warmer fresher conditions along the entire western boundary of the
419 Weddell Gyre and cooler saltier conditions on the eastern continental shelf (Figs. 2h and 2i). These results agree well with
420 those of Mathiot et al. (2017). The impact of opening LCIS can be seen via the maintenance of cold bottom properties
421 immediately to the north (despite the fact that the shelf circulation has changed so that HSSW no-longer floods this region),
422 along with the presence of a large negative salinity anomaly indicative of ice shelf melt (Fig. 2i). As the simulation is only
423 124 years long, the impact of opening the cavities on AABW cannot be fully assessed due to the slow renewal of this water
424 mass at the bottom of the global ocean. A small change in signature of AABW can, however, be seen in the volumetric T-S
425 plot (Supplementary Material Fig. S3a), where explicit ocean-ice shelf interaction results in a shift in volume towards cooler,
426 fresher AABW (Open - Closed weighted average shift in AABW volume by -0.008 °C and -0.003 psu). This shift is
427 accompanied by a small increase in volume of the water mass by 0.23 % (AABW limits delineated in green in Fig. S3a).

428
429 The impact of opening the RIS cavity on offshore properties can be seen in Figs. 3h and 3i. Similar to the Weddell Sea,
430 conditions in the west, where in the reference run HSSW was built up, now become warmer and fresher as the path under the
431 ice shelf is open. The signature of the cold plumes of dense shelf water (Fig. 5g) on either side of Roosevelt Island can
432 clearly be seen in the temperature difference plot (Fig. 3h), but curiously they do not possess the same salinity anomaly (Fig.
433 3i). The positive salinity difference of the western plume indicates that this water is a variety of HSSW which has circulated
434 under the ice shelf and was previously not present in this area. The small negative anomaly to the east indicates that this cold
435 plume is, as previously hypothesised, outflowing ISW. Small temperature differences on the continental slope and further
436 offshore indicate that there has been some communication of the changes in shelf waters further afield. The volumetric T-S
437 plot for the Ross Sea found in Supplementary Material (Fig. S3b) indicates that opening the RIS cavity has moved the core
438 of AABW towards slightly cooler fresher values, accompanied by a 0.34 % decrease in volume of AABW as defined by the
439 original water mass limits (delineated in green in Fig. S3b; Open - Closed weighted average shift in AABW volume by $-$
440 0.001 °C and -0.005 psu).

441 442 **4.4 Comparison with ice shelf front CTD observations**

443
444 The differences in circulation patterns and in thermohaline properties that result from opening the RIS and FRIS cavities
445 documented above do not elucidate whether or not we have reduced biases and improved the realism of shelf waters in

446 eORCA1. For this, a direct comparison with in-situ observations is necessary. Due to the remote location of these ice shelves
 447 and the harsh conditions associated with obtaining hydrographic samples in these areas, there are limited observations, and
 448 so optimally interpolated atlases such as WOA or ocean reanalysis products like SOSE miss important local features or
 449 seasonal variability. For comparison purposes, we have consequently selected CTD data from research cruises that have
 450 sampled transects across the front of the ice shelves and extracted the model data corresponding to the approximate ship's
 451 track using PAGO, a tool to analyze gridded ocean datasets (Deshayes et al., 2014).
 452

