13 **Keywords:** Soil NO emissions; Ground-level ozone; BDSNP; OSAT

14  
15 **Abstract.** Elevated ground-level ozone concentrations have emerged as a major environmental  
16 issue in China. Nitrogen oxide (NO<sub>x</sub>) is a key precursor to ozone formation. Although control  
17 strategies aimed at reducing NO<sub>x</sub> emissions from conventional combustion sources are widely  
18 recognized, soil NO<sub>x</sub> emissions (mainly as NO) due to microbial processes have received little  
19 attention. The impact of soil NO emissions on ground-level ozone concentration is yet to be  
20 evaluated. This study estimated soil NO emissions in China using the Berkeley-Dalhousie soil  
21 NO<sub>x</sub> parameterization (BDSNP) algorithm. A typical modeling approach was used to quantify  
22 the contribution of soil NO emissions to surface ozone concentration. The Brute-force method  
23 (BFM) and the Ozone Source Apportionment Technology (OSAT) implemented in the  
24 Comprehensive Air Quality Model with extensions (CAMx) were used. The total soil NO  
25 emissions in China for 2018 were estimated to be 1157.9 Gg N, with an uncertainty range of  
26 715.7~1902.6 Gg N. Spatially, soil NO emissions are mainly concentrated in Central China,  
27 North China, Northeast China, northern Yangtze River Delta (YRD) and eastern Sichuan Basin,  
28 with distinct diurnal and monthly variations that are mainly affected by temperature and the  
29 timing of fertilizer application. Both the BFM and OSAT results indicate a substantial  
30 contribution of soil NO emissions to the maximum daily 8-hour (MDA8) ozone concentrations  
31 by 8~12.5 μg/m<sup>3</sup> on average for June 2018, with the OSAT results consistently higher than  
32 BFM. The results also showed that soil NO emissions led to a relative increase in ozone  
33 exceedance days by 10%~43.5% for selected regions. Reducing soil NO emissions resulted in  
34 a general decrease in monthly MDA8 ozone concentrations, and the magnitude of ozone  
35 reduction became more pronounced with increasing reductions. However, even with complete  
36 reductions in soil NO emissions, approximately 450.3 million people are still exposed to  
37 unhealthy ozone levels, necessitating multiple control policies at the same time. This study

38 highlights the importance of soil NO emissions for ground-level ozone concentrations and the  
39 potential of reducing NO emissions as a future control strategy for ozone mitigation in China.

## 40 **1. Introduction**

41 A substantial decrease in the atmospheric fine particulate matter (PM<sub>2.5</sub>) concentrations has  
42 been witnessed during the past decade in China (Zhai et al., 2019; Xiao et al., 2020; Maji, 2020)  
43 while the ground-level ozone (O<sub>3</sub>) concentrations do not exhibit a steady downward trend (Lu  
44 et al., 2020; Lu et al., 2021; Wang et al., 2022a; Sun et al., 2021). Because high ozone  
45 concentration increases respiratory and circulatory risks (Malley et al., 2017; Cakaj et al., 2023;  
46 Wang et al., 2020) and reduces crop yields (Feng et al., 2019; Lin et al., 2018; Mukherjee et al.,  
47 2021; Montes et al., 2022), the coordinate control of PM<sub>2.5</sub> and O<sub>3</sub> was proposed as part of the  
48 14<sup>th</sup> Five-year plan (State Council, 2021). A continuous increase in summertime surface ozone  
49 was observed across China's nationwide monitoring network from 2013 to 2019, followed by  
50 an unprecedented decline in 2020 (except for Sichuan Basin) (Sun et al., 2021), which is equally  
51 attributed to meteorology and anthropogenic emissions reductions (Yin et al., 2021). As a  
52 secondary air pollutant, ozone is generated by the photochemical oxidation of volatile organic  
53 compounds (VOC) in the presence of nitrogen oxides (NO<sub>x</sub> = NO + NO<sub>2</sub>), both of which are  
54 considered ozone precursors. The control strategies to mitigate ozone pollution in China  
55 focused on reducing NO<sub>x</sub> emissions at an early stage and started to stress the control of VOCs  
56 emissions in recent years (e.g., the 2020 action plan on VOCs mitigation), including control of  
57 fugitive emissions, stringent emissions standards, and substituting raw materials with low  
58 VOCs content (Ecology, 2020). Ding et al. (2021) concluded that for North China Plain (NCP),  
59 a region that experienced the most severe PM<sub>2.5</sub> and ozone pollution in China, reductions in  
60 NO<sub>x</sub> emissions are essential regardless of VOC reduction.

61 Existing control strategies for NO<sub>x</sub> emissions are almost exclusively targeted at combustion  
62 sources, for example, power plants, industrial boilers, cement production, and vehicle exhausts  
63 (Sun et al., 2018; Ding et al., 2017; Diao et al., 2018). However, NO<sub>x</sub> emissions from soils  
64 (mainly as NO), as a result of microbial processes (e.g., nitrification and denitrification), could  
65 make up a substantial fraction of the total NO<sub>x</sub> emissions (Lu et al., 2021; Drury et al., 2021),  
66 yet is often overlooked. In California, soil NO<sub>x</sub> emissions in July accounted for 40% of the  
67 state's total NO<sub>x</sub> emissions (when using an updated estimation algorithm) and resulted in 23%  
68 of enhanced surface ozone concentration (Sha et al., 2021). However, a wide range of annual  
69 soil NO<sub>x</sub> emissions from 8,685 tons (as NO<sub>2</sub>, (Guo et al., 2020) to 161,100 metric tons of NO<sub>x</sub>-  
70 N (Almaraz et al., 2018) were reported depending on different methods. Romer et al. (2018)  
71 estimated that nearly half of the increase in hot-day ozone concentration in a forested area of  
72 the rural southeastern United States is attributable to the temperature-induced increases in NO<sub>x</sub>  
73 emissions, mostly likely due to soil microbes.

74 Soil NO emissions are affected by many factors, including nitrogen fertilizer application, soil  
75 organic carbon content, soil temperature, humidity, and pH (Vinken et al., 2014; Yan et al., 2005;  
76 Wang et al., 2021; Skiba et al., 2021). The amount of nitrogen fertilizer application in China  
77 was estimated to account for one-third of the global nitrogen fertilizer application (Heffer and  
78 Prud'homme, 2016), with most of the land under high nitrogen deposition (Liu et al., 2013; Lü  
79 and Tian, 2007). Therefore, soil NO emissions in China are expected to be significant, and their  
80 impacts on ozone pollution need to be systematically evaluated. So far, only a limited number  
81 of studies have addressed this issue in China (Lu et al., 2021; Shen et al., 2023; Wang et al.,  
82 2008; Wang et al., 2022b). Lu et al. (2021) concluded that soil NO significantly reduced the  
83 ozone sensitivity to anthropogenic emissions in NCP, therefore, causing a so-called “emissions  
84 control penalty”. Wang et al. (2022b) reported NO<sub>x</sub> emissions from cropland contributed 5.0%  
85 of the maximum daily 8h average ozone (MDA8 O<sub>3</sub>) and 27.7% of NO<sub>2</sub> concentration in NCP.  
86 These studies focused solely on NCP, a region with persistent O<sub>3</sub> pollution in warm seasons  
87 (Liu et al., 2020; Lu et al., 2020). The impact of soil NO emissions on ozone concentrations  
88 over other regions, for example, the northern Yangtze River Delta (YRD) and Sichuan Basin,  
89 where soil emissions are high (see Section 3.1) and ozone pollution is also severe (Shen et al.,  
90 2022; Yang et al., 2021), has not been much evaluated in details (Shen et al., 2023). In addition,  
91 the method employed in existing studies to evaluate soil NO emissions on ozone concentration  
92 is the conventional “brute-force” zero-out approach, which might be inappropriate given the  
93 strong nonlinearity of the ozone chemistry (Clappier et al., 2017; Thunis et al., 2019).

