Abstract. The Mt. Samalas eruption, thought to have occurred in Summer 1257, ranks as one of the most explosive sulfur-rich eruptions of the Common Era. Despite recent convergence, several dates have been proposed for the eruption ranging between 1256-1258, with as of yet, no single combination of evidence has been able to robustly distinguish between, and exclude the other dates proposed for the Mt Samalas eruption. Widespread surface cooling and hydroclimate perturbations following the eruption have been invoked as contributing to a host of 13th Century social and economic crises, although regional scale variability in the post-eruption climate response remains uncertain. In this study we run ensemble simulations using the UK Earth System Model (UKESM1) with a range of eruption scenarios and initial conditions in order to compare our simulations with the most complete globally resolved multi-proxy database for the Mt. Samalas eruption to date, incorporating tree-rings, ice cores, and historical records. This allows more-precise constraints to be placed on the year and season of the Mt. Samalas eruption as well as an investigation into the regionally heterogeneous post-eruption climate response. Using a multi-proxy to model comparison, we are able to robustly distinguish between July 1257 and January 1258 eruption scenarios where the July 1257 ensemble simulation achieves considerably better agreement with spatially averaged and regionally resolved proxy surface temperature reconstructions. These reconstructions suggest the onset of significant cooling across Asia and Europe in 1258, and thus support the plausibility of previously inferred historical connections. Model-simulated temperature anomalies also point to severe surface cooling across the Southern Hemisphere with as of yet unexplored historical implications for impacted civilizations. Model simulations of polar sulfate deposition also reveal distinct differences in the timing of ice sheet deposition between the two simulated eruption dates, although comparison of the magnitude or asymmetric deposition of sulfate aerosol remains limited by large inter-model differences and complex intra-model dependencies. Overall, the multi-proxy to model comparison employed in this study has strong potential in constraining similar uncertainties in eruption source parameters for other historical eruptions where sufficient coincident proxy records are available, although care is needed to avoid the pitfalls of model-multi proxy comparison.

34 **1 Introduction**

35 The Mt. Samalas eruption, which occurred on the Indonesian Island of Lombok between 1257 and 1258, is identified in ice
36 cores as one of the largest volcanic sulfate deposition events of the last 2500 years (Palais et al., 1992, Zielinski et al., 1994,
37 Sigl et al., 2015). Petrological analysis suggests a release of ~120Tg of sulfur dioxide (SO₂) into the stratosphere, with a
38 maximum estimated plume height of 43 km and volcanic explosivity index (VEI) of 7, meaning the eruption ranks as one of
39 the most-explosive sulfur-rich eruptions of the Common Era (Lavigne et al., 2013, Vidal et al., 2015, Toohey and Sigl, 2017).
40 Tree-ring reconstructions suggest a peak Northern Hemisphere (NH) average summer cooling of -0.8°C to -1.2°C between
41 Summer 1258 and 1259 (Schneider et al., 2015, Guillet et al., 2017, Wilson et al., 2016, Büntgen et al., 2022). The surface air
42 temperature (SAT) anomalies and potential hydroclimate perturbations induced by the eruption have been invoked by
43 historians as contributing factors to a host of 13th Century social and economic crises (Campbell, 2017, Malawani et al., 2022,
44 Guillet et al., 2017, Bierstedt, 2019, Stothers 2000, Green 2020, Di Cosmo et al., 2021).

45

46 The full span of dates proposed for the Mt Samalas eruption ranges from 1256 to 1258, with suggestions including an eruption
47 in spring 1256 (Bauch, 2019), summer 1257 (Lavigne et al., 2013, Oppenheimer 2003), and early 1258 (Stothers 2000). Whilst
48 consensus has converged on a summer 1257 eruption date, as of yet, no single combination of evidence has been able to
49 robustly distinguish between, and exclude the other dates proposed for the Mt Samalas eruption. The suggestion of Spring
50 1256 was based on historical evidence for a dust veil over Asia and the Middle East in late 1256 and early 1257 (Bauch, 2019).
51 This is more likely attributed to a smaller eruption such as the 1256 Medina eruption which had only localized impacts (Saliba,
52 2017). A mid-1257 eruption date was first proposed by Oppenheimer (2003) based on the spatial distribution of negative
53 temperature anomalies across both hemispheres for 1257-59. Radiocarbon dating of the pyroclastic flow deposits associated
54 with the eruption also yield a youngest eruption age boundary of 1257, with some samples being older, but no samples being
55 younger than 1257 (Lavigne et al., 2013). Based on the westerly displacement of ash isopachs, Lavigne et al., (2013) proposed
56 that easterly winds prevailed at the time of the eruption, indicative of the eruption occurring during the May-Oct dry season.
57 Negative tree-ring width (TRW) growth anomalies in the late 1257-growth season (Büntgen et al., 2022) and frost rings (Salzer
58 and Hughes, 2007) in the Western US in 1257 and 1259 also add support for a potential eruption date prior to August 1257.
59 Modelling studies for the Mt. Samalas eruption have achieved best agreement with tree-ring reconstructions for a May-July
60 eruption window (Stoffel et al., 2015). Nonetheless, Stothers (2000) suggests a later eruption date of early 1258 based on peak
61 sulfate deposition for the Mt. Samalas eruption occurring in 1259 (from Hammer et al., 1980) and the first historical reports
62 of a dust veil over Europe appearing in Summer 1258, which they suggest is most compatible with an early 1258 eruption.
63 Therefore, there is still a need to constrain the year and season of the eruption with greater certainty, with implications for
64 evaluating the robustness of inferred connections to synchronous historical events, as well as in the role of the eruption sulfate
65 deposition spike as a key temporal calibration marker in ice core records.

66

67 The regionally heterogeneous climate response to the Mt. Samalas eruption also remains largely unconstrained at a global
68 level. Guillet et al., (2017) utilized a wealth of historical records and tree-ring chronologies to assess the impact of the eruption
69 across the NH, with particular focus on the climate response to the eruption revealed by historical sources in Western Europe.
70 Medieval chronicles point to abnormal weather conditions in Summer 1258, with economic records highlighting delayed and
71 poor harvests which likely aggravated ongoing grain shortages. Stothers (2000) suggested that frequently cold and rainy
72 weather lead to widespread crop damage and famine, also noting the outbreak of plague across Europe and the Middle East in
73 1258-59. Suggestions that the Samalas eruption can be linked to the initiation of the “Big Bang” diversification event which
74 led to the Branch 1 strain of *Yersinia pestis* responsible for the Black Death in Europe (Fell et al., 2020) have recently been
75 refuted, with consensus forming instead that this plague proliferation event can be traced to the Tian Shan region much earlier
76 in the 13th century (Green, 2020, Green, 2022). Nonetheless, connections have still been drawn between the anomalous climatic
77 conditions following the eruption and the fall of Bagdad to the Mongol empire in 1258, as well as the subsequent defeat of the
78 Mongol Army at the battle of Ayn Jālūt in 1260 which marked the collapse of the Mongol westward advance (Green, 2020,
79 Di Cosmo et al., 2021). Without a comprehensive understanding of the extent and chronology of climate response to the
80 eruption on a regional scale, the robustness of these inferred connections between post-eruption climate response and historical
81 events remains difficult to constrain.

82

83 The magnitude and spatial distribution of the post-eruption climate response following large volcanic eruptions is known to
84 show a strong seasonal dependency (Stevenson et al., 2017, Toohey et al., 2011). Asymmetric cooling between hemispheres
85 occurs due to seasonal variation in Brewer-Dobson circulation which modulates hemispheric aerosol distribution (e.g., Toohey
86 et al., 2011). Asymmetric aerosol distribution combined with enhanced land-albedo feedbacks during NH winter can therefore
87 increase the magnitude of temperature anomalies between hemispheres (Stevenson et al., 2017). Hemispheric temperature
88 contrasts can subsequently drive latitudinal shifts in the Inter-Tropical Convergence Zone (ITCZ), an equatorial band of
89 enhanced rainfall and lower pressure, away from the hemisphere of greatest cooling resulting in hydroclimate perturbations
90 (Broccoli et al., 2006). Therefore, depending on if the Mt. Samalas eruption occurred in Summer 1257 or in early 1258,
91 differences in the magnitude and spatial distribution of resulting SAT and precipitation anomalies are expected.