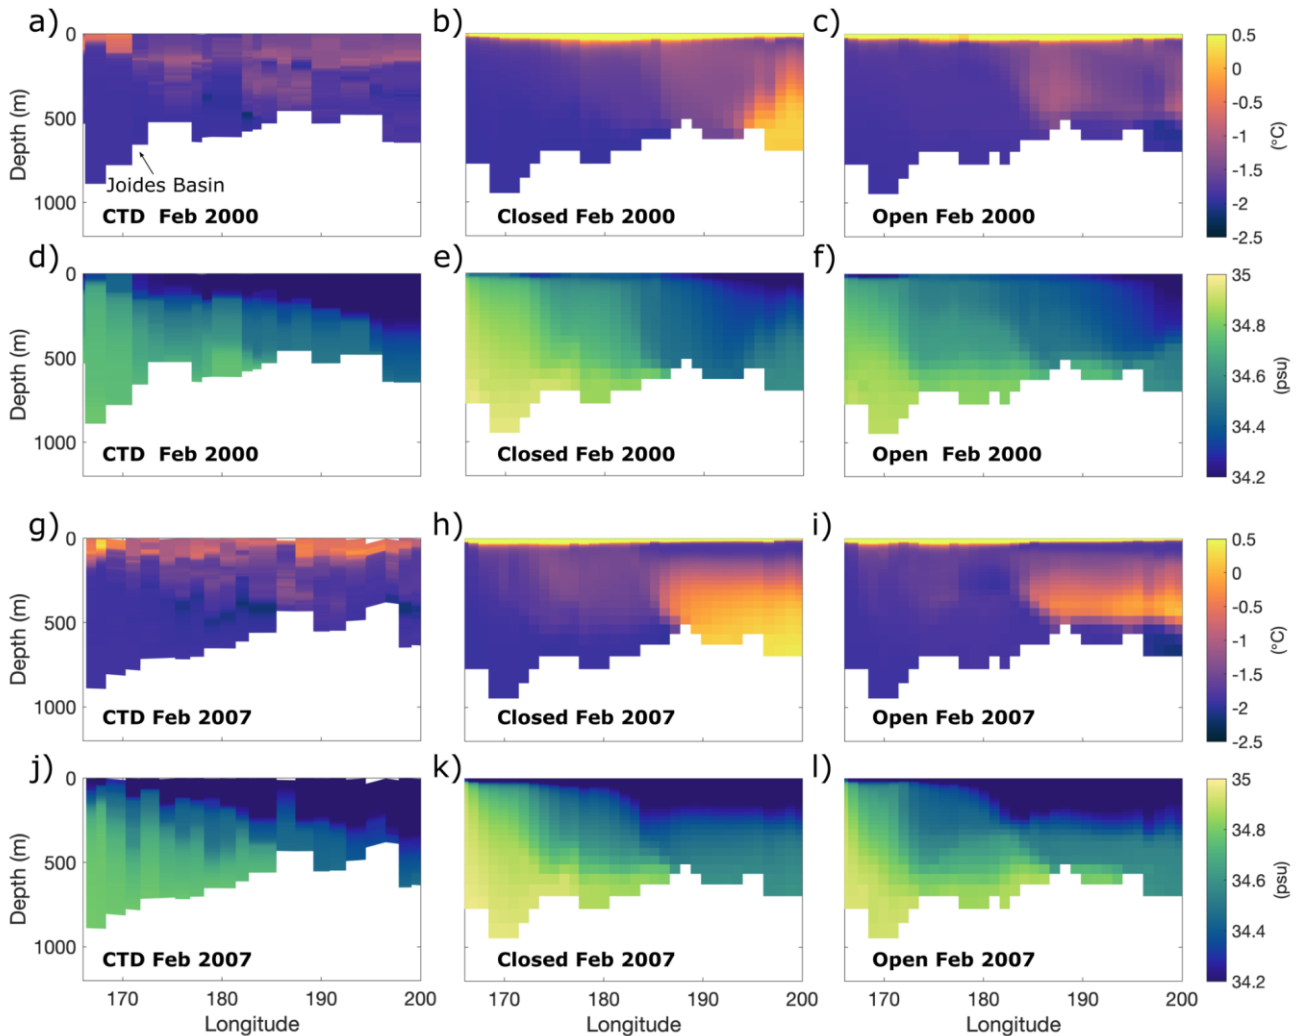

453
 454
 455 Figure 6: Validation of properties across the Filchner Ronne Ice Shelf front by comparing closed and open cavity NEMO
 456 results with measured values from CTD sections performed in 1980 (Rohardt et al., 2016) and 1995 (Janout et al., 2021).
 457 The model output for the corresponding equivalent year and month was extracted for more accurate comparison.
 458 Bathymetric features discussed in the text are labelled in subplot (a).
 459

460 For FRIS we use two CTD sections across the ice shelf front undertaken in 1980 and 1995 on board the RV Polarstern by the
461 Alfred Wegener Institute (Rohardt et al., 2016; Janout et al., 2021). The location of the section selected in NEMO to
462 approximately overlay the CTD transects can be seen as a magenta dotted line in Fig. 1a. The output from NEMO
463 corresponding to the same months and same equivalent year (for the second cycle of CORE forcing) in the simulation was
464 selected for both “Closed” (prescribed freshwater flux) and “Open” (FRIS, LCIS and RIS) cavity runs. A comparison
465 between the CTD data and NEMO can be seen in Figs. 6a to 6f for January 1980 and Fig. 6g to 6l for February to March
466 1995. In terms of surface waters, NEMO does not capture the fine scale horizontal variability and overestimates the
467 subsurface salinity. For both observational years, evidence of warm, fresh, MCDW intrusions can be seen in the middle of
468 the CTD sections (Central Trough; Figs. 6a and 6g). While the model struggles to capture the coherence of this sub-surface
469 temperature maximum, the counterclockwise circulation cell set up on the central continental shelf in the open cavity
470 simulation does aid the advection of MCDW towards the ice shelf, thereby producing a slightly better representation of this
471 warm intrusion in Figs. 6c and 6i. The presence of cold ISW in Filchner Trough is clearer in the 1995 CTD data than in 1980
472 where the sampling frequency was sparser and this region not well covered. The 2018 Polarstern sampling of the Jason
473 Trough was the highest resolution yet and while we cannot directly compare with the simulation output as the CORE forcing
474 ends in 2009, the presence of a tongue of ISW focused on the western bank of Filchner Trough is evident in Fig. 3 of Janout
475 et al. (2021) and so should be kept in mind for comparison. Opening the FRIS cavity overall improves the thermohaline
476 properties at the ice shelf front, most notably by spreading out the pool of HSSW from the Ronne Depression (e.g. Fig. 6k)
477 across the continental shelf (e.g. Fig. 6l) and by facilitating the production and thus outflow of ISW within Filchner Trough
478 (Figs. 6c and 6i).