94 With the deepening of emissions control measures for power, industrial and on-road sectors,  
95 anthropogenic NO<sub>x</sub> emissions from combustion sources have decreased at a much faster rate  
96 (by 4.9% since 2012) than that from soil (fertilizer application decreases at a rate of 1.5% since  
97 2015, Fig. S1). Therefore, understanding the impacts of soil NO emissions on ground-level  
98 ozone concentration, particularly considering the spatial heterogeneities over different regions  
99 of China, is of great importance for formulating future ozone mitigation strategies. In this study,  
100 soil NO emissions in China for 2018 were estimated based on a most recent soil NO  
101 parameterization scheme with updated fertilizer data as input. The spatial and temporal  
102 variations of soil NO emissions were described first. Uncertainties associated with estimation  
103 of soil NO emissions were discussed. An integrated meteorology and air quality model was  
104 applied to quantify the impact of soil NO emissions on surface ozone concentration based on  
105 two different methods. Lastly, we evaluated the changes in ozone concentration and exposed  
106 population under different emission scenarios to highlight the effectiveness of reducing soil NO  
107 emissions as potential control policy. Our results provide insights into developing effective  
108 emissions reduction strategies to mitigate the ozone pollution in China.

## 109 2. Methodology

### 110 2.1. Estimation of soil NO emissions in China

111 Soil NO emissions were estimated based on the Berkeley-Dalhousie Soil NO<sub>x</sub> Parameterization  
112 (BDSNP) that is implemented in the Model of Emissions of Gases and Aerosols from Nature  
113 (MEGAN) version 3.2 (<https://bai.ess.uci.edu/megan/data-and-code>, accessed on September 1<sup>st</sup>,  
114 2021). The BDSNP algorithm estimates the soil NO emissions by adjusting a biome-specific  
115 NO emissions factor in response to various conditions, including the soil temperature, soil  
116 moisture, precipitation-induced pulsing, and a canopy reduction factor (Eq. 1, Rasool et al.,  
117 2016):

$$NO_{\text{emission flux}} = A'_{\text{biome}}(N_{\text{avail}}) \times f(T) \times g(\theta) \times P(l_{\text{dry}}) \times CRF(LAI, Biome, Meteorology) \quad \text{Eq. 1}$$

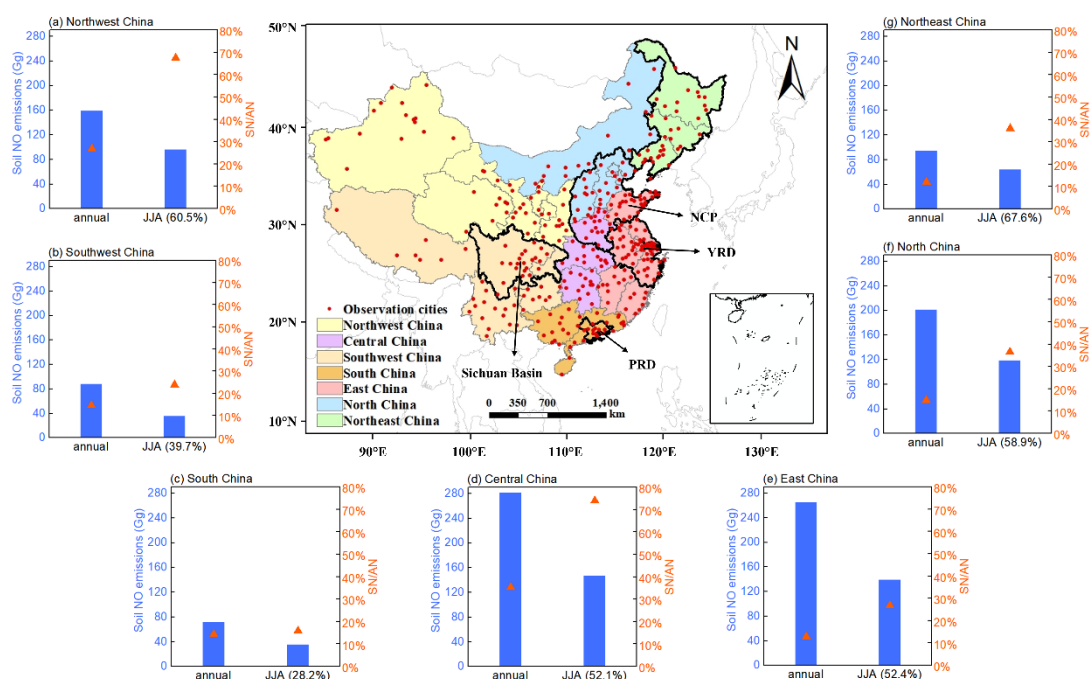

118 where  $f(T)$  and  $g(\theta)$  is the temperature ( $T$ , unit: K) and soil moisture ( $\theta$ , unit:  $\text{m}^3/\text{m}^3$ ) dependence  
119 functions, respectively;  $P(l_{\text{dry}})$  represents the pulsed soil emissions due to wetting of dry soils;  
120  $l_{\text{dry}}$  (hours) is the antecedent dry period of a pulse; and CRF describes the canopy reduction  
121 factor, which is a function of the leaf area index (LAI,  $\text{m}^2/\text{m}^2$ ) and the meteorology.  $A'_{\text{biome}}$  ( $\text{ng}$   
122  $\text{N m}^{-2} \text{s}^{-1}$ ) is the biome-specific emission factor, which is further calculated as Eq.2:

$$A'_{\text{biome}} = A_{w,\text{biome}} + N_{\text{avail}} \times \bar{E} \quad \text{Eq. 2}$$

123 In Eq. 2,  $A_{w,\text{biome}}$  ( $\text{ng N m}^{-2} \text{s}^{-1}$ ) is the wet biome-dependent emission factor;  $N_{\text{avail}}$  is the available  
124 nitrogen from fertilizer and deposition;  $\bar{E}$  is the emission rate based on an observed global  
125 estimates of fertilizer emissions (Rasool et al., 2016). The detailed expressions of these  
126 parameters are presented in the Supporting Information. More information on the BDSNP  
127 parameterizations can be found in previous studies (Hudman et al., 2012).

128 The default N fertilizer input data provided with the BDSNP algorithm is based on the a (Potter  
129 et al., 2010), which gives a number of 19.6 Tg N/a. In this study, we collected fertilizer data  
130 from statistical yearbooks at the provincial level. The total amount of pure nitrogen fertilizer  
131 (hereafter N fertilizer) applied in the year 2018 is 20.7 Tg N/a, which is similar (5.6% higher)  
132 to IFA value. However, besides the N fertilizer, NPK compound fertilizer (containing nitrogen  
133 (N), phosphorous (P), and potassium (K)) is being increasingly applied in China. According to  
134 the statistical yearbook, the amount of N fertilizer applied decreased from 23.5 Tg in 2010 to  
135 20.7 Tg in 2018 (a relative reduction of 11.9%). In contrast, NPK fertilizer increased from 18.0  
136 in 2010 to 22.7 Tg in 2018 (a relative increase of 26.1%). We assumed one-third of the NPK  
137 fertilizer is nitrogen (Liu, 2016); thus, the total amount of nitrogen applied as fertilizer is 28.2  
138 Tg N in 2018, which is 43.9% higher than the value from Potter et al. (2010). We divided China  
139 into seven regions for emission analysis at regional scale, namely Northeast China, North China,  
140 Central China, East China, South China, Southwest China, and Northwest China, as indicated  
141 by different colors in Fig. 1 (see Table S1 for the list of provinces in each region). At the regional

142 level, the amount of total fertilizer differs by as much as 9.1% to 46.4% from the default  
143 fertilizer (Table S2).