92

93 In this study we utilize a multi-proxy to model comparison to place more precise constraints on the year and season of the Mt.
94 Samalas eruption, tested across the whole window of proposed eruption dates. We utilize both model and proxy constraints to
95 assess regionally heterogeneous impacts of the Mt. Samalas eruption, with reference to proposed historical consequences. Van
96 Dijk et al., 2023 demonstrated the effectiveness of this model multi-proxy approach in their investigation of the regional
97 climatic and social consequences in Scandinavia following the 536/540 CE double eruption event, including incorporating
98 additional archaeological evidence. UK Earth System Model (UKESM1) simulations were run across January and July
99 eruption scenarios and a globally resolved database of proxy records was collated consisting of tree-ring chronologies,
100 historical sources, and ice core records (Supplementary Sheet 1). Our study demonstrates the ability of a multi-proxy to model

101 comparison to more precisely constrain the date of the Mt. Samalas eruption, where previous studies have tended to utilize
102 only a single-proxy approach (Stothers, 2000, Bauch, 2019, Büntgen et al., 2022, Stoffel et al., 2015). The multi-proxy to
103 model comparison employed in this study is shown to have significant potential in constraining similar uncertainties in eruption
104 source parameters for other historical eruptions where sufficient coincident proxy records are available.
105

106 **2 Methods**

107 **2.1 Model Simulations Using the UK Earth System Model (UKESM)**

108 The state-of-the-art interactive aerosol-climate model UKESM1 (Sellar et al., 2019) was used, consisting of the physical global
109 climate model HadGEM3-GC3.1 with additional configurations for terrestrial and marine biogeochemistry, land and ocean
110 physics, ocean-sea ice, and dynamic terrestrial vegetation. The model also includes the UK Chemistry and Aerosol (UKCA)
111 interactive stratospheric-tropospheric chemistry and aerosol schemes (Archibald et al., 2020, Mulcahy et al., 2020). The full
112 life cycle of stratospheric sulfur and sulfate aerosol particles is included, from injection of SO₂, oxidation, particle formation
113 and subsequent growth, to sedimentation and removal.
114

115 The model has a horizontal atmospheric resolution of 1.875° by 1.25° and a 1° by 1° resolution in the ocean, giving a vertical
116 resolution of 85 levels in the atmosphere and 75 levels in the ocean. This results in well-resolved ocean and atmosphere
117 dynamics and an internally generated Quasi-Biennial Oscillation (QBO). Coupled ocean-atmosphere simulations were run
118 with greenhouse gases set to a representative pre-industrial (AD 1850) background state. The difference between a
119 preindustrial and bespoke 13th century background state is small compared to model internal variability and thus does not
120 represent a significant limitation of the approach.
121

122 Eighteen UKESM eruption-perturbed ensemble simulations were run, with nine simulating a January eruption (JAN1258) and
123 nine a July eruption (JUL1257), where January and July are winter/summer representatives. Given the preindustrial
124 background the January/July ensemble groupings are not constrained to a specific year and therefore the two ensemble
125 groupings have been used to assess the full range of dates proposed for the Mt. Samalas eruption between the years 1256 and
126 1258. The ensembles sample a range of initial conditions, with the starting phase of both QBO and the El Niño Southern
127 Oscillation (ENSO) varying between ensembles. For full details of ensemble initial condition classification see Supplementary
128 Document Table S1. Across the eighteen ensembles only the eruption season and initial conditions were varied, with all other
129 eruption source parameters held constant and as listed in Table 1.
130

131 119 Tg of SO₂ was taken from the updated database of VSSI estimates (eVolv2k; Toohey and Sigl, 2017), which is within
132 error of the 126 +/- 9.6 Tg estimated by Vidal et al. (2016). In our simulations, the injection height is set at 18-20 km to be

133 consistent with the 1991 Mt. Pinatubo eruption and to allow for lofting of aerosol to higher altitudes in the stratosphere. This
134 height is lower than the estimated 38-40 km column heights (Lavigne et al., 2013, Vidal et al., 2015) however, those column
135 heights refer to the maximum altitude of tephra and ash rather than the height of sulfur injection in the stratosphere or the
136 maximum altitude of the SO₂ plume. A 24-hr eruption duration agrees well with Lavigne et al., (2013) who estimated the
137 eruption duration to be 23.8 +/- 10.3 hrs.

138
139 An equivalent control ensemble, with identical starting conditions but no eruption perturbation, was run for each of the
140 individual eruption-perturbed ensemble simulations. Anomalies were calculated with respect to a climatological background
141 constructed from the control ensemble mean.

142

143 **Table 1: Eruption Source Parameter values used in the ensemble simulations.**

Eruption Source Parameter	Ensemble Value
Volcanic stratospheric sulfur injection (VSSI)	119 Tg of SO ₂
Injection Height	18-20 km
Duration	24hrs
Latitude	8°S (Single Grid Box)

144 **2.2 Multi-Proxy Database of Surface Temperature Impacts**

145 The proxy database (See Supplementary Sheets 1 and 2 for full details) was constructed by compiling records indicative of
146 changes to climate (tree-ring chronologies, ice core records, and historical sources) that span the range of dates proposed for
147 the eruption with a minimum of annual resolution. Whilst the aim was to create a global database of proxy records, this was
148 significantly impeded by the limited global distribution of all types of proxy records, which show a strong bias to the NH,
149 European, and North American localities. No suitable data was found for this study from Africa or South America.

150 **2.2.1 Tree-Ring Chronologies**

151 We include 24 region-specific tree-ring studies, distributed predominantly across the NH, although two studies from Australia
152 and New Zealand are included. The parameter used for temperature reconstruction varies between studies, as does the tree
153 species analysed and season of reconstruction depending on study location (see Supplementary Sheet 1 for details). SAT
154 anomalies for 1258 and 1259 were taken either directly from the referenced study or calculated from reconstructed SAT

155 anomalies using a background climatology which was constructed from the 10-year average prior to the eruption. Where
156 studies reported that frost rings were present, they have also been included in the database.

157

158 In addition to the 24 region-specific studies, four NH spatially averaged reconstructions have also been incorporated (Wilson
159 et al., 2016, Schneider et al., 2015, Büntgen et al., 2021, Guillet et al., 2017), along with the N-TREND reconstruction which
160 is spatially resolved for the NH (Anchukaitis et al., 2017, see figure S3 for the spatial distribution of records used in the
161 NTREND reconstruction). For consistency in this study all tree-ring-reconstructed SAT anomalies are calculated from the 10-
162 year average prior to 1257.

163 **2.2.2 Ice Core Records**

164 We include six $\delta^{18}\text{O}$ isotope series ice core records from Greenland and Antarctica, where records were chosen on the basis of
165 both annual resolution and an age dating precision of +/- 1 year. Linear regression analysis was applied to calibrate the series
166 to JJA gridded temperature anomalies (with respect to 1990-1960) from the BEST dataset (). An additional SAT constraint is
167 also included in Greenland for Summer 1258 from analysis by Guillet et al., (2017) who utilised three Greenland ice cores at
168 GRIP, CRETE, and DYE3 (Vinther et al., 2010) to calculate a clustered SAT anomaly for the region. Additional ice core
169 records were investigated to expand this analysis such as the Illimani Ice Core in Bolivia and the Belukha Ice Core in Altai,
170 Siberia; however, these records lacked the annual resolution required to constrain abrupt temperature changes associated with
171 volcanic eruptions and/or the age dating precision to clearly identify signatures from the Samalas eruption.

172 **2.2.3 Historical Sources**

173 Historical sources consist predominantly of medieval chronicles which refer to abnormal and/or extreme weather events in the
174 years 1258-59. Analysis of medieval chronicles and economic records for the years 1258-59 by Guillet et al., (2017) form the
175 basis of historical constraints in Europe. Additional chronicles include references from the Russian Annals in the Altai
176 Mountains (Borisenkov and Pasetsky, 1988, Guillet et al., 2017), the Chronicle of Novgorod from Central Russia (Stothers,
177 2000), the Þorgils Saga Skarða in Iceland (Bierstedt, 2019), and Azuma Kagami from Japan (Farris, 2006). References to
178 abnormally dark lunar eclipses are also included from the Chronicle of the Abbey of St. Edmunds (Stothers, 2000) and the
179 Annales Ianuenses (Guillet et al., 2017). Additional historical sources across Europe, as well as some from the Middle East,
180 report plague, famine, and economic crises for 1258-60 (Stothers, 2000). These sources have not been incorporated into the
181 database as they refer to social and economic disturbances rather than making direct references to abnormal climatological
182 phenomena.

183 **2.3 Simulated SAT Anomalies**

184 **2.3.1 Northern Hemisphere Average**

185 Spatially averaged NH summer land SAT anomalies were calculated for the mean of the nine JUL1257 and JAN1258
186 ensembles respectively. Constraints were applied to model-simulated surface temperature outputs to make them most
187 comparable to tree-ring reconstructions (Latitudes of 40°N-75°N, land only, June-July-August (JJA) was taken as
188 representative of the growth season.) Using four NH spatially averaged tree-ring chronologies (Wilson et al., 2016, Schneider
189 et al., 2015, Büntgen et al., 2021, Guillet et al., 2017 – see Supplementary Document, Figure S1 for individual chronology
190 comparison) a mean NH summer SAT anomaly time series was also calculated to which the model-simulated anomalies are
191 compared.