479
480 The CTD sections used for comparison along the front of RIS were obtained through the World Ocean Circulation
481 Experiment Database (Boyer et al., 2018) and correspond to cruises undertaken on board the RVIB Nathaniel B. Palmer in
482 2000 (cruise id: US010404; Smethie and Jacobs, 2005) and in 2007 (cruise id: US034357). Data was extracted from the
483 eORCA1 simulation corresponding to the dates of these cruises and the approximate ship track across the ice shelf front
484 (magenta dotted line in Fig. 1b). Similar to the Weddell Sea, the model tends to overestimate the subsurface temperature and
485 salinity (Figs. 7b, 7e, 7h and 7k), suggestive of biases in the representation of coastal processes, including vertical mixing.
486 This effect is somewhat reduced by allowing for circulation under RIS, especially by decreasing subsurface salinities
487 (Figures 7f and 7l). At depth, NEMO captures the east-west distribution of haline properties such as the HSSW pool located
488 within Joides Basin, albeit with somewhat amplified salinities. In terms of temperature, the model has a clear bias to the east,
489 especially in the closed cavity run, where CDW is detected at the ice shelf front. Both the temperature and salinity biases are
490 reduced in the open cavity run (e.g. Figs. 7c and 7f). In particular, the significant reduction in the extent and magnitude of
491 the sub-surface warm water intrusions brings the model more in-line with observations.

492

493

494

495 Figure 7: Same as Fig. 7 but for Ross Ice Shelf front for CTD sections performed in 2000 (Smethie and Jacobs, 2005) and

496 2007 (Boyer et al., 2018).

497

498 A recurring theme throughout the results presented here is that the model is overall too salty, driven by what appears to be an
 499 over-production of HSSW in the Ronne Depression and Joides Basin. One driver for this could be the overestimated polynya
 500 activity which forms the totality of parent waters of AABW in the absence of ice shelves in eORCA1. This can be seen in
 501 Fig. 8 where the mean winter (July-August-September) mixed layer depths (MLD) in the reference run for the years 1971-
 502 2009 are compared to the climatology from Sallee et al. (2021) for the same time period and using the same criteria for
 503 calculation (Fig. 8a and 8b; MLD defined as the depth at which density exceeds the 10 m density by 0.03 kg m^{-3}). The model
 504 greatly overestimates winter MLDs in the Weddell Sea, both on the continental shelf adjacent to FRIS, where the depth of
 505 the base of the mixed layer aligns with bathymetric features indicating deep convection right to the ocean floor, and offshore
 506 of the continental slope where a large region of MLD greater than 1000m is present (Fig. 8c). This level of open ocean deep