144  
145 **Figure 1.** Modeling domain and region definitions. Surrounding charts show the annual and  
146 summer (June-July-August, JJA) soil NO emissions and ratio of soil NO to anthropogenic  
147 NOx emissions for each region.

## 148 2.2. Model configurations

149 A typical modeling approach was applied to evaluate the contribution of soil NO emissions to  
150 surface ozone concentration. The Weather Research and Forecasting (WRF) model (version 3.7,  
151 <https://www.mmm.ucar.edu/wrf-model-general>, accessed on December 1<sup>st</sup>, 2021) and the  
152 Comprehensive Air Quality Model with Extension (CAMx, version 7.0, <http://www.camx.com/>,  
153 accessed on December 1<sup>st</sup>, 2021) were applied to simulate the meteorological fields and  
154 subsequent ozone concentrations. Table S3 listed the detailed model configurations for WRF  
155 and CAMx. Anthropogenic emissions include the Multi-resolution Emission Inventory of  
156 China for 2017 (MEIC, <http://www.meicmodel.org>, accessed on December 1<sup>st</sup>, 2021) and the  
157 2010 European Commission's Emissions Database for Global Atmospheric Research (EDGAR,  
158 <http://edgar.jrc.ec.europa.eu/index.php>, accessed on December 1<sup>st</sup>, 2021) for outside China.  
159 Biogenic emissions were calculated along with the soil NO emissions using MEGAN3.2. Open  
160 biomass burning emissions are adopted from the Fire INventory from NCAR version (FINN,  
161 version 1.5, <https://www.acom.ucar.edu/Data/fire/>) with MOZART speciation and converted to  
162 CAMx CB05 model species. The gaseous and aerosol modules used in CAMx include the CB05  
163 chemical mechanism (Yarwood et al., 2010) and the CF module. The aqueous-phase chemistry  
164 is based on the updated mechanism of the Regional Acid Deposition Model (RADM) (Chang

165 et al., 1987). A base case simulation was conducted for June 2018 when soil NO emissions  
166 reached maxima (Section 3.1) and ozone pollution was severe over eastern China (Mao et al.,  
167 2020; Jiang et al., 2022). Base case model performances have been evaluated in our previous  
168 studies (Huang et al., 2021; Huang et al., 2022b). Here we evaluated simulated ozone  
169 concentrations using the Pearson correlation coefficient (R), mean bias (MB), root-mean-square  
170 error (RMSE), normalized mean bias (NMB), and normalized mean error (NME) against hourly  
171 observed ozone concentrations for 365 cities in China. The formula for each of the statistical  
172 metrics is given in Table S4. Observed hourly ozone concentrations were obtained from the  
173 China National Environmental Monitoring Center.

### 174 2.3. Brute-force and OSAT

175 In this study, two methods were used to quantify the impact of soil NO emissions on surface  
176 ozone concentration during the simulation period. The first is the conventional brute-force  
177 method (BFM), which involves comparing the simulated ozone concentration between the base  
178 case and a scenario case without soil NO emissions. The difference between these two scenarios  
179 was considered to represent the contribution of soil NO emissions to ozone. The second method  
180 applies the widely used Ozone Source Apportionment Technology (OSAT) implemented in  
181 CAMx (Yarwood et al., 1996), with soil NO emissions being tagged as an individual emission  
182 group. OSAT attributes ozone formation to NO<sub>x</sub> or VOCs based on their relative availability  
183 and apportions NO<sub>x</sub> and VOCs emissions by source group/region (Ramboll, 2021). In addition  
184 to soil NO emissions, anthropogenic and natural emissions (including biogenic VOC emissions,  
185 lightning NO emissions, and open biomass burning) were also tagged as individual emission  
186 groups.

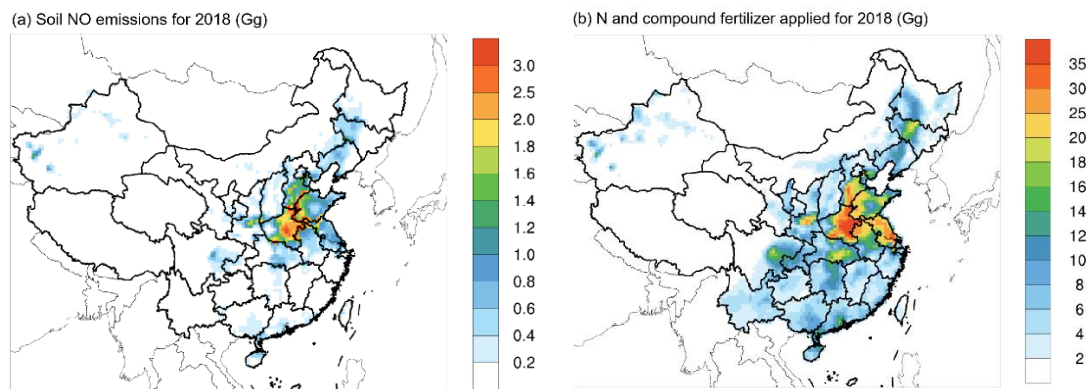

## 187 **3. Results and discussions**

### 188 3.1. Soil NO emissions for 2018 in China

#### 189 3.1.1. Spatial and temporal variations

190 National total soil NO emissions for 2018 is estimated to be 1157.9 Gg N, with an uncertainty  
191 range of 715.7~1902.6 Gg N, which will be discussed more in Section 3.1.2. On an annual scale,  
192 soil NO emissions accounted for 17.3% of the total anthropogenic NO<sub>x</sub> emissions in China for  
193 2017 (based on MEIC inventory). This ratio varies from 12.0% to 35.3% at regional scale.  
194 Unlike the anthropogenic NO<sub>x</sub> emissions that concentrate over densely populated regions (e.g.,  
195 NCP, YRD), soil NO emissions are most abundant in Central China, particularly Henan  
196 Province and nearby provinces, including Hebei and Shandong in the NCP, Jiangsu and Anhui  
197 in northern YRD (Fig. 2a). Other hotspots of soil NO emissions include Northeast China and  
198 the eastern part of the Sichuan Basin. As expected, the spatial distribution of soil NO emissions  
199 closely mirrors that of the fertilizer application (Fig. 2b). Henan (located in Central China),

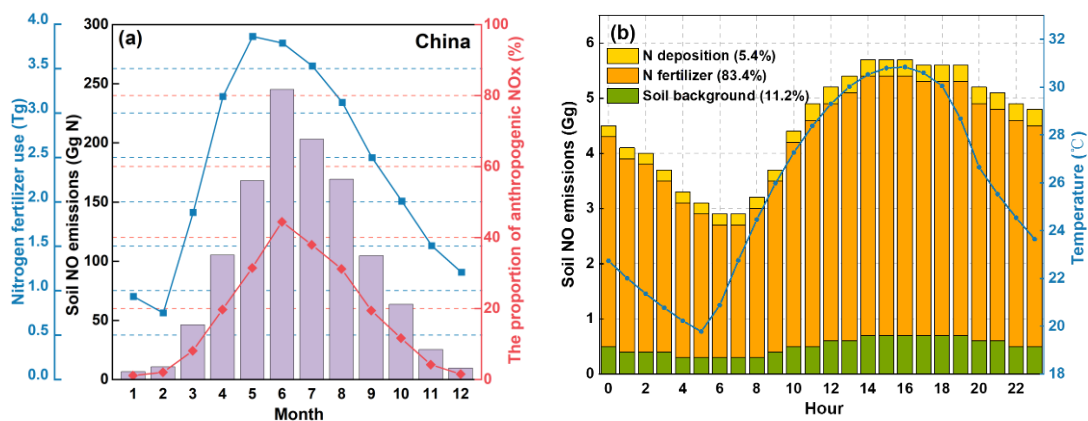

200 Shandong (NCP), and Hebei (NCP) are the top three provinces that have the highest fertilizer  
201 application (together accounting for 24.1% of national totals in 2018) and thus highest soil NO  
202 emissions (together accounting for 35.7%).