192 **2.3.2 Spatially Resolved Comparison**

193 Spatially resolved model-simulated summer (JJA) SAT anomalies were calculated globally and for the NH between 1258-
194 1259. This time window was chosen because the JUL1257 and JAN1258 ensemble simulations show the greatest divergence
195 in SAT anomalies for Summers 1258-59. Model-simulated NH SAT anomalies were re-gridded and masked to facilitate more
196 direct comparison with the N-TREND dataset (Anchukaitis et al., 2017). An analysis of variance (ANOVA) test was performed
197 by eruption season to determine at which grid points the variance in means between the 1258 and 1259 perturbed ensembles
198 exceeded 95% significance relative to the control ensemble simulations, where the null hypothesis was that there was no
199 difference between the mean grid point anomalies for the perturbed 1258 and 1259 ensembles compared to the control
200 ensemble.

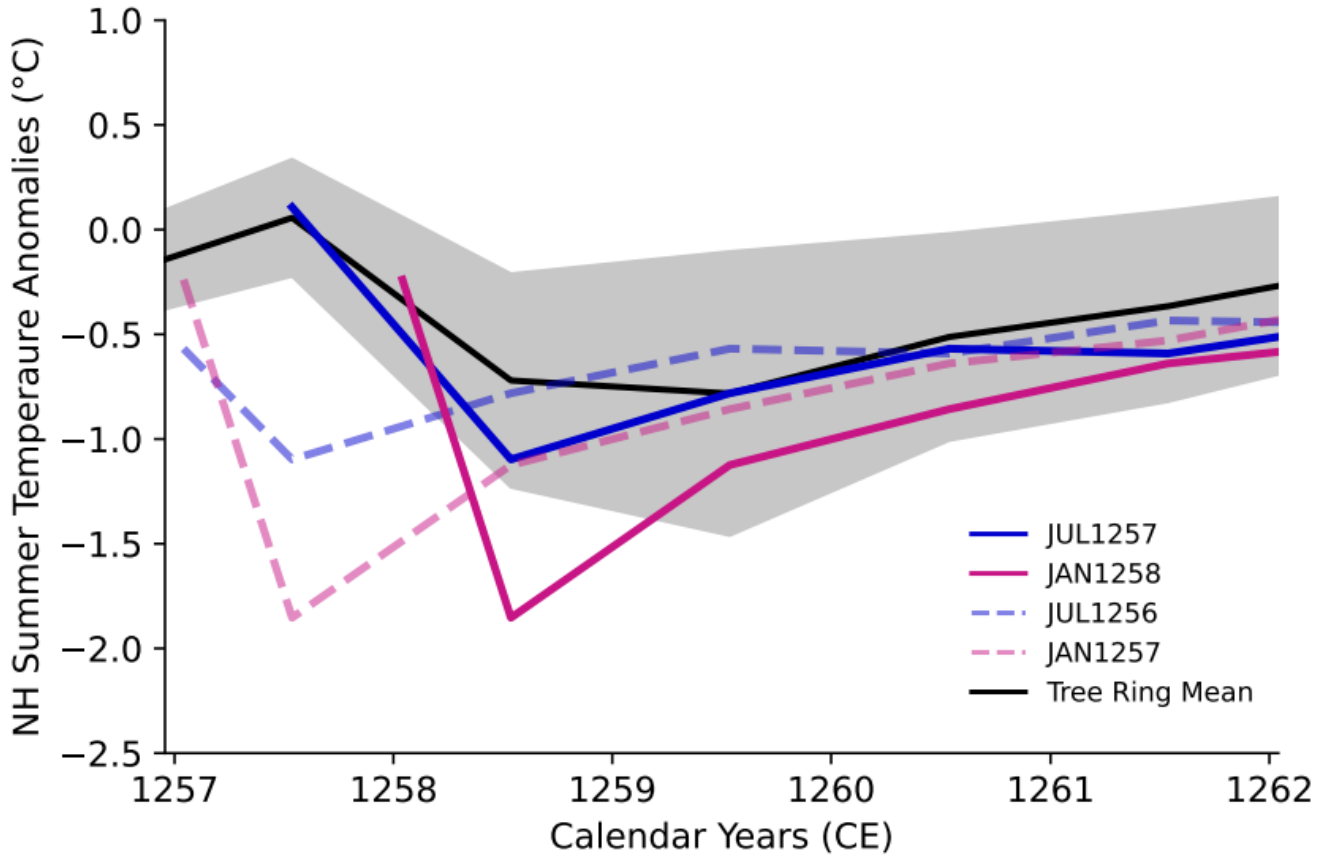

201 **3. Results**

202 **3.1 Multi-Proxy to Model Comparison**

203 **3.1.1 Northern Hemisphere**

204 Figure 1 shows that the JUL1257 ensemble mean (solid blue line) is the only eruption scenario to lie consistently within 2σ of
205 the tree-ring mean (grey band around the black line), with good agreement with tree-ring-reconstructed anomalies for both the
206 timing and magnitude of peak cooling across the whole period (1257-1262). The JAN1258 eruption ensemble mean (solid
207 pink line) also results in peak cooling occurring in Summer 1258 although the magnitude of model-simulated cooling is much
208 greater (by over 1°C) than the peak tree-ring reconstructed cooling. Across individual JAN1258 eruption ensembles (shown
209 in Supplementary Document, Figure S2) only two lie within 2σ of the tree-ring mean for the whole period. By contrast for the
210 individual JUL1257 eruption ensembles seven lie within 2σ of the tree-ring mean for the whole period (Supplementary
211 Document, Figure S2). Both JUL1256 (dashed blue line) and JAN1257 (dashed pink line) eruption scenarios result in peak

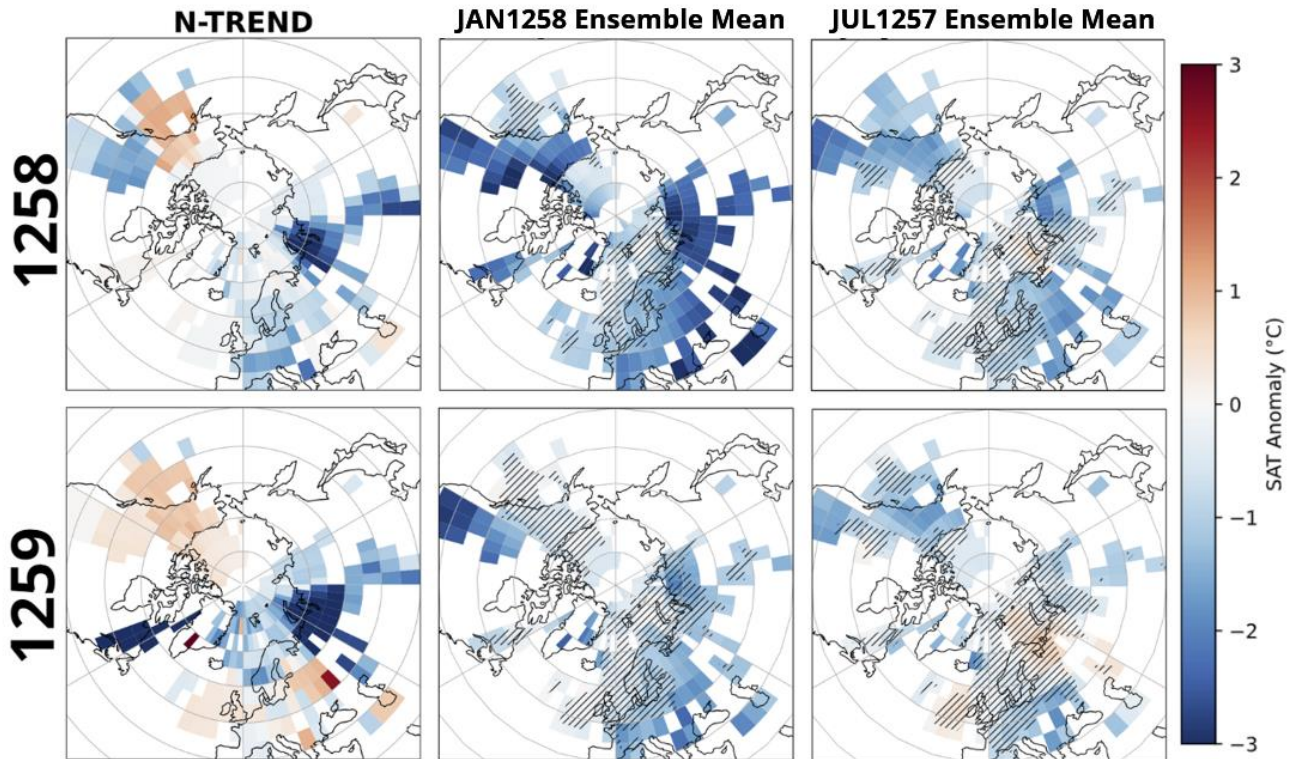

212 cooling occurring a year early relative to the tree-ring-reconstructed mean and across both scenarios no individual ensemble
213 members lie within 2σ of the tree-ring mean for 1257-1260.