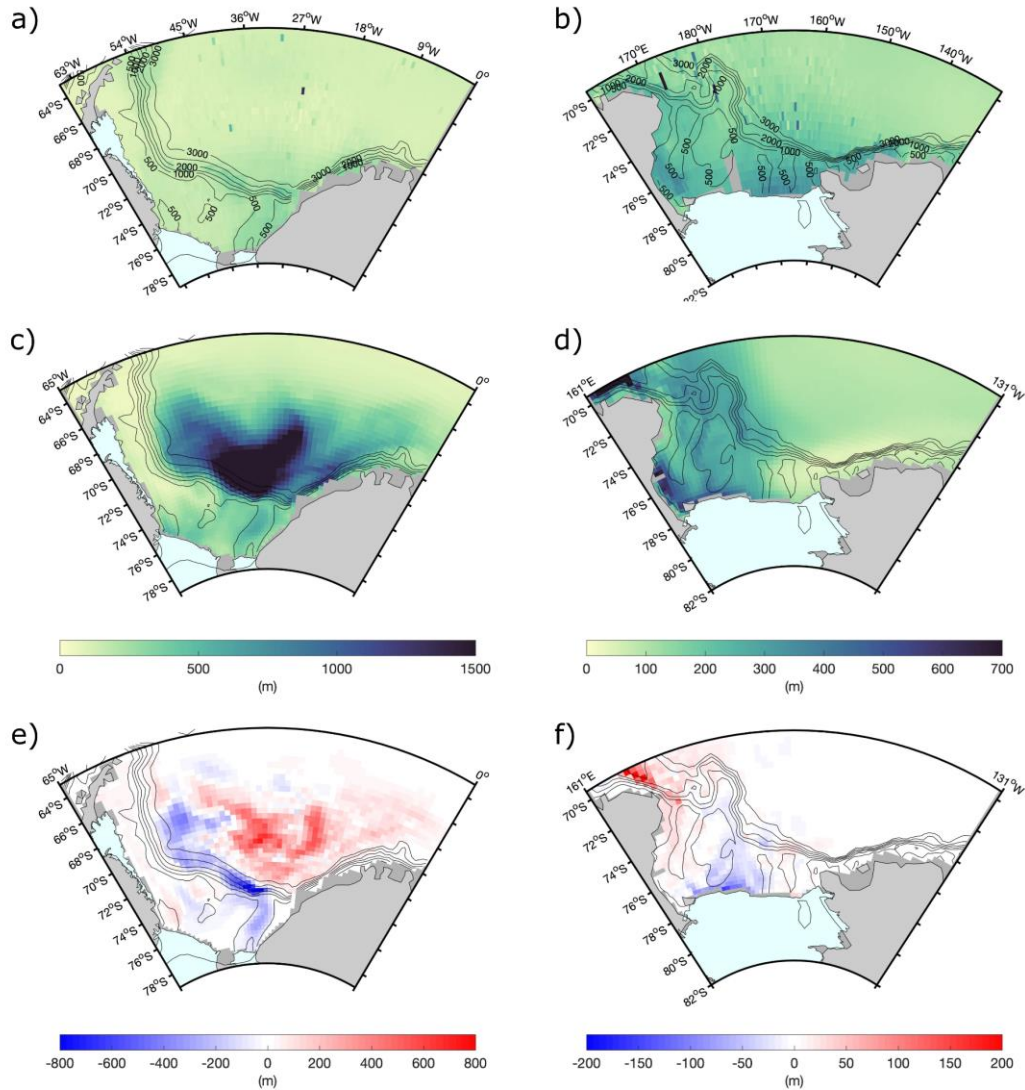

507 convection has in reality only once been observed, during the 1974-1976 Weddell Polynya event near Maud Rise (3° E, 66°
508 S), indicating a gross overestimation of winter MLDs in the model (Heuze et al., 2021; Killworth et al., 1983). Ross Sea
509 MLDs (Fig. 8d) compare better with observations, but show values indicating a full water-column-depth convection in Terra
510 Nova Bay which is not reported in Sallee et al. (2021). Curiously, NEMO actually under-estimates winter mixed layers in the
511 eastern portion of the Ross continental shelf showing mean MLDs of under 100m where the observational climatology
512 indicates values of around 400m (Fig. 8d compared to Fig. 8b). This too-strong stratification could be one of the factors
513 facilitating the intrusion of CDW to the ice shelf front seen in Figs. 7b and 7h.

514

515 The authors note that the biased MLDs could be one of a number of factors contributing to the overly saline conditions;
516 wrong sea-ice parameters and biases in the atmospheric forcing could also play an important (and related) role. High sea ice
517 production is seen on the southwest continental shelves of the Weddell and Ross Seas in Supplementary Figs. S2a and S2b.
518 Opening the cavities slightly reduces the magnitude of ice production in the Ronne Depression (Fig. S2c) and at the location
519 of the Terra Nova Bay Polynya (Fig. S2d) and increases the production of ice further east. There is no overall change in the
520 principal location of polynya activity and the slight west/east decrease/increase in sea ice is presumed to have a negligible
521 effect on the total amount of HSSW generated. As such, the reduction of the highly saline HSSW signature seen in Figs. 2g
522 and 3g when cavities are opened is likely due to a conversion to ISW (and not from a decrease in HSSW production itself).
523 Please see the Supplementary Information Sect. 3 for an evaluation of simulated polynyas near the studied ice shelves and a
524 diagnosis of the effect of opening the cavities on ice production.

525

526 Once a model is able to explicitly form the parent waters of AABW in the right locations on the continental shelf (and export
527 this dense water), it will become necessary for modelers to tone-down open ocean deep convection as this workaround will
528 be longer relied upon to form the totality of AABW. Here we explore the impact that opening the cavities has on MLD to
529 diagnose the extent of vertical convection in the model. Some reduction in MLD is seen on the continental shelf and slope in
530 the Filchner (Fig. 8e) and Challenger Troughs (Fig. 8f) due to the increase in stratification as a result of the greater bottom
531 densities associated with outflowing ISW (Fig. S4a and S4c). The presence of ISW appears to promote slightly increased ice
532 production in these areas, as discussed earlier. In this case, it is therefore the ocean properties that drive sea ice and the brine
533 rejection associated with elevated ice production is found to have a minor effect on water properties. Within the region of
534 exaggerated MLDs off the Weddell continental slope, the MLDs deepen in the “Open” cavity experiment (positive
535 anomalies Figs. 8e). We hypothesise that this deepening is associated with an overall cooling of the subsurface layers due to
536 a horizontal mixing of ISW, unimpeded by a relatively weak and diffuse Antarctic Slope Current (discussed in the following
537 section). Overall, in wintertime, mixed layers are on average 19 m deeper over the whole Weddell Sea region in the “Open”
538 cavity experiment compared to the reference “Closed” simulation. This reinforcement of the high MLD bias highlights the
539 need for work to be done on reducing wintertime deep convection, together with better representing dense water overflows.