203 **Figure 2.** Spatial distribution of (a) soil NO emissions for 2018 and (b) N and compound  
204 fertilizer applied for 2018.

205 In terms of the monthly variations, the total soil NO emissions show a unimodal pattern (as  
206 shown in Fig. 3a with the highest emissions occurring in the summer months of June, July, and  
207 August), except for South China and Southeast China (Fig. S2), where the peak emissions occur  
208 in April or May. Soil NO emissions during the summer months account for 28.2% (South China)  
209 to 67.6% (Northeast China) of the annual totals (Fig. 1 and Table S5). The shape of monthly  
210 soil NO emissions is influenced by temperature and the timing of fertilizer application. The  
211 BDSNP algorithm assumes that 75% of the annual fertilizer is applied over the first month of  
212 the growing season, with the remaining 25% applied evenly throughout the rest of the growing  
213 season. This assumption results in a significant amount of fertilizer being applied from April to  
214 August (Fig. 3a). In contrast, anthropogenic NO<sub>x</sub> emissions display weaker monthly variations  
215 (Zheng et al., 2021). Consequently, the ratio of soil NO emissions to anthropogenic NO<sub>x</sub>  
216 (SN/AN) is much higher during the summer months. In regions such as Central China and  
217 Northwest China, where soil NO emissions are high and anthropogenic NO<sub>x</sub> emissions are  
218 relatively low, SN/AN reaches 74.0% and 67.5% during the summer months (Fig. 1 and Table  
219 S5). In East China and North China, where anthropogenic NO<sub>x</sub> emissions are high, SN/AN  
220 ranges from 26.8% to 36.5% during the summer months. These findings align with Chen et  
221 al. (2022), who reported that soil NO emissions made up 28% of total NO<sub>x</sub> (soil NO +  
222 anthropogenic NO<sub>x</sub>) emissions in summer and could reach 50–90% in isolated areas and  
223 suburbs. The substantial contribution of soil NO emissions during the ozone pollution season  
224 implies a potentially significant impact on surface ozone concentration. In terms of diurnal  
225 variations, soil NO emissions peak in the afternoon due to diurnal temperature fluctuations. As  
226 illustrated by Fig. 3b, the average hourly soil NO emissions over NCP for June 2018 closely  
227 follow the WRF simulated temperature changes.

228 The BDSNP algorithm identifies three sources of soil nitrogen: background, atmospheric  
 229 nitrogen deposition, and fertilizer application, with the latter being the primary contributor. A  
 230 decomposition analysis of soil NO emissions for NCP reveals that fertilizer application  
 231 accounts for 83.4% of total NO soil emissions (Fig. 3b), while background and atmospheric  
 232 nitrogen deposition only contribute for 11.2% and 5.4%, respectively. Thus, although soil NO  
 233 emissions are generally considered a “natural” source (Galbally et al., 2008) and are not  
 234 currently targeted in NO<sub>x</sub> emission mitigation strategies, human fertilizer activities render soil  
 235 NO emissions an anthropogenic source.

236 **Figure 3.** (a) Monthly fertilizer (N + compound) applied and soil NO emissions in China and  
 237 (b) hourly soil NO emissions for 2018 June in NCP and domain-averaged hourly 2-m  
 238 temperature simulated by WRF.

### 239 3.1.2. Limitations and Uncertainties associated with soil NO emission estimation

240 Although the current BDSNP algorithm is considered more sophisticated than the old YL95  
 241 algorithm, it still suffers certain limitations. For example, the current BDSNP parameterization  
 242 employs a static classification of “arid” versus “non-arid” soils, upon which the relationship  
 243 between soil NO emissions and soil moisture relies (Hudman et al., 2012). However, recent  
 244 studies (Sha et al., 2021; Huber et al., 2023) have shown more dynamic representation of this  
 245 classification is needed to capture the emission characteristics as observed by many chamber  
 246 and atmospheric studies (e.g., Oikawa et al. 2015; Huang et al. 2022a). Huber et al. (2023) also  
 247 showed that the emission estimated based on the static classification are very sensitive to the  
 248 soil moisture and thus could not produce self-consistent results when using different soil  
 249 moisture products.

250 In addition to the aforementioned limitation, the estimated soil NO emissions are also subjected  
 251 to certain limitations and large uncertainties. The first uncertainty comes from the amount of  
 252 fertilizer application, which has been identified as the dominant contributor to soil NO  
 253 emissions, as mentioned above. According to the global dataset (Potter et al., 2010), the amount  
 254 of fertilizer applied is 19.6 Tg, which is comparable to the sum of nitrogen fertilizer for 2018

255 (20.7 Tg) obtained from provincial statistical yearbooks. However, compound fertilizer, usually  
256 with a nitrogen, phosphorus, and potassium ratio of 15: 15: 15, has been used more in China.  
257 Since 2016, the amount of nitrogen fertilizer has been decreasing annually at an average rate of  
258 4.6%, while the amount of compound fertilizer has been increasing since 2010 at an average  
259 rate of 3.3%. The ratio of compound fertilizer to nitrogen fertilizer has increased from 76.4%  
260 in 2010 to 109.8% in 2018. Consequently, soil NO emissions may be largely underestimated if  
261 the compound fertilizer is not taken into account. Our calculation shows that if only nitrogen  
262 fertilizer is considered, the estimated total soil NO emissions are 805.2 Gg N/a for 2018, which  
263 is comparable to the value (770 Gg N/a averaged during 2008-2017) reported by Lu et al. (2021),  
264 but 30.5% lower than that based on both nitrogen fertilizer and compound fertilizer. Regionally,  
265 this underestimation ranges from 11.1%~41.5%, with a larger underestimation in Central China  
266 and East China (Fig. S3).