214
215 **Figure 1. NH Summer June-July-August Surface temperature anomalies. Blue: JUL1257 ensemble mean. Pink:**
216 **JAN1258 ensemble mean. Solid and dashed lines indicate different eruption years. Black line shows the mean of the**
217 **tree-ring-reconstructed summer surface air temperature anomalies and grey band shows 2σ around the tree-ring mean.**
218 **Tree-Ring data: Wilson et al., (2016), Schneider et al., (2015), Büntgen et al., (2021), Guillet et al., (2017). See**
219 **Supplementary Sheet 2 for details of each tree-ring study.**

220
221 When compared to the N-TREND spatially resolved tree-ring reconstructed anomalies (first column in Figure 2) the JUL1257
222 ensemble mean (third column in Figure 2) results in more consistent agreement with the magnitude and spatial distribution of
223 SAT anomalies across the NH for Summers 1258 and 1259. For Summer 1258 the mean grid point difference between N-
224 TREND reconstructions and the JUL1257 Ensemble mean is +0.19 ($\sigma = 1.08$) whilst the difference with the JAN1258
225 Ensemble mean is +0.78 ($\sigma = 0.99$), with the JAN1258 ensemble mean (second column in Figure 2) tending to overpredict
226 summer SAT anomalies relative to N-TREND reconstructions. Across the US West Coast and Central and Northern Europe

227 N-TREND reconstructions suggest cooling of -1°C to -2°C whereas model-simulated anomalies for the JAN1258 ensemble
228 mean are on the order of -2°C to -3°C . By contrast the JUL1257 ensemble mean shows widespread but more moderate negative
229 SAT anomalies of -1°C to -2°C across the NH for Summer 1258 and thus achieves better agreement with N-TREND
230 reconstructions. Nonetheless, model-simulated anomalies for the JUL1257 mean suggest cooling of up to -2°C in Central and
231 Northwest Asia which is an underprediction relative to N-TREND tree-ring reconstructions which suggest cooling of up to -
232 3°C in Summer 1258.
233

234
235 **Figure 2. Spatially resolved N-TREND-Model comparison for June-July-August average 1258-59 for the Northern**
236 **Hemisphere (40-90°N). N-TREND data from Anchukaitis et al., (2017). First column shows N-TREND reconstructed**
237 **summer surface temperature anomalies. Second column shows model-simulated summer surface temperature**
238 **anomalies for the JAN1258 ensemble mean and third column shows the same for the JUL1257 ensemble mean. Hashed**
239 **areas show regions of less than 95% significance as determined using a grid box ANOVA analysis.**

240
241 Greater regional variability is seen in N-TREND SAT anomalies for summer 1259. N-TREND reconstructions suggest
242 negative SAT anomalies in Northern Eurasia and Quebec of up to -3°C and between -1°C to -2°C in Northern Europe and
243 Central Asia. Positive SAT anomalies of up to $+1^{\circ}\text{C}$ are seen in Alaska and Western Europe. The JAN1258 ensemble mean

244 shows continued widespread negative anomalies of -1°C to -3°C across the whole NH and thus does not achieve consistent
245 agreement with reconstructed anomalies across North and Western Europe, US West Coast or Alaska. By contrast, the
246 JUL1257 ensemble mean shows moderate positive SAT anomalies in Northern and Western Europe of up to $+0.5^{\circ}\text{C}$ although
247 still somewhat under predicts the magnitude of cooling in Central and Northern Asia and the US East coast relative to N-
248 TREND reconstructions.

249
250 Notably neither the JUL1257 or JAN1258 ensemble mean achieves agreement with positive SAT anomalies reconstructed in
251 Alaska for Summers 1258 and 1259. Across individual ensembles (See Supplementary Document, Figures S4-S7) only 1
252 JUL1257 and 4 JAN1258 ensembles show positive SAT anomalies in this region. Of these ensembles three are classified as
253 having warm phase ENSO initial conditions. N-TREND reconstructions show moderate SAT anomalies in Alaska from 1255-
254 56, with strong positive SAT anomalies first appearing in reconstructions for Summer 1257 (shown in Supplementary
255 Document, Figure S8).

256 **3.1.2 Globally Resolved Multi-Proxy Constraints**

257 Model-simulated SAT anomalies for a JUL1257 eruption (first row) and a JAN1258 eruption (second row) across Summers
258 (JJA) 1258 (left) and 1259 (right) are shown in Figure 3 with symbols denoting the degree of agreement with multi-proxy-
259 reconstructed SAT anomalies. The locations and SAT anomalies constrained by proxy records are shown in Figure S3. Overall,
260 the JUL1257 ensemble mean shows more consistent agreement with proxy SAT constraints across Europe, Asia, and North
261 America, whilst the JAN1258 ensemble mean tends to overpredict the magnitude of negative SAT anomalies relative to
262 quantitative proxy constraints.

263

264 Summer 1258

265 For Summer 1258 large negative SAT anomalies are well constrained across Central Asia, with tree-ring reconstructions
266 suggesting cooling in the region of up to -0.4°C in Tibet and -1.1°C in Mongolia (Xu et al., 2019, Davi et al., 2015, Davi et
267 al., 2021) as well as the presence of frost rings late in the 1258 growth season (D'Arrigo et al., 2001). In Japan the Mirror of
268 the East refers to persistent cold and wet conditions. Negative SAT anomalies are constrained across northern Russia, with
269 cooling up -2.7°C (Briffa et al., 2013), and frost rings also present in the Polar Urals, Siberia (Hantemirov et al., 2004). Both
270 JAN1258 and JUL1257 model ensembles suggest strong cooling across Central and Northern Asia, however, only the JUL1257
271 ensemble mean lies consistently within $\pm 1^{\circ}\text{C}$ of the proxy constraints whilst anomalies of up to -4°C for the JAN1258
272 ensemble mean are an overprediction relative to proxy constraints (see filled symbols on Figures 3C and 3E).

273

274 Across Northern, Central, and Western Europe negative SAT anomalies are constrained by a combination of tree-ring
275 reconstructions, with moderate cooling of up to -0.3°C in Europe (Büntgen et al., 2011), and a multitude of medieval chronicles
276 across France, Germany, and England which refer to cold and wet conditions (Guillet et al., 2017). The JUL1257 ensemble