540
541

542 Figure 8: Winter mixed layer depths (MLD) from observational atlas of Sallee et al. (2021) shown in (a) and (b) for the
543 Weddell and Ross Sea respectively, are compared with the winter mean from NEMO v4.2 eORCA1 forced model reference
544 configuration equivalent years 1971-2009 in (c) and (d). The differences in MLDs between the “Open” cavity run and
545 reference “Closed” run are shown in subplots (e) and (f).

546

547 4.5 Offshore export of continental shelf properties

548

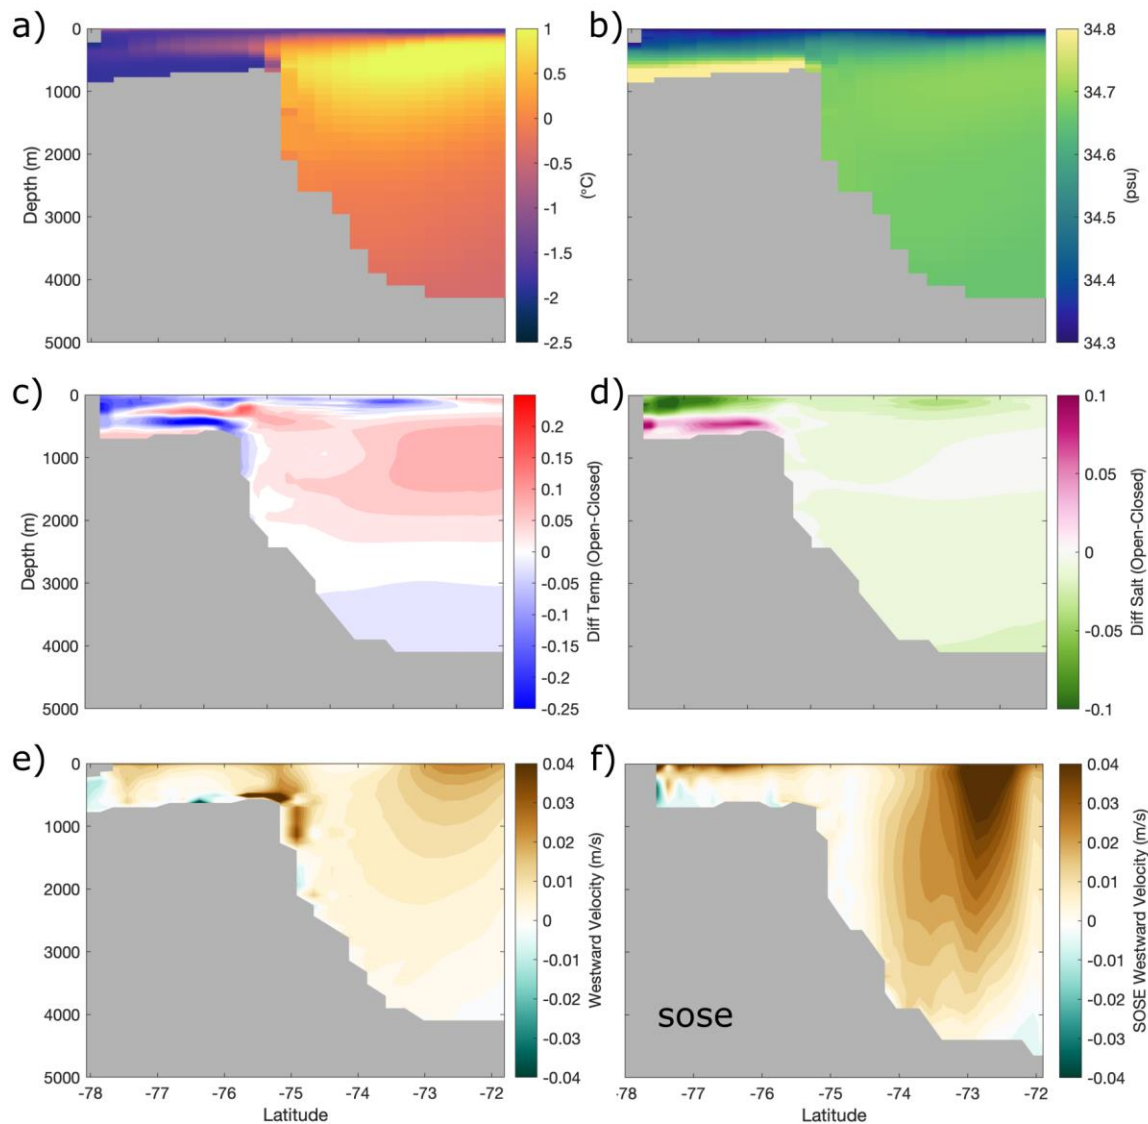

549 We have seen how opening the large, cold, ice shelf cavities in eORCA1 leads to a better representation of continental shelf
550 circulation and thermohaline property distributions. But the question remains regarding the transfer of these now more
551 realistic dense shelf waters downslope and offshore, to feed the globally important AABW. While the simulation period of