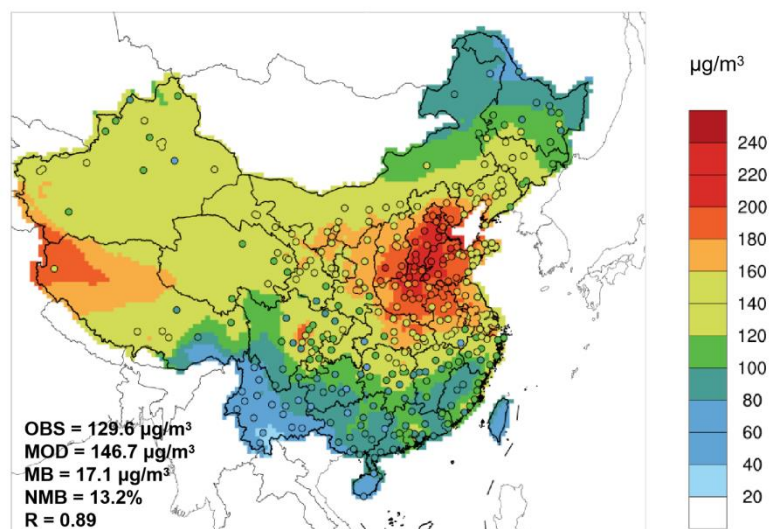

267 Another major uncertainty in estimating soil NO emissions is the temperature dependence  
268 factor  $f(T)$  in Eq.1. According to the BDSNP scheme, soil NO emissions increase exponentially  
269 with temperature between 0 and 30°C and reach a maximum when the temperature exceeds  
270 30°C. The default temperature dependence coefficient (i.e.,  $k$  in Eq. S2) follows the value used  
271 in the YL95 scheme, which is  $0.103 \pm 0.04$ . However, as shown by Table 3 in Yienger and Levy  
272 (1995), this value is the weighted average of values reported for different land types, which  
273 shows a wide range from 0.040 to 0.189. Even for the same crop type (e.g., corn), the value of  
274  $k$  could be quite different (0.130 vs. 0.066). We conducted a sensitivity analysis to examine the  
275 impact of varying the  $k$  value on estimated soil NO emissions. When the  $k$  value decreases or  
276 increases by 20%, the estimated total soil NO emissions change from 715.7 to 1902.6 Gg N/a,  
277 representing a relative difference of -38.2~64.3% deviation from the default value (1157.9 Gg  
278 N/a). Using the default  $k$  value would result in a large overestimation of simulated NO<sub>2</sub>  
279 concentrations over NCP and YRD and underestimation over Northeast China (Fig. S4).  
280 According to the total sown areas of farm crops reported in the provincial statistical yearbook,  
281 the primary crops grown in these regions are wheat and corn, which have a relatively low  $k$   
282 value (0.066~0.073). Therefore, we adjusted  $k$  for NCP (reduced by 20%), YRD (reduced by  
283 10%), and Northeast China (increased by 10%). CAMx simulation results show that this  
284 adjustment would not significantly affect the simulated MDA8 O<sub>3</sub> concentration but could  
285 reduce the NO<sub>2</sub> gap between observation and simulation (Fig. S4-S5). Therefore, we applied  
286 this adjustment to soil NO emissions in the following CAMx simulations.

## 287 3.2. Contribution of soil NO emissions to ground-level ozone

### 288 3.2.1. Base case model evaluation

289 Fig. 4 shows the monthly averaged MDA8 ozone concentration simulated for June 2018 with  
290 observed values presented on top. Overall the model well captured the spatial distribution of

291 MDA8 with a spatial correlation  $R = 0.89$ . Over the 365 cities in China, the simulated monthly  
 292 averaged MDA8 ozone concentration is  $146.7 \pm 36.1 \mu\text{g}/\text{m}^3$ , which is slightly higher than the  
 293 observed value of  $129.6 \pm 37.6 \mu\text{g}/\text{m}^3$  (NMB = 13.2%). Regionally, model shows better  
 294 performance in Northeast China (MB =  $2.4 \mu\text{g}/\text{m}^3$ , NMB = 1.9%) and NCP (MB =  $13.3 \mu\text{g}/\text{m}^3$ ,  
 295 NMB = 7.7%). Over-prediction is observed for Sichuan Basin and YRD (Table S6). Simulated  
 296 ozone concentration over the northwest Qinghai-Tibet Plateau was also much higher than  
 297 observed values. Our OSAT results (shown later) show that the high ozone concentration over  
 298 the Qinghai-Tibet Plateau is mostly contributed by the transport of boundary ozone, which  
 299 includes both horizontal and vertical (i.e., stratosphere) directions. For regions with high  
 300 altitude (e.g., the Qinghai-Tibet Plateau), vertical ozone intrusion from the stratosphere is most  
 301 substantial, which is consistent with the finding by Chen et al. (2023) that the boundary layer  
 302 height was identified as the most important feature for ozone over the Qinghai-Tibet Plateau.

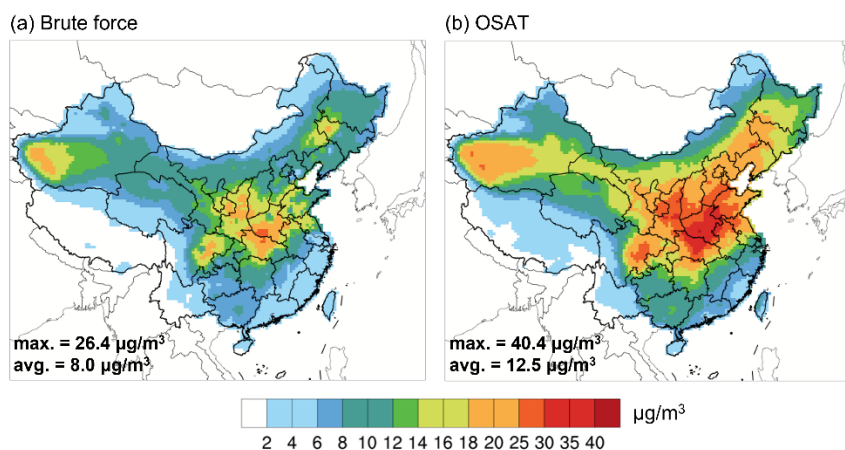

304 **Figure 4.** Comparison of simulated (base colors) and observed (scatter points) values of  
 305 MDA8 ozone in China in June 2018.

### 306 3.2.2. Impacts on regional ozone

307 To assess the contribution of soil NO emissions to surface ozone, both the brute-force method  
 308 (BFM) and the OSAT method were applied, and the results are shown in Fig. 5. Generally, the  
 309 two methods show consistent ozone contribution from soil NO emissions but with different  
 310 magnitudes. The BFM method shows widespread ozone enhancement due to soil NO emissions  
 311 with a spatial pattern that aligns with the distribution of soil NO emissions. Substantial ozone  
 312 enhancement is found over Central China, Sichuan Basin, northern YRD, and eastern Northeast  
 313 China. Maximum ozone enhancement ( $\Delta\text{MDA8}$ ) due to soil NO emissions is  $26.4 \mu\text{g}/\text{m}^3$  with  
 314 a domain-average value of  $8.0 \mu\text{g}/\text{m}^3$ . For selected key regions, the ozone contribution ranges  
 315 from low to high: PRD ( $3.8 \pm 1.1 \mu\text{g}/\text{m}^3$ ), YRD ( $8.7 \pm 4.7 \mu\text{g}/\text{m}^3$ ), Sichuan Basin ( $9.1 \pm 0.9$