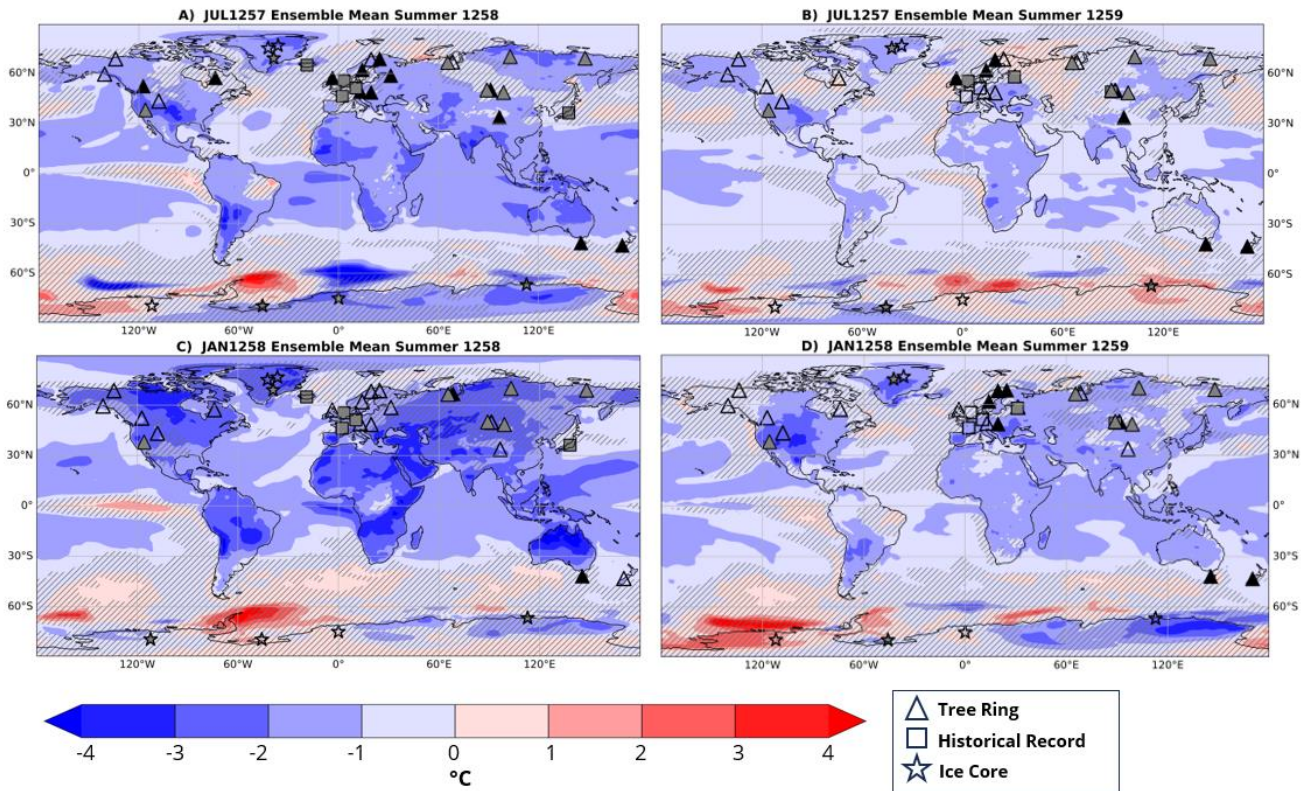

277 shows SAT anomalies of up to -1°C in good agreement with proxy constraints on the magnitude of cooling (see filled triangles
278 across Europe in Figure 3A), whereas the JAN1258 ensemble mean shows cooling between -2°C and -3°C . The Þorgils Saga
279 Skarða in Iceland also refers to abnormally cold and wet weather during 1258 (Bierstedt, 2019) although ice core
280 reconstructions in Greenland show only minor SAT anomalies of between $+0.09^{\circ}\text{C}$ and -0.1°C (Guillet et al., 2017, Vinther
281 et al., 2010, Fischer et al., 1998, Vinther et al., 2006). JAN1258 and JUL1257 ensemble means suggest cooling of up to -3°C
282 and -2°C respectively and so both overpredict the magnitude of cooling across Greenland. Ice core records across Antarctica
283 all show moderate negative SAT anomalies of up to -0.1°C . The JUL1257 ensemble mean does show negative anomalies
284 across three of the four ice core sites, although the magnitude of model simulated cooling (-2°C to -3°C) is much greater. The
285 JAN 1258 ensemble shows more variable SAT anomalies with both warming and cooling anomalies across Antarctica.

286

287 SAT anomalies are more variable across North America with reconstructions in Eastern Canada showing both positive and
288 negative SAT anomalies of 0.09°C and -1.6°C respectively (Gennaretti et al., 2014, Moore et al., 2001). The JUL1257
289 ensemble shows agreement with both proxy constraints suggesting cooling of up to -2°C on Baffin Island and showing no
290 significant SAT anomaly in the Quebec region, whilst the JAN1258 ensemble mean shows cooling of up to -3°C and thus
291 overpredicts cooling in both regions. Tree-ring reconstructions in the Western US and Canadian Rockies suggest negative SAT
292 anomalies of up to -0.5°C and -1.6°C (Martin et al., 2020, Luckman et al., 2005). The JAN1258 ensemble overpredicts the
293 magnitude of cooling relative to proxy constraints with SAT anomalies of up to -3°C whilst the JUL1257 ensemble mean
294 shows more moderate anomalies of up to -2°C . Positive SAT anomalies are well constrained by tree-ring reconstructions in
295 the Gulf of Alaska with warming of up to 0.1°C and 0.9°C (Wiles et al., 2014), however, neither JAN1258 nor JUL1257
296 ensemble means show positive SAT anomalies in this region.

309

310 Summer 1259

311 Persistent strong negative SAT anomalies are well constrained for Central Asia with tree-ring reconstructions suggesting
 312 continued cooling of up to -2.3°C in Mongolia and -0.3°C in Tibet (Davi et al., 2015, Xu et al., 2019) as well as frost rings
 313 present early in the 1259 growth season (Churakova et al., 2019, D'Arrigo et al., 2001). The Russian Chronicle of Novgorod
 314 refers to abnormal summer snowfall in the Altai mountains and unusual summer frost days (Stothers, 2000, Borisenkov and

315 Pasetsky, 1988) with tree-ring reconstructions showing continued negative SAT anomalies across Northern Russia of up to -
316 4°C (Briffa et al., 2013). Both JAN1258 and JUL1257 ensemble means show moderate negative anomalies of between -1°C
317 and -2°C in Central Asia, however, only the JAN1258 ensemble mean shows stronger negative SAT anomalies of up to -3°C
318 in Northern Russia whilst anomalies for the JUL1257 ensemble mean do not exceed 95% significance. Tree-ring
319 reconstructions show some positive SAT anomalies across Central Europe of up to 0.2°C (Büntgen et al., 2011) and in Western
320 Europe medieval chronicles refer to a hot and dry summer (Guillet et al., 2017). Very moderate SAT anomalies across Europe
321 are only shown by the JUL1257 ensemble mean, whilst the JAN1258 ensemble continues to show cooling in the region of up
322 to -2°C. Ice core records in Greenland show very moderate SAT anomalies of 0.02°C (Fischer et al., 1998) and -0.009°C
323 (Vinther et al., 2006) however, both JAN1258 and JUL1257 ensemble means show cooling across Greenland of -1°C to -2°C.
324

325 Negative SAT anomalies persist across Eastern North America with cooling of up to -2.6°C (Gennaretti et al., 2014). Cooling
326 of up to -2°C is shown by both ensemble means across Baffin Island (NE Canada), however, neither ensemble achieves
327 agreement with the stronger cooling signal in Quebec. Along the Western coast of North America tree-ring reconstructions
328 yield positive SAT anomalies of up to +0.8°C in the Missouri River Basin and +0.3°C in the Canadian Rockies (Martin et al.,
329 2020, Luckman et al., 2005). Both ensembles continue to show cooling along the US West Coast although the magnitude is
330 more moderate for the JUL1257 ensemble. In the Gulf of Alaska tree-ring reconstructions suggest continued positive SAT
331 anomalies of up to +0.7°C (Wiles et al., 2014). The JAN1258 ensemble mean shows no anomalies exceeding 95% significance
332 in Alaska whilst the JUL1257 ensemble mean shows continued cooling of up to -2°C and so neither eruption scenario achieves
333 good agreement with proxy constraints. Ice core records across Antarctica continue to show moderate cooling anomalies of up
334 to -0.15°C apart from the Law Dome (Plummer et al., 2012 - 112°E) core which shows a moderate warming anomaly of +0.16.
335 The JUL1257 ensemble mean does show a warming anomaly in the east of Antarctica, however cooling anomalies are more
336 isolated in west Antarctica compared to those reconstructed from ice core records. The JAN1258 ensemble mean shows poor
337 agreement with ice core records with warm SAT anomalies in the east of Antarctica and cool SAT anomalies in the west.

338 **3.2 Re-evaluating Evidence for a January 1258 Eruption Date**

339 Two lines of evidence have previously been invoked to support an early 1258 eruption date: references in medieval chronicles
340 to a “dark lunar eclipse” in mid-May 1258 (Stothers, 2000) and peak sulfate fall out in Greenland Ice Cores in early 1259
341 (Hammer et al., 1980). Figure 4a shows model-simulated Stratospheric Aerosol Optical Depth (SAOD) averaged across
342 western Europe for the years following the eruption with the black line showing the eVolV2k SAOD for the PMIP4 forcing
343 which is based on a July 1257 eruption date (Toohey & Sigl, 2017). Marked by the grey lines are the dark lunar eclipses of 18-
344 19th May 1258 and 12-13th Nov 1258 identified by Stothers (2000) in the Bury Saint Edmunds Abbey chronicle and Guillet
345 et al., (2017) in the Annales Ianuenses respectively, where for the moon to appear dark an SAOD > 0.1 is needed (Stothers,
346 2000). Whilst a JAN1258 eruption scenario does result in a later SAOD peak, both a JUL1257 and a JAN1258 eruption result
347 in SAOD >> 0.1 during both May and November 1258 and therefore either eruption scenario could account for observations

348 of darkened lunar eclipses. This is supported by findings from Guillet et al., (2023) that a dark total lunar eclipse is most likely
 349 to be observed 3 to 20 months following an eruption. SAOD in the UKESM for both JUL1257 and JAN1258 ensembles decays
 350 more rapidly than SAOD under PMIP4 forcing, for which SAOD remains > 0.1 until mid-1260 AD.