552 124 years (two CORE forcing cycles) is too short to explore the impact of these changes far afield, it is sufficient to
 553 investigate the changes on the continental shelf and slope adjacent to the large ice shelves. To do this, we use PAGO
 554 (Deshayes et al., 2014) to select a cross section of data following the bathymetric troughs of the Weddell and Ross Seas
 555 which are thought to be important for dense water export (Foldvik et al., 1985; Jacobs, 1991), namely the Filchner and
 556 Challenger Troughs (sections shown in green in Fig. 1).

557
 558 Figure 9: Cross section of properties along the Filchner Trough and down the adjacent continental slope of the Weddell Sea
 559 for (a)-(e) NEMO and (f) SOSE. Subplots (a) and (b) show temperature and salinity for the open cavity configuration, to be
 560 compared to (c) and (d) which show the differences (Open - Closed) with the reference configuration. Subplot (e) shows
 561 cross sectional velocities with westward as positive for the open cavity run, to be compared with SOSE values shown in
 562 subplot (f).
 563

564 The thermohaline cross sections of Filchner Trough and a continuation down the continental slope can be seen in Figs. 9a
 565 and 9b for the open cavity run and the difference between these values and the reference run (Open-Closed) are shown in
 566 Figs. 9c and 9d. By opening the sub-ice shelf cavity, the properties within Filchner Trough have decreased in temperature
 567 and increased in salinity as the candidate parent waters of AABW build up on the continental shelf. This results in a net
 568 increase in density at the bottom of the trough (Fig. S4b), but there is very little indication of a coherent cascading of this
 569 water down the continental slope.

570
 571
 572 Figure 10: Same as Fig. 9 but for the Challenger Trough and the Ross Sea continental slope.
 573

574 A cross section of the Challenger Trough (Fig. 10) reveals depth-varying thermohaline changes. Opening the sub-ice shelf
 575 cavity has allowed for the water adjacent to the ice shelf to advect into the cavity leaving the bottom properties here slightly

576 warmer. The layer immediately above conversely experiences cooling and salinification due to the outflow of ISW driven by
577 the ‘ice pump’ (Fig. 10c). Here we see some evidence indicating the translation of this dense cold water tongue over the
578 continental shelf break and downslope (Figs. 10c and S4d). The overflow of this water results in the pulling in of warmer
579 offshore water at intermediate depth (Fig. 10c). A horizontal redistribution of surface waters simultaneously takes place due
580 to the anti-clockwise circulation pattern (Fig. 5e) which in turn produces a cooling and freshening in the surface layer (Figs.
581 10c and 10d).

582
583 For both the Filchner and Challenger Troughs, the downslope export of the ISW tongue is limited due to the commonly-
584 known and acknowledged problem of correctly capturing this overflow in a coarse z-coordinate model (Heuze et al., 2021).
585 The aptitude of representing dense water overflows is thought to increase with models of higher resolution, but this is
586 difficult to achieve in a global model for climate coupling purposes without a nested zoom (Storkey et al., 2018; Colombo et
587 al., 2020; Solodoch et al., 2022).

588
589 Another important dynamic for Antarctic shelf water realism is the ASC (red arrows in Fig. 1) and related Antarctic Slope
590 Front, which together restrict the lateral mixing of offshore and shelf water masses, acting as an effective barrier protecting
591 the large cold ice shelves from warm water masses of circumpolar origin (Thompson et al., 2018). Some CDW, or a
592 modified version thereof, is carried within the ASC and occasionally fluxes onshore to mix with dense shelf waters
593 (Beadling et al., 2020; Bull et al., 2021). This interaction between dense shelf water and CDW is important for the formation
594 of AABW, as the onshore flux of water replaces the dense water transported offshore and thus sustains formation of shelf
595 water (Thompson et al., 2018). Figure 9e shows a velocity cross section for the Weddell Sea shelf and slope where westward
596 velocities are positive so as to correspond with the direction of the ASC and the net westward transport across the section is
597 9.8 Sv (1 Sv is $10^6 \text{ m}^3 \text{ s}^{-1}$). This can be compared to Fig. 9f which is a cross section from SOSE output (same time periods
598 used) where the net transport is three times higher at 32.8 Sv. Similarly for the Ross Sea, Fig. 10e shows a cross section of
599 westward velocities in eORCA1 where the volume transport is 13.3 Sv which is less than half of that estimated from SOSE
600 in Fig. 10f of 20.9 Sv. As can be seen from both SOSE cross sections, the ASC flows eastward as a narrow jet, closely
601 following the shelf break in the Weddell Sea and slightly further offshore in the Ross Sea. It is well known that coarse
602 resolution models are unable to correctly represent the ASC as a resolution of at least 0.5° is needed to capture the dynamics
603 and net transport (Mathiot et al., 2011). The absence of realistic ASC in NEMO eORCA1 (Figs. 9e and 10e) has important
604 consequences, as a weaker and more diffuse ASC allows for a greater level of onshore-offshore exchange of water masses.
605 This is one important restriction that needs to be kept in mind when using this coarse resolution configuration for process
606 studies in the area.