316  $\mu\text{g}/\text{m}^3$ ), Northeast ( $9.3 \pm 3.0 \mu\text{g}/\text{m}^3$ ), and NCP ( $13.9 \pm 4.4 \mu\text{g}/\text{m}^3$ ), respectively. A similar spatial  
317 pattern is observed with the OSAT results, but the magnitudes are much higher. Maximum  
318 ozone contribution by soil NO emissions reaches  $40.4 \mu\text{g}/\text{m}^3$  according to OSAT results, which  
319 is 53.0% higher than the brute force method. The corresponding ozone contribution for each  
320 selected region is  $6.7 \pm 1.2 \mu\text{g}/\text{m}^3$  (PRD),  $13.5 \pm 7.4 \mu\text{g}/\text{m}^3$  (Sichuan Basin),  $14.5 \pm 4.9 \mu\text{g}/\text{m}^3$   
321 (Northeast China),  $16.2 \pm 7.8 \mu\text{g}/\text{m}^3$  (YRD) and  $25.7 \pm 5.3 \mu\text{g}/\text{m}^3$  (NCP). The scatter plots  
322 between BFM and OSAT results show good correlations (Fig. S6,  $R^2 = 0.78\sim 0.97$ ), with OSAT  
323 results higher by 10%~61%. For YRD, Sichuan Basin, and Northeast, the difference between  
324 the OSAT method and BFM increases with the absolute ozone concentration (Fig. S7), while  
325 NCP shows the opposite trend. The difference between the two methods reflects the nonlinear  
326 ozone response to NO<sub>x</sub> emissions. This nonlinearity becomes stronger in regions with larger  
327 NO<sub>x</sub> concentrations, especially where O<sub>3</sub> production is characterized as NO<sub>x</sub>-saturated (or  
328 VOC-limited), such as the NCP. In such cases, removing a portion of the NO emissions (e.g.,  
329 zeroing out soil NO for the BFM simulation) makes O<sub>3</sub> production from the remaining NO  
330 emissions more efficient, which lessens the O<sub>3</sub> response. As shown later in Figure 7a, the O<sub>3</sub>  
331 response for NCP is more curved (nonlinear) than other regions, consistent with NCP tending  
332 to have more NO<sub>x</sub>-saturated O<sub>3</sub> production. This nonlinear effect also explains smaller O<sub>3</sub>  
333 attribution to soil NO by the BFM than OSAT, especially over the NCP. Attributing a secondary  
334 pollutant to a primary emission (e.g., O<sub>3</sub> to NO) is inherently tricky with nonlinear chemistry,  
335 as Koo et al. (2009) discussed. Therefore, it is useful to present estimates from different  
336 methods. The Path Integral Method (PIM) is a source apportionment method that explicitly  
337 treats nonlinear responses with mathematical rigor (Dunker et al., 2015). However, applying  
338 the PIM is more costly than the BFM or OSAT.

339 In addition to soil NO contribution, OSAT also gives ozone contributions from other source  
340 groups, including anthropogenic emissions within China, boundary contribution, natural  
341 emissions (e.g., biogenic emissions, open biomass burning, lightning NO<sub>x</sub>), and emissions  
342 outside China. The spatial distribution for each source category is presented in Fig. S8, and the  
343 relative contribution for each selected region is shown in Fig. S9. Overall, boundary transport  
344 (56.5%) and anthropogenic emissions (24.0%) contribute most to MDA8 ozone for June 2018.  
345 Boundary contribution is high over the western and northern parts of China, while the  
346 contribution from anthropogenic emissions is substantial over eastern China, where  
347 anthropogenic emissions are extensive. On a national scale, soil NO emissions exhibit a relative  
348 ozone contribution of 9.1%, and regionally this value ranges from 6.1% in PRD to 13.8% in  
349 NCP.

350  
 351 **Figure 5.** Ozone contribution from soil NO emissions based on (a) brute force method and (b)  
 352 OSAT method.

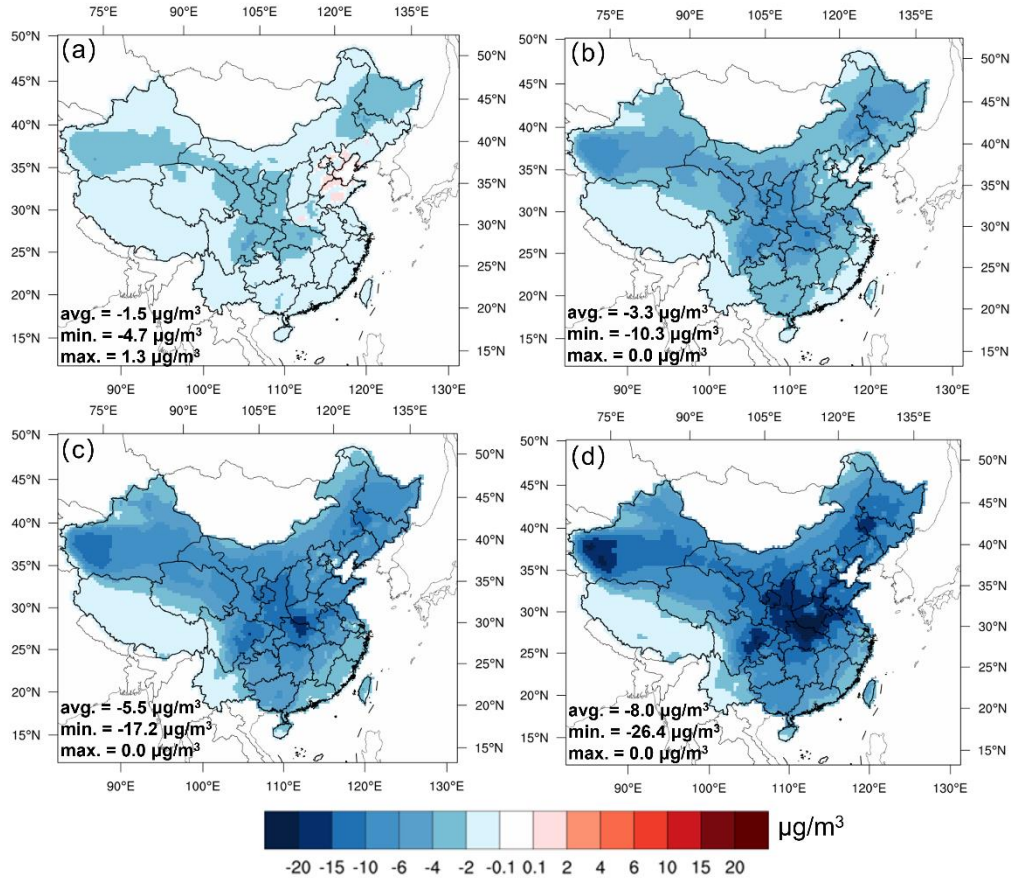

353 We further evaluated the impact of soil NO emissions on the number of ozone exceedances  
 354 days (i.e., days with MDA8 O<sub>3</sub> higher than 160 µg/m<sup>3</sup>) during June 2018 based on the relative  
 355 response factor (RRF) method and results from the brute force method. The total number of  
 356 ozone exceedances days during June 2018 for the five selected regions ranged from 50 days in  
 357 PRD to 985 days in NCP (Table 1). The number of ozone exceedance days per city ranged from  
 358 3.1 days in Sichuan Basin to 18.2 days in NCP, suggesting the severe ozone pollution in June  
 359 2018 over NCP. RRF was first calculated for each city as the ratio of simulated ozone  
 360 concentration between the base case and the case with soil NO emissions excluded and applied  
 361 to the observed ozone concentrations to obtain adjusted ozone concentrations without soil NO  
 362 emissions. Soil NO emissions are estimated to lead to 121 ozone exceedance days in NCP,  
 363 followed by 84 days in the Northeast and 70 days in YRD, corresponding to a percent change  
 364 of 12.3%, 32.8%, and 10.5%, respectively. In Sichuan Basin, where soil NO emissions are also  
 365 substantial, soil NO emissions contribute 30 ozone exceedances days, which accounts for 43.5%  
 366 of the total ozone exceedances days. These results suggest the substantial contribution of soil  
 367 NO emissions to the number of ozone pollution days over regions with high soil NO emissions.

368 **Table 1.** Number of ozone exceedances over selected regions during June 2018.