351

352 **Table 2: Comparison between ice core average (from Table S2) and ensemble means for JUL1257 and**
 353 **JAN1258 model simulations for the timing of SO₄ rise, peak, and total deposition in Greenland and**
 354 **Antarctica.**

	JUL1257 Ensemble Mean	JAN1258 Ensemble Mean	Ice Core Mean (Average from Table S2)
SO ₄ Rise Greenland	Jan 1258	May 1258	February 1258
SO ₄ Rise Antarctica	Oct 1257	March 1258	August 1257
Offset in SO₄ Rise (months, Antarctica - Greenland)	3	2	6
SO ₄ Peak Greenland	July 1258	Jan 1259	March 1259
SO ₄ Peak Antarctica	February 1258	Sept 1258	July 1258
Offset in SO₄ Peak (months, Antarctica - Greenland)	5	4	8
Greenland Sulfate Deposition (Kg km ⁻²) (Toohey & Sigl 2017)	26.8	23.2	105
Antarctica Sulfate Deposition (Kg km ⁻²) (Toohey & Sigl 2017)	54.3	28.0	73
Greenland/Antarctica	0.49	0.83	1.4

355

356

357 Figures 4B and 4C show ice sheet-averaged model-simulated sulfate deposition across Greenland and Antarctic ice sheets
 358 respectively, for JUL1257 and JAN1258 eruption scenarios. The mean beginning of sulfate rise and the timing of peak sulfate
 359 deposition across four high resolution ice sheets (see Table S2) are also shown as vertical black lines. Table 2 shows a
 360 comparison between ice core average (from Table S2) and ensemble means for JUL1257 and JAN1258 model simulations for

361 the timing of SO₄ rise, peak, and total deposition in Greenland and Antarctica. The JUL1257 ensemble shows the beginning
362 of sulfate rise in January 1285 in Greenland and October 1257 in Antarctica, with peak deposition occurring in July 1258 and
363 February 1258 respectively. Whilst the JAN1258 ensemble shows sulfate rise beginning in May and March 1258 in Greenland
364 and Antarctica respectively, with peak deposition in Jan 1259 and September 1258. Across four high resolution ice cores
365 (Table S2) the mean onset of sulfate rise occurs in February 1258 in Greenland and August 1257 in Antarctica, thus showing
366 closest agreement with the timing of simulated sulfate rise for a July 1257 eruption date, where only an eruption in summer
367 1257 can account for the beginning of sulfate deposition in Antarctica in autumn 1257. Across the four ice core records mean
368 peak deposition in Greenland occurs in March 1259 whilst mean peak deposition in Antarctica occurs earlier in July 1258. The
369 timing of peak deposition therefore shows better agreement with simulated peak deposition for a January 1258 eruption date
370 with peak model-simulated deposition occurring too early in the JUL1257 ensemble relative to ice core records. Ice core
371 records also suggest an asymmetry in sulfate dispersal and deposition, with sulfate rise and peak deposition in Antarctica being
372 6 and 8 months ahead of Greenland respectively. The JUL1257 ensemble shows a greater degree of asymmetry compared to
373 the JAN1258 ensemble, although offsets of 3 and 5 months between Antarctica and Greenland are still lower than the offset
374 suggested by the ice core record. Whilst the offset between the beginning of sulfate rise and peak sulfate deposition is
375 approximately a year in both Greenland (13 months) and Antarctica (11 months), the offset for model-simulated deposition in
376 the UKESM is considerably shorter across both JUL1257 and JAN1258 ensembles (ranging from 4-8 months). This may
377 represent a limitation specific to the UKESM, where Marshall et al., 2018 suggested the poleward transport of volcanic aerosol
378 may be too weak (or midlatitude deposition too strong) in the UKESM relative to other models tested. This weaker poleward
379 transport may also contribute to the lower magnitude of total polar deposition simulated by the UKESM relative to ice core
380 records, where Marshall et al., 2018 also found that the UKESM simulates two times too little deposited sulfate compared to
381 mean ice-core-derived estimates for the Tambora 1815 eruption. Both model-simulated ensembles show greater total sulfate
382 deposition in Antarctica compared to Greenland, whilst ice core records suggest the opposite asymmetry favouring greater
383 deposition in Greenland.

384

 392 **timeseries from NEEM and WDC ice core records respectively (Sigl et al., 2015) with grey bars showing ± 1 -year**
 393 **uncertainty for the timing of peak deposition.**

394 4. Discussion

395 4.1 Constraining the Eruption Year and Season of the Mt. Samalas eruption

396 As shown in Figure 1, both JUL1256 and JAN1257 eruption scenarios result in peak surface cooling occurring a year too early
397 relative to reconstructed SAT anomalies. Thus, an early eruption date such as Spring 1256, as proposed by Bauch (2019), is
398 unfeasible for the Mt. Samalas eruption. Across the two remaining eruption scenarios only the JUL1257 eruption ensemble
399 lies consistently within 2σ of the tree ring-reconstructed mean between 1258-1262. By contrast, the JAN1258 eruption
400 ensemble results in peak cooling being over 1°C greater than tree ring reconstructions for Summer 1258.

401
402 When compared with spatially resolved N-TREND reconstructions model-simulated SAT anomalies for the JAN1258
403 ensemble mean continue to consistently overpredict the magnitude of cooling for both 1258 and 1259 across the NH. Whilst
404 the spatial agreement of SAT anomalies for the JUL1257 ensemble mean does not precisely replicate those reconstructed from
405 the N-TREND tree ring record it does show widespread but less extreme negative SAT anomalies across the NH and thus
406 achieves better agreement with reconstructed anomalies on a regional basis. This is supported by comparison between globally
407 resolved model-simulated ensemble mean SAT anomalies and multi-proxy-reconstructed anomalies where the JAN1258
408 ensemble mean consistently over predicts the magnitude of cooling in key regions across Europe, Central Asia, and the US,
409 whilst the JUL1257 ensemble mean results in generally better agreement across these regions with more moderate negative
410 SAT anomalies.

411
412 A re-evaluation of evidence for a January 1258 eruption finds that a Summer 1257 eruption can also satisfy constraints from
413 both ice core records and historically documented dark lunar eclipses. Model-simulated ice sheet sulfate deposition shows that
414 for eruption scenarios 6 months apart there is a distinguishable off-set in the timing and magnitude of deposition, with the bi-
415 polar Greenland/Antarctica ratio of simulated sulfate depositions between northern and southern hemisphere ice sheets varying
416 depending on eruption season. The onset of model-simulated sulfate deposition in Greenland and Antarctica for the JUL1257
417 ensemble mean achieves better agreement with ice core record tie points, where the onset of sulfate deposition in Antarctica
418 in August 1257 can only be aligned with an eruption during or prior to Summer 1257. Nonetheless, the timing of peak model-
419 simulated sulfate deposition achieves better agreement with the JAN1258 ensemble mean, potentially reflecting limitations in
420 aerosol transport within the UKESM leading simulated aerosol decay being too-rapid (Marshall et al., 2018).

421
422 Overall, the multi-proxy to model comparison utilized in this study provides a clear distinction between JULY1257 and
423 JAN1258 eruption scenarios, with better agreement between proxy reconstructions and model-simulated anomalies being
424 shown for a July 1257 eruption date. This is consistent with the May-August 1257 date constraint suggested by Guillet et al.,
425 (2023) based on their analysis of contemporary reports of total lunar eclipses, combined with tree ring-based climate proxies
426 and aerosol model simulations. Although consensus has converged on a Summer 1257 date for the Samalas eruption, it remains

427 to be seen if a more precise constraint (i.e to a specific month) could be achieved given current model and proxy uncertainties
428 (as discussed in Section 4.3 below). Nonetheless, this four-month window remains an improvement upon previous dating
429 uncertainty and is still sufficient at present for interrogating both climatic and human consequences following the eruption.

430

431 **4.2 Regionally Heterogenous Climate Response**

432

433 Multi-Proxy SAT reconstructions highlight the regionally heterogenous climate response following the Mt. Samalas eruption.
434 The largest negative SAT anomalies occur across Central Asia and Northern Russia, with cooling of -2°C to -4°C between
435 1258 and 1259, making these as some of the most severely impacted regions in the NH. The role of sudden and severe cooling
436 associated with the Mt. Samalas eruption in the collapse of the Mongol westward advance is therefore plausible (Di Cosmo et
437 al., 2021). Alongside references to extreme and abnormal weather conditions, the Azuma Kagami in Japan also highlights the
438 severity of the Shôga famine between 1257-60 (Farris, 2006). Model-simulated cooling of up to -1°C across Japan suggest the
439 severity of this famine could have been amplified by the climate response to the Mt. Samalas eruption in 1258-59. Similar
440 evidence exists in the Middle East with famine and pestilence reported across Syria, Iraq, and Southern Turkey in 1258
441 (Stothers, 2000). A model-simulated JUL1257 eruption scenario suggests cooling of up to -2°C in the region and thus supports
442 a possible association with the Mt. Samalas eruption. Reconstructed and model-simulated SAT anomalies suggest less severe
443 cooling across Europe for 1258 ($<-1^{\circ}\text{C}$) and relative warming in the region for 1259. Nonetheless, this is still associated with
444 significant economic and social disturbances, with historical records reporting famine and social unrest (Guillet et al., 2017,
445 Stothers, 2000). Van Dijk et al., (2023) find similar regional variability in both the climatic effects and social consequences
446 across Scandinavia following the 536/540 double eruption event, finding the severity of impacts depended heavily both on
447 local topography and the subsistence methods employed by different communities.