607 608 **5 Summary and Discussion**

609
610 Explicitly representing ocean-ice shelf interactions is of great interest to modelers as these processes play an important role
611 in global ocean dynamics, climate and future sea level rise. The formation of dense shelf waters (HSSW and ISW) along the
612 Antarctic coastline provides the principal source for AABW, which in turn facilitates the ventilation of the deep ocean and
613 constitutes the lower limb of the global overturning circulation (Killworth, 1983; Johnson, 2008; Orsi, 2010).

614
615 Our results focus on the Weddell and Ross seas as they are respectively the main ventilation source of the abyssal Atlantic
616 and Indian basins, and the abyssal Pacific basin (Solodoch et al., 2022). Explicitly simulating the sub-ice shelf cavities of
617 FRIS and LCIS in the Weddell Sea leads to a re-organisation of continental shelf circulation with thermohaline patterns in
618 agreement with those reported by other NEMO model studies (Mathiot et al., 2017; Storkey et al., 2018 and Bull et al.,
619 2021), namely warming and freshening in the west and cooling and salinification in the east. Notably, opening a pathway for

620 HSSW under FRIS allows for an anticlockwise circulation of water under the ice shelf, triggering basal melt and re-freezing,
621 and producing the super-cold ISW.

622
623 By comparing model output with two CTD sections performed across the front of FRIS in 1980 and 1995 (Rohardt et al.,
624 2016; Janout et al., 2021), we see clear evidence of an improvement in the realism of water properties with the opening of
625 the sub-ice shelf cavity. Similarly in the Ross Sea, an anticlockwise sub-ice shelf cavity circulation cell facilitates the spread
626 of HSSW across the continental shelf and ocean-ice shelf interactions create a cold ISW plume to the east of Roosevelt
627 Island. By evaluating the model output against CTD sections performed in 2000 and 2007 (Smethie and Jacobs, 2005; Boyer
628 et al., 2018), we see that opening the cavity significantly ameliorates the sub-surface warm water bias otherwise seen to the
629 east of RIS in the reference configuration, and brings a significant improvement in the horizontal thermohaline distributions.

630
631 The mean total melt fluxes of FRIS, LCIS and RIS are found to be within the uncertainty range of observational estimates
632 and other model studies. Notably, the melt rate pattern of FRIS agrees surprisingly well with the high resolution regional
633 model of Haussmann et al. (2020) and the satellite observations of Rignot et al. (2013), showing details of melt and
634 refreezing that were not expected at a 1° resolution, although the meanders of the grounding line are not well represented at
635 1° . For RIS, the net melt is higher than all observed estimates but lower than that predicted by other model studies. RIS melt
636 rates are strongly related to the supply of warm water to the ice shelf base (Arzeno et al., 2014), and correctly representing
637 this in models presents a challenge due to the close proximity of CDW to the ice shelf front in this area.

638
639 Meltwater and modified HSSW mix on the continental shelves of the Weddell and Ross Sea and in reality cascade down the
640 continental slope, mixing with ambient water masses during the descent, to eventually feed AABW. This process is poorly
641 represented in NEMO eORCA1, a common problem with coarse z-coordinate models, as exaggerated vertical and horizontal
642 mixing erodes the signatures of the dense overflow tongue. As mentioned by Storkey et al. (2018), the use of a terrain
643 following coordinate system (known as sigma coordinate) can greatly improve the representation of these density currents,
644 and so is something worth exploring in the future. Improvement in the representation of the overflows along with a reduction
645 of open-ocean deep convection should together allow for a coherent communication of the now more realistic properties of
646 dense water on the continental shelf offshore to AABW.