Region (No. of cities)	Number of ozone exceedance days (% of total days)	Δozone exceedances days when soil NO emissions are removed	% of total ozone exceedances days
NCP (54)	985 (60.8%)	-121	-12.3%
YRD (55)	666 (41.1%)	-70	-10.5%
PRD (9)	50 (18.5%)	-6	-12.0%
Sichuan Basin (22)	69 (10.5%)	-30	-43.5%
Northeast (37)	256 (23.1%)	-84	-32.8%

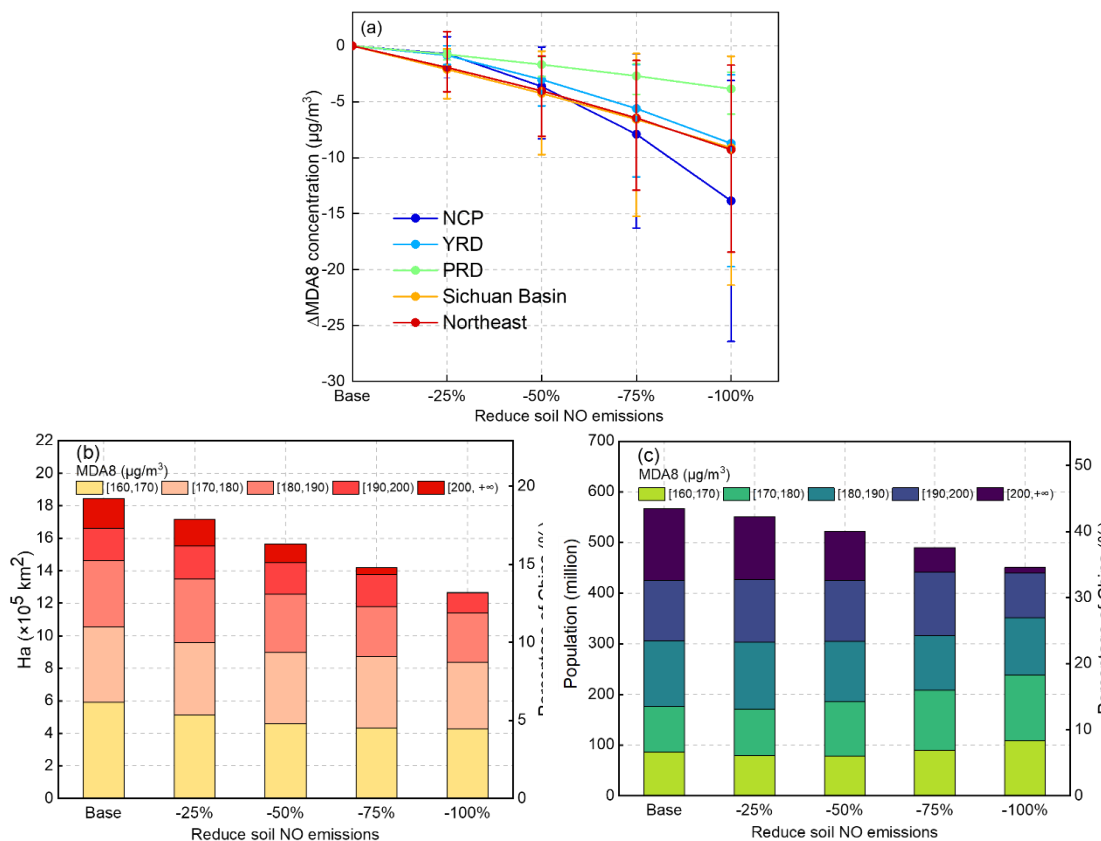

### 369 3.3. Ozone responses to reductions in soil NO emissions

370 Current NO<sub>x</sub> emission control policies primarily target combustion sources, such as power  
371 plants (Du et al., 2021) and on-road vehicles (Park et al., 2021). Nitrification inhibitors, such  
372 as dicyandiamide (DCD, C<sub>2</sub>H<sub>4</sub>N<sub>4</sub>), have been found to be effective in reducing nitrogen loss,  
373 thereby reducing NO emissions from soil (Abalos et al., 2014). Studies have shown that using  
374 5% DCD with nitrogen fertilizer can reduce NO emissions by up to 70% (Xue et al., 2022). In  
375 light of this, it is important to evaluate the impact of reduced soil NO emissions on ozone  
376 concentration. To address this question, four sensitivity simulations were carried out for June  
377 2018, with soil NO emissions reduced by 25%, 50%, 75%, and 100% relative to the base case.  
378 As shown by Fig. 6, reducing soil NO emissions led to a general decrease in monthly MDA8  
379 ozone concentration ( $\Delta$ MDA8), with the magnitude of  $\Delta$ MDA8 becoming more significant  
380 with the reduction ratio. With a 25% reduction in soil NO emissions, there was a widespread  
381 small decrease in monthly average MDA8 ozone concentration ( $\Delta$ MDA8:  $-1.5 \pm 0.9 \mu\text{g}/\text{m}^3$ ),  
382 except over NCP where ozone showed a slight increase (up to  $1.3 \mu\text{g}/\text{m}^3$ ) in Shandong and  
383 Henan province. When soil NO emissions were cut by 50%,  $\Delta$ MDA8 showed a ubiquitous  
384 decrease across entire China with an average  $\Delta$ MDA8 of  $-5.5 \mu\text{g}/\text{m}^3$ . When soil NO emissions  
385 were removed entirely, the maximum  $\Delta$ MDA8 could exceed  $25 \mu\text{g}/\text{m}^3$  over central China, part  
386 of the Sichuan Basin, Northeast China, and Northeast China. Regions with strong ozone  
387 responses generally aligned with regions that also had high soil NO emissions. However, it  
388 should be noted that the ozone response to soil NO reductions not only depends on the  
389 magnitude of soil NO emissions but is also affected by (1) the local ozone formation regime  
390 that is further determined by the relative abundance of NO<sub>x</sub> and VOCs, and (2) changes in  
391 transport of upwind ozone.

392  
 393 **Figure 6.** Spatial distribution of  $\Delta\text{MDA8}$  under (a) 25%, (b) 50%, (c) 75%, and (d) 100%  
 394 reductions of soil NO emissions in June 2018.

395 Fig. 7a provides further details on the domain-averaged  $\Delta\text{MDA8}$  under different reduction scenarios  
 396 for the five key regions. As expected, the ozone response in each region increased as the reduction  
 397 in the soil NO emissions increased. NCP exhibited the strongest ozone responses to changes in soil  
 398 NO emissions, with  $\Delta\text{MDA8}$  increasing from  $-0.7 \pm 0.8 \mu\text{g}/\text{m}^3$  with 25% reductions to  $-13.9 \pm 4.4$   
 399  $\mu\text{g}/\text{m}^3$  when all soil NO emissions were removed. YRD, Sichuan Basin, and Northeast China exhibit  
 400 similar ozone responses when soil NO emissions are reduced. Under the 25% scenario,  $\Delta\text{MDA8}$   
 401 ranged from -4.7 to  $1.3 \mu\text{g}/\text{m}^3$  for these three regions; with 100% soil NO reductions,  $\Delta\text{MDA8}$   
 402 ranged from -21.4 to  $-0.9 \mu\text{g}/\text{m}^3$ .  $\Delta\text{MDA8}$  in PRD was relatively small. Even with a 100% reduction,  
 403 the average  $\Delta\text{MDA8}$  in PRD was less than  $5 \mu\text{g}/\text{m}^3$ , which is associated with the small soil NO  
 404 emissions in PRD. It is interesting to note that all regions except NCP exhibited an approximate  
 405 linear ozone response to changes in soil NO emission reductions. NCP showed more significant  
 406 ozone reductions as the reduction ratio increased, suggesting that NCP would gain more benefits  
 407 with more aggressive reductions in soil NO emissions compared to other regions.