448

449 Büntgen et al., (2022) find negative TRW growth anomalies along the US West Coast for Summer 1257 and suggest this is
450 evidence for the onset of climate perturbations in the NH before the end of the 1257 growth season and therefore support a
451 Summer 1257 eruption date. Model-simulated anomalies for a JUL1257 eruption, however, show no significant anomalies
452 occurring across the US or NH during Summer 1257 (see Supplementary Document, Figure S9). The presence of frost rings
453 in 1257 and 1259 (Salzer and Hughes, 2007), but not in 1258, also contradicts model-simulated cooling, which consistently
454 shows the strongest cooling in 1258. Model-simulated SAT anomalies for a JUL1257 eruption only show significant negative
455 SAT anomalies in late summer 1257 across South America, Africa, and Oceania, with cooling in some regions of up to -2°C ,
456 although without well-dated, geographically distributed climate proxies in the SH it will remain difficult to resolve whether
457 this is potential model/proxy discrepancy in the SH (Neukom et al., 2014). However, if extreme and sudden cooling did occur
458 in the SH would be expected to have significant, but as yet unknown, consequences for communities and civilizations in the
459 Southern Hemisphere. Additional large volcanic eruptions in 1269, 1276 (UE5), and 1286 (UE6), which combined with the
460 eruption in 1257, make the sulfate loading in the 13th century two to ten times larger than any other century in the last 1500

461 years (Gao et al., 2008, Guillet et al., 2023), may have led to further climate anomalies with effects on impacted civilisations
462 being prolonged throughout the latter half of the 13th century. For example, the first settlement of New Zealand most likely
463 occurred between 1250–1275, with suggestions this may have reflected a climate-induced migration associated at least in part
464 with the impacts of the Mt. Samalas, and subsequent, eruptions (Anderson, 2016, Bunbury et al., 2022). Apart from recent
465 analysis of the localized impacts and recovery following the Mt. Samalas eruption (Malawani et al., 2022) the general sparsity
466 of currently available proxy data across the SH precludes definitive conclusions as to climate and social response in the SH
467 following the Mt. Samalas eruption.

468
469 Notably, neither the JAN1258 or JUL1257 ensemble mean replicates reconstructed positive SAT anomalies in Alaska for
470 Summer 1258 or the wider US west coast for Summer 1259. Across individual realisations only five show positive SAT
471 anomalies in this region for 1258-59, and of these ensembles 3 are classified as having warm phase ENSO initial conditions.
472 N-TREND spatially resolved reconstructions show positive SAT anomalies over Alaska from Summer 1257-59, with warm
473 phase El Niño-like conditions during this period being supported by positive tree ring-reconstructed temperature anomalies in
474 Alaska (Guillet et al., 2017) and the muted absolute temperature signal seen in $\delta^{18}\text{O}$ coral reconstructions from the central
475 tropical Pacific (most likely explained by the superposition of a volcanic cooling signal and a warm El Niño-like signal (Dee
476 et al. 2020, Robock 2020)). The role of volcanic eruptions in perturbing ENSO remains debated (Mann et al. 2005, Stevenson
477 et al. 2018, Dee et al. 2020, Robock 2020) although climate simulations and proxy records suggest an increased probability
478 for the occurrence of an El Niño event in the first or second year after a large volcanic eruption (see McGregor et al 2020 for
479 a full review). El Niño-like warm conditions may therefore have prevailed at the time of the Mt. Samalas eruption with
480 subsequent volcano-ENSO interactions potentially acting to enhance these pre-existing El Niño-like conditions.

481 **4.3 Model and Proxy Limitations**

482 The majority of temperature anomaly constraints applied in this study are provided by SAT tree ring reconstructions, where
483 tree-ring data has been shown to effectively record extreme cooling events synchronous with evidence for explosive volcanic
484 eruptions over the last two millennia without chronological errors (Stoffel et al., 2015, Büntgen et al., 2020; Büntgen et al.,
485 2016; Sigl et al., 2015) and in good agreement with instrumental observations following large eruptions (Esper et al., 2013).
486 Lücke et al., (2019) highlight the importance of accounting for biologically based memory effects, which can lead to
487 dampening of volcanic cooling signals in ring width-based chronologies. However, many of the tree ring-based reconstructions
488 utilised in this work do incorporate maximum latewood density (MXD) data as well as TRW (see Figure S3) which has been
489 shown to reduce attenuation of volcanic cooling signals (Esper et al., 2014, Stoffel et al., 2015). Additional temperature
490 anomaly constraints are also provided by historical sources, although these records are inherently more limited being non-
491 quantitative and subjective accounts. The application of historical records to the model-multi proxy framework is limited by
492 the sparsity of historical records, both spatially, being predominantly concentrated in the NH, and temporally, being biased in
493 frequency, dating accuracy, and traceability towards more recent volcanic eruptions, although have been applied effectively to

494 understand the aftermath and impacts of the Mt Samalas 1257 eruption (Malawani et al., 2022). In this study ensemble
495 simulations do show hydroclimate perturbations following the Samalas eruption for both JUL1257 and JAN1258 scenarios
496 (Figure S10), although due to the limited number of realisations these are not included in our model-proxy framework.
497 Nonetheless, the magnitude of precipitation anomalies for Summer 1258 being greatest in the equatorial regions, potentially
498 indicative of a shift in the ITCZ due to asymmetric cooling between hemispheres. Therefore, future studies may also consider
499 including hydroclimate proxies alongside SAT reconstructions in order to add an additional constraint on model-proxy
500 agreement.

501
502 Model-simulated anomalies are strongly dependent on model set up, including model resolution, modelled stratospheric winds,
503 aerosol microphysics and sedimentation and deposition schemes (Marshall et al., 2018, Quaglia et al., 2023). In recent model
504 intercomparison studies (Marshall et al., 2018, Quaglia et al., 2023) the UKESM showed a bias towards stronger transport to
505 the NH extratropics, resulting in a hemispherically asymmetric aerosol load. The spatial distribution of volcanic forcing can
506 influence subsequent growth of sulphate aerosols and their global distribution, in turn affecting the persistence of aerosols in
507 the stratosphere (Quaglia et al., 2023). Compared to other global aerosol models the UKESM also has relatively weaker
508 poleward transport, with stronger meridional deposition which may lead to a more equatorially focussed aerosol distribution
509 and deposition (Marshall et al., 2018). The UKESM does not have prescribed OH which may prevent the timescale for sulfate
510 formation to be properly simulated and thus result in a bias towards low aerosol effective radius in the UKESM compared to
511 observations (Clyne et al., 2021, Dhomse et al., 2014). Disentangling large inter-model differences from the range of model
512 components that contribute to this uncertainty remains challenging, although future multi-model multi-proxy studies may be
513 of use.

514
515 Even within a single model, uncertainties persist in initial eruption conditions (e.g., phase of atmospheric modes, aerosol size
516 distribution) and volcanic forcing parameters (e.g., timing, magnitude, injection height and latitude of eruption). Timmerick et
517 al., (2021) demonstrated that both the magnitude of forcing as well as its spatial structure can similarly affect reconstruction-
518 simulation comparisons, particularly in the NH extratropics. This is supported by Lucke et al., (2023) who demonstrate a
519 significant spread in the temperature response due to volcanic forcing uncertainties which can strongly affect agreement with
520 proxy reconstructions. The VSSI estimate used in this study was taken from the eVol2k reconstruction (Toohey and Sigl,
521 2017) and is within error of other SO₂ emission estimates for the Mt Samalas eruption (Vidal et al., 2016, Lavigne et al.,
522 2013). Whilst maximum plume heights have been estimated for the Samalas eruption (~ 43 km Vidal et al., 2015) the injection
523 height remains unknown. In our simulations the injection height is set to 18-20 km, which may be too low, but does allow for
524 upwards lofting of aerosol. Moreover, Stoffel et al., (2015) found that increasing plume height from 22-26 km to 33-36 km
525 for simulations of the Mt Samalas 1257 eruption increased the magnitude of the peak post-eruption NH JJA temperature
526 anomaly to -4°C for a January eruption and -1°C and -2°C for May and July eruption scenarios respectively. A higher plume
527 height than the 20km used in our study would therefore likely further enforce our central conclusion that better agreement

528 between proxy and model temperature anomalies is achieved for a summer 1257 eruption date, whilst a greater plume height
529 for a January 1258 eruption would only further overpredict the magnitude of post-eruption cooling. Timmreck et al., (2009)
530 also highlight the strong dependence of model-simulated post-eruption climate responses following large volcanic eruptions
531 on the aerosol particle size distribution due to self-limiting effects of larger particles (Pinto et al., 1989). These particle
532 characteristics are difficult to constrain retrospectively for historic eruptions such as Mt. Samalas and thus represent a
533 significant uncertainty with modelling historic eruptions.