647 648 **6 Conclusion**

649
650 In this paper the authors focus on improving the properties of AABW parent waters in a global NEMO configuration. We
651 compare the model simulations with in situ observations, in addition to gridded climatologies, so as to deepen understanding
652 and expertise regarding the impact of opening sub-ice shelf cavities on ocean dynamics. As ocean models used for climate
653 simulations with multiple scenarios (such as CMIP) need to be at a coarse resolution to permit long integrations, we use the
654 NEMO global ocean 1° configuration, eORCA1, here. The results presented are for CORE inter-annual forcing, with a fixed
655 cavity geometry, as this allows us to clearly identify the impact of ocean-ice shelf interactions at a few critical locations
656 without the obscuring effect of coupling feedbacks. We present here a validated configuration of NEMO 4.2 eORCA1 with
657 explicit ocean-ice shelf interactions only within the largest 3 cold cavities: FRIS, LCIS and RIS. Limitations of this choice
658 are that together FRIS, LCIS and RIS only represent 63 % of the total area of Antarctic ice shelves and, while they are
659 responsible for the formation of the majority of the parent waters of AABW, interactions with remote unresolved ice shelves
660 are missing (Nakayama et al., 2020). The next steps in terms of increasing complexity in NEMO eORCA1 are to open other
661 intermediate size cavities, such as Amery, Riiser-Larsen and Fimbul, in a fixed geometry configuration, and leave smaller
662 cavities parameterized due to resolution constraints. As the residence time needed to flush these intermediate cavities is
663 shorter than for FRIS and RIS, we suggest that the complex initialization methods presented here are not needed. This work

664 is aimed at building understanding so as to eventually move to coupling with an ice sheet model thereby allowing for fully
665 evolving cavity geometry and iceberg calving from the ice shelf front.

666
667 Given the critical role that the Southern Ocean plays in regulating global climate, it is paramount that ocean models work
668 towards improving the representation of key processes in order to provide state-of-the-art simulations of the ocean in a
669 changing climate (Beadling et al., 2020). The global configuration of NEMO presented here, has been proven to improve the
670 realism of water masses in the Weddell and Ross Seas. We advocate for climate modelers to use it, as it enables a more
671 accurate representation of the formation of the parent waters of AABW, and a first step in the perspective of representing
672 ocean-ice shelf interactions in climate applications.

673 674 **7 Author contribution**

675
676
677 KH, JD and PM together contributed to the conceptualization of the research outlined in this manuscript. KH led the formal
678 analysis and investigation with the assistance of JD, CR, CL, NJ and PM. MV led the sea ice research component with
679 assistance from CR and CL. Validation of the model was undertaken by KH with PM. CE led the programming, code
680 management and supervised all the model runs undertaken by KH. The project was supervised by JD and NJ, providing
681 guidance and critical feedback. The whole group contributed to the writing and review of the submitted manuscript.

682 683 **8 Competing interests**

684
685 The authors declare that they have no conflict of interest.

686 687 **9 Acknowledgements of financial support**

688
689 Katherine Hutchinson received financial support of the European Union's Horizon 2020 research and innovation programme
690 Marie Skłodowska-Curie grant agreement No 898058 (Project OPEN). Nicolas Jourdain received support from the European
691 Union's Horizon 2020 research and innovation programme under grant agreement no. 101003536 (ESM2025). Pierre
692 Mathiot acknowledges support from the European Union's Horizon 2020 research and innovation programme under grant
693 agreement no. 820575 (TiPACCs). This work was performed using HPC resources from GENCI-IDRIS (Grant 2021-
694 A0100107451) and from the IPSL Mesocentre ESPRI.

695 696 **10 Code and data availability**

697
698 The NEMO ocean model code is available via open software license from the NEMO website (<https://www.nemo-ocean.eu>).
699 The NEMO output for the Weddell and Ross Seas (focus of this study), plus the namelists used, bathymetry, ice shelf draft,
700 freshwater input and initial condition files are available via the data repository stored here:

701 <https://doi.org/10.5281/zenodo.7561767>. Some example scripts for data extraction, calculations and plotting can also be
702 found in this repository. The World Ocean Atlas hydrographic data of Locarnini et al. (2019) and Zweng et al. (2019) can be
703 found here: <https://www.nodc.noaa.gov/OC5/woa18/woa18data.html> and Southern Ocean State Estimate data of Mazloff et
704 al. (2010) can be accessed here: http://sose.ucsd.edu/sose_stateestimation_data_05to10.html. The mixed layer depth data
705 from Sallee et al. (2021) can be accessed here: <https://doi.org/10.5281/zenodo.5776180>. The CTD transects used for
706 comparisons across the ice shelf front for FRIS 1980 and 1995 can be respectively found here:
707 <https://doi.org/10.1594/PANGAEA.860066> and here <https://folk.uib.no/ngfso/Data/CTD/>. The RIS CTD data from the 2000

708 (US010402) and 2007 (US034357) RVIB Nathaniel B. Palmer cruises are available from the World Ocean Data Base at
709 https://www.nodc.noaa.gov/OC5/WOD/pr_wod.html. The PAGO toolbox used to extract model output along a line in front
710 of the ice shelf from Deshayes et al. (2014) can be accessed here: <https://www.whoi.edu/science/PO/pago/>.