408 **Figure 7.** (a)  $\Delta$ MDA8 concentrations in five key regions under different emission reduction  
 409 scenarios (b) Area and (c) population exposed to different ozone levels under different soil  
 410 NO emission reduction scenarios.

411 We evaluated the impact of different soil NO emission reduction scenarios on the area and  
 412 population exposed to varying ozone levels. The results, presented in Fig. 7b and 7c, revealed  
 413 a decrease in coverage and exposed population under high ozone concentrations as soil NO  
 414 emissions decrease. The data presented in the plots are for grid cells with monthly MDA8 ozone  
 415 concentrations exceeding  $160 \mu\text{g}/\text{m}^3$ . In the Base scenario, the estimated coverage of MDA8  
 416 ozone exceeding  $160 \mu\text{g}/\text{m}^3$  was  $1.84 \times 10^6 \text{ km}^2$ , equivalent to 19.2% of the national land area.  
 417 The population exposed to ozone concentrations exceeding  $160 \mu\text{g}/\text{m}^3$  amounts to 566.6 million,  
 418 representing 43.4% of the entire population. The areas with extremely high ozone  
 419 concentrations ( $\text{MDA8} > 200 \mu\text{g}/\text{m}^3$ ) account for 1.9% of the national land area, with a  
 420 corresponding exposed population of 10.9%, indicating that densely populated areas experience  
 421 higher ozone concentrations. When soil NO emissions are halved, there is a 15.2% reduction in  
 422 the coverage of non-attainment areas and an 8.0% reduction in the total exposed population. If  
 423 soil NO emissions are eliminated, the total area coverage and population exposed to MDA8  
 424 ozone concentrations exceeding  $160 \mu\text{g}/\text{m}^3$  would be  $1.27 \times 10^6 \text{ km}^2$  and 450.3 million,  
 425 respectively, representing 13.2% and 34.5% of the total. Compared to the Base scenario, a 100%  
 426 theoretical reduction in soil NO emissions leads to a 31.3% and 20.5% reduction in the exposed

427 area and population under high ozone concentration, respectively, indicating substantial health  
428 benefits gained when soil NO emissions are mitigated.

429 Fig. S10-S11 displays similar area and population plots for selected key regions. The overall  
430 trends for each sub-region are consistent. With 100% reductions in soil NO emissions, the area  
431 with high ozone concentration decreased by 17.8%, 22.3%, 65.4%, and 100% for NCP, YRD,  
432 Sichuan Basin, and Northeast. The corresponding values for the exposed population are 91.4%,  
433 60.3%, 9.8%, and 0.0%. While the relative change is more significant in Sichuan Basin and  
434 Northeast China, NCP and YRD gain more health benefits due to the significantly higher total  
435 population for these two regions. However, it is worth noting that even with the complete  
436 elimination of soil NO emissions, a total of 450.3 million people are still exposed to ozone  
437 levels exceeding the national standard, necessitating multiple control policies at the same time,  
438 such as synergistic control of anthropogenic VOC emissions (Chen et al., 2022; Ding et al.,  
439 2021).

#### 440 3.4 Comparison with existing studies

441 The soil NO emissions estimated in this study were also compared with values reported by  
442 existing studies based on either field measurement or model estimation (Table S7). Previous  
443 studies report a wide range of soil NO emissions from 480 to 1375 Gg N and soil NO flux  
444 ranging from 10 to 47.5 ng N m<sup>-2</sup> s<sup>-1</sup>. The soil NO emissions estimated in our study are 1157.9  
445 Gg N with the default *k* value and 951.9 Gg N with region-adjusted *k* value, which falls within  
446 the upper range of previously reported values. The averaged soil NO flux over NCP in June  
447 2018 estimated in our study is 35.4 ng N m<sup>-2</sup> s<sup>-1</sup>, which is within the range reported by previous  
448 studies (12.9~40.0 ng N m<sup>-2</sup> s<sup>-1</sup>).

449 The simulated ozone contribution by soil NO emissions is compared with other studies. In  
450 California, soil NO was estimated to cause a 23.0% increase in surface O<sub>3</sub> concentrations (Sha  
451 et al., 2021). Constrained by satellite measured NO<sub>2</sub> column densities, Wang et al. (2022b)  
452 reported MDA8 ozone contribution of 9.0 μg/m<sup>3</sup> (relative contribution of 5.4%) from cropland  
453 NO<sub>x</sub> emissions over NCP during a growing season in 2020. Lu et al. (2021) showed an  
454 interactional effect of domestic anthropogenic emissions with soil NO emissions of 9.5 ppb in  
455 the NCP during July 2017. In addition, soil NO<sub>x</sub> emissions strongly affect the sensitivity of  
456 ozone concentrations to anthropogenic sources in the NCP. In a most recent study by Shen et  
457 al. (2023), addition of the soil NO<sub>x</sub> emissions was shown to result in up to 15 ppb increase of  
458 ozone concentration over Xinjiang, Tibet, Inner Mongolia, and Heilongjiang, although a minor  
459 reduction was evident over the Yangtze River basin. When soil NO<sub>x</sub> emissions were reduced  
460 by 30%, ozone concentrations increased by 3-5 ppb over Inner Mongolia, Heilongjiang,  
461 Xinjiang, and Tibet, while decreased by 0-2 ppb over the Yangtze River basin. Surprisingly,  
462 when soil NO<sub>x</sub> emissions were increased by 30%, nearly identical ozone responses were

463 observed.

#### 464 **4. Conclusions**

465 Soil NO emissions are non-negligible NO<sub>x</sub> sources, particularly during summer. The  
466 importance of soil NO emissions to ground-level ozone concentration in China is much less  
467 evaluated than combustion NO<sub>x</sub> emissions. In this study, the total national soil NO emissions  
468 were estimated to be 1157.9 Gg N in 2018, with a spatial distribution closely following that of  
469 fertilizer application. High soil NO emissions were mainly concentrated over Henan, Shandong,  
470 and Hebei provinces, which differs from anthropogenic NO<sub>x</sub> emissions. Distinct diurnal and  
471 seasonal variations in soil NO emissions were simulated, mainly driven by the changes in  
472 temperature as well as the timing of fertilizer application. Uncertainty analysis reveals a range  
473 of 715.7~1902.6 Gg N of soil NO emissions that warrant further constraints from observations.  
474 Using two methods (BFM and OSAT), we evaluated the contribution of soil NO emissions to  
475 ground-level ozone concentration for June 2018. Both methods suggest a substantial  
476 contribution of soil NO emissions to MDA8 ozone concentrations by 8~12.5 µg/m<sup>3</sup> on average  
477 for June 2018, with the OSAT results consistently higher than BFM. Soil NO emissions were  
478 shown to lead to a relative increase of ozone exceedances days by 10.0%~43.5% for selected  
479 regions. Reducing soil NO emissions could generally reduce the ground-level ozone  
480 concentrations and populations exposed to unhealthy ozone levels (MDA8 > 160 µg/m<sup>3</sup>),  
481 especially over NCP and YRD. With a 50% reduction in soil NO emissions, the coverage of  
482 non-attainment areas and the population exposed to unhealthy ozone levels decreased by 15.2%  
483 and 8.0%, respectively. However, even with the complete removal of soil NO emissions,  
484 approximately 450.3 million populations are still exposed to unhealthy ozone levels,  
485 necessitating multiple control policies at the same time, such as synergistic control of  
486 anthropogenic VOC emissions.