534

535 Model-simulated ice sheet sulfate deposition (Fig. 4) shows a clear distinction between JAN1258 and JUL1257 eruption
536 scenarios in both the timing and hemispheric distribution of deposition. For the same stratospheric SO₂ injection, an eruption
537 during NH summer results in more pronounced asymmetric polar deposition, with the magnitude of peak deposition in
538 Antarctica being nearly a factor of 3x greater than for an eruption during the SH summer, likely due to the stronger branch of
539 the Brewer-Dobson circulation and seasonal effects on aerosol transport and depositional processes. Nonetheless, modelling
540 of the Tambora 1815 eruption by Marshall et al., 2018 found a strong model dependency for the timing, magnitude, and spatial
541 distribution of sulfate deposition. Polar sulphate deposition in the UKESM was 2x less than in ice cores for the Tambora 1815
542 eruption and considerably lower than deposition in the other MAECHAM5-HAM and SOCOL-AER models tested (See Table
543 S3). In our JUL1257 and JAN1258 simulations for the Samalas 1257 eruption total mean deposition in Antarctica (55-28 Kg
544 km⁻²) and Greenland (26-23 Kg km⁻²) was also lower than total deposition from ice cores records (73 and 105 Kg km⁻²
545 respectively, see Table 2). The overall lower polar total sulfate deposition may reflect weaker poleward transport (or stronger
546 meridional deposition) in the UKESM (Marshall et al., 2018). For our JUL1257 and JAN1258 model simulated sulfate
547 deposition both eruption scenarios result in Greenland/Antarctica ratios < 1, with a Summer 1257 eruption showing a much
548 more asymmetric distribution (0.49) than a January 1258 eruption (0.83). These ratios, however, disagree with the
549 Greenland/Antarctica ratio derived from ice cores (1.4, Toohey and Sigl, 2017) suggesting that aerosol transport in the UKESM
550 may not sufficiently transport to the NH and favours distribution to the SH. Of the four models tested by Marshall et al., 2018
551 for the Tambora 1815 eruption the UKESM was one of two models which had greater deposition in Greenland compared to
552 Antarctica (Table S3, Greenland/Antarctica = 1.7). Both the Tambora 1815 and Mt Samalas 1257 were large magnitude
553 eruptions at a similar latitude, therefore this intra-model difference in the asymmetric distribution of sulphate aerosol likely
554 reflects variation in initial internal conditions within the model (such as QBO or other atmospheric mode phases). Moreover,
555 this further highlights the complications of disentangling inter-model differences and intra-model parameter-specific variation.
556 Given both these inter and intra-model differences in hemispheric aerosol distribution and deposition, the current robustness
557 of this parameter in distinguishing between eruption scenarios when compared to ice core records is limited, with further work
558 being needed to understand model and starting condition specific effects.

559 Whilst comparisons of simulated and reconstructed climate responses following large volcanic eruptions have been used
560 effectively by a multitude of studies (van Dijk et al., 2023, Büntgen et al., 2022, Stoffel et al., 2015), several risks remain
561 surrounding this approach. Given the uncertainties associated with both proxy reconstructions and model simulations neither

562 can be taken as the inherently “correct” baseline with which to fit the other, and thus particular care should be taken when
563 using model-proxy comparison to validate the correctness of underlying records or model input parameters. For example, the
564 missing tree ring hypothesis (Mann et al., 2012), which has since been widely rejected, proposed that the mismatch between
565 climate simulations and proxy reconstructions resulted from chronological errors due to missing growth rings. This has,
566 however, since been resolved with improved estimates of volcanic forcing (Toohey & Sigl 2017) and the greater inclusion of
567 MXD records in tree ring reconstructions (Stoffel et al., 2015; Schneider et al. 2015; Wilson et al., 2016; Anchukaitis et al.
568 2017). When utilising an array of different proxy data there is the risk of confirmation bias meaning records which show
569 significant agreement with model simulations being given greater weighting than those which show less agreement. A more
570 quantifiable approach to model-proxy comparison, where a greater number of model realisations would allow for more robust
571 statistical evaluation would therefore be a considerable improvement for the application of the model-multi proxy framework.

572 **5 Conclusions**

573 We have utilized eighteen aerosol-climate UKESM1 ensemble simulations for the 1257 Mt. Samalas eruption in combination
574 with the most complete globally resolved multi-proxy database to date for the Mt. Samalas eruption. This allowed more precise
575 constraints on the year and season as well as the regionally heterogeneous climate response following the Mt. Samalas eruption.
576 Comparison with NH averaged and spatially resolved tree ring reconstructions showed that a Summer 1257 eruption scenario
577 agrees best with reconstructed SAT anomalies, with a January 1258 eruption consistently over predicting the magnitude of
578 cooling relative to reconstructions. The regionally variable SAT response following the eruption is revealed by multi-proxy
579 reconstructions which lend support to inferred social, economic and historical consequences across Europe and Asia following
580 the eruption. Model-simulated SAT anomalies also suggest the onset of sudden a severe cooling across the SH, with the
581 potential for significant social and economic consequences in impacted communities across South America, Africa, and
582 Oceania. The spatial distribution of SAT anomalies shows sensitivity to initial atmospheric-ocean conditions, with positive
583 SAT anomalies in Alaska being potentially indicative of warm El Niño-like conditions at the time of the eruption, with potential
584 ENSO-Volcano interactions enhancing these conditions further.

585
586 Overall, the proxy to model comparison employed in this study has been shown as an effective approach to constrain uncertain
587 eruption source parameters. Model-multi proxy frameworks have similarly been employed by other recent studies (see Guillet
588 et al., 2023 and van Dijk et al., 2023) which have also demonstrated its potential in constraining unknown initial conditions as
589 well as regional climatic impacts for historic eruptions where there is sufficient concurrent proxy evidence. A greater global
590 distribution of proxy evidence, especially in the Southern Hemisphere where all types of proxy evidence are sparse, will
591 strengthen this proxy-model framework approach for future analysis. The incorporation of hydroclimate anomalies in
592 particular has the potential to add further independent constraints, although relies on the development of higher resolution
593 records, especially at low latitude sites. Model simulations of polar sulfate deposition also reveal distinct differences in the

594 timing of ice sheet deposition between the two simulated eruption dates, although comparison of the magnitude or asymmetric
595 deposition of sulfate aerosol remains limited by large inter-model differences and complex intra-model dependencies.

596

597 Finally, both proxy-reconstructed and model-simulated temperature anomalies highlight the severity of the global climate
598 response following a large tropical explosive eruption, with historical records confirming widespread and severe economic
599 and social consequences. This adds further weight to recent calls (Cassidy and Mani, 2022) for increased global preparedness
600 for the next large magnitude explosive volcanic eruption, given profound global consequences that would be expected, as
601 clearly demonstrated by the Mt. Samalas eruption.

609

610 **Author Contributions**

611

612 LW, LM, and AS jointly conceived the project methodology. LM ran the UKESM model simulations. LW performed the
613 analysis, visualisation, and writing of the manuscript with supervision from LM and AS. All authors jointly reviewed and
614 edited the paper.

615

616 **Competing Interests**

617 The authors declare that they have no conflict of interest.

618

619 **Acknowledgements**

620 This research formed part of LW's MSci Thesis at the University of Cambridge. LW would like to thank O. Shorttle and E.
621 Harper for their additional supervision and encouragement throughout this project, as well as Newnham College for supporting
622 the presentation of this work through a travel bursary. LM and AS acknowledge support from NERC grant NE/S000887/1
623 (VOL-CLIM), and AS additionally acknowledges funding from NERC grant NE/S00436X/1 (V-PLUS). The authors would
624 also like to thank M. Sigl and K. Anchukaitis for providing ice core and tree ring data sets utilized in this project, and N.L.
625 Abraham for technical modelling support. This work used the ARCHER UK National Supercomputing Service
626 (<http://www.archer.ac.uk>) and JASMIN, the UK collaborative data analysis facility. The authors would also like to thank M.
627 Green for her correspondence and insightful perspectives on the historical context for the eruption.

628

629 **Financial Support**

630 This research was supported by NERC grant NE/S000887/1 (VOL-CLIM) and NERC grant NE/S00436X/1 (V-PLUS).
