**Abstract.** The Mt. Samalas eruption, thought to have occurred between 1257 and 1258, ranks as one of the most explosive sulfur-rich eruptions of the Common Era. However, the precise year and season of the eruption remains unconstrained with evidence indicating both summer 1257 and early 1258 as potential eruption dates. Widespread surface cooling and hydroclimate perturbations following the eruption have been invoked as contributing to a host of 13th Century social and economic crises, although regional scale variability in the post-eruption climate response remains uncertain. In this study we run ensemble simulations using the UK Earth System Model (UKSEM1) with a range of eruption scenarios and initial conditions in order to compare our simulations with the most complete globally resolved multi-proxy database for the Mt. Samalas eruption to date, incorporating tree-ring, ice core, lake sediment, and historical records. This allows more-precise constraints to be placed on the year and season of the Mt. Samalas eruption as well as an investigation into the regionally heterogeneous post-eruption climate response. Using a multi-proxy to model comparison, we are able to robustly distinguish between July 1257 and January 1258 eruption scenarios where the July 1257 ensemble simulation achieves considerably better agreement with spatially averaged and regionally resolved proxy surface temperature reconstructions. These reconstructions suggest the onset of significant cooling across Asia and Europe in 1258, and thus support the plausibility of previously inferred historical connections. Model-simulated temperature anomalies also point to severe surface cooling across the Southern Hemisphere with as of yet unexplored historical implications for impacted civilizations. A re-evaluation of the use of ice core sulfate deposition records to constrain eruption season and volcanic stratospheric sulfur injection (VSSI) estimates also highlights current limitations in this approach, with our model simulations revealing distinct differences in the timing and magnitude of the ice sheet deposition between the two seasons. Overall, the multi-proxy to model comparison employed in this study has strong potential in constraining similar uncertainties in eruption source parameters for other historical eruptions where sufficient coincident proxy records are available.

## 1 Introduction

The Mt. Samalas eruption, which occurred on the Indonesian Island of Lombok between 1257 and 1258, is identified in ice  
35 cores as one of the largest volcanic sulfate deposition events of the last 2500 years (Palais et al., 1992, Zielinski et al., 1994).  
Petrological analysis suggests a release of ~120Tg of sulfur dioxide (SO<sub>2</sub>) into the stratosphere, with a maximum estimated  
plume height of 43 km and volcanic explosivity index (VEI) of 7, meaning the eruption ranks as one of the most-explosive  
sulfur-rich eruptions of the Common Era (Lavigne et al., 2013, Vidal et al., 2015, Toohey and Sigl, 2017). Tree-ring  
reconstructions suggest a peak Northern Hemisphere (NH) average summer cooling of -0.8°C to -1.2°C between Summer  
40 1258 and 1259 (Wade et al., 2020, Guillet et al., 2017, Wilson et al., 2016, Büntgen et al., 2022). The surface air temperature  
(SAT) anomalies and potential hydroclimate perturbations induced by the eruption have been invoked by historians as  
contributing factors to a host of 13th Century social and economic crises (Campbell, 2017, Malawani et al., 2022, Guillet et  
al., 2017, Bierstedt, 2019, Stothers 2000, Fell et al., 2020, Kern et al., 2021).

45 Summer 1257 and January 1258 are the two most commonly cited dates for the Mt. Samalas eruption, however, as of yet, no  
single suite of evidence has been able to robustly distinguish the precise year and season of the eruption. The full span of  
dates proposed ranges from 1256 to 1258, however the earliest date of Spring 1256 was based on historical evidence for a  
dust veil over Asia and the Middle East in late 1256 and early 1257 (Bauch, 2019). This is more likely attributed to a smaller  
eruption such as the 1256 Medina eruption which had only localized impacts (Saliba, 2017). A mid-1257 eruption date was  
50 first proposed by Oppenheimer (2003) based on the spatial distribution of negative temperature anomalies across both  
hemispheres for 1257-59, with radiocarbon dating of the pyroclastic flow deposits associated with the eruption also yielding  
an earliest date of 1257. Based on the westerly displacement of ash isopachs, Lavigne et al., (2013) proposed that easterly  
winds prevailed at the time of the eruption, indicative of the eruption occurring during the May-Oct dry season. Büntgen et  
al., (2022) also show that the earliest onset of potential tree-ring width (TRW) growth anomalies in the Western US occur in  
55 the late 1257-growth season, adding their support for an eruption date prior to August 1257. Modelling studies for the Mt.  
Samalas eruption have achieved best agreement with tree-ring reconstructions for a May-July eruption window (Stoffel et  
al., 2015). Nonetheless, peak sulfate deposition in ice cores is recorded for 1259 and the first historical reports of a dust veil  
over Europe appear in Summer 1258, which has been suggested to be most compatible with an early 1258 eruption (Stothers  
2000). Therefore, there is still a need to constrain the year and season of the eruption with greater certainty, with  
60 implications for evaluating the robustness of inferred connections to synchronous historical events, as well as in the role of  
the eruption sulfate deposition spike as a key temporal calibration marker in ice core records.

The regionally heterogeneous climate response to the Mt. Samalas eruption also remains largely unconstrained at a global  
level. Guillet et al., (2017) utilized a wealth of historical records and tree-ring chronologies to assess the impact of the  
65 eruption across the NH, with particular focus on the climate response to the eruption revealed by historical sources in

Western Europe. Medieval chronicles point to abnormal weather conditions in Summer 1258, with economic records highlighting delayed and poor harvests which likely aggravated ongoing grain shortages. Stothers (2000) suggested that frequently cold and rainy weather lead to widespread crop damage and famine, also noting the outbreak of plague across Europe and the Middle East in 1258-59. It has also been suggested that the epidemiological progression of *Y. pestis*, the bacterium responsible for the Black Death, can be traced to the climatic perturbations associated with the Mt. Samalas eruption (Fell et al., 2020). The climatic aftereffects of the eruption may have also included a shift in the Asian Monsoon and therefore be linked to the series of epidemics, droughts, and famines, associated with the decline of the Mongol Empire (Kern et al., 2021). Nonetheless, without a comprehensive globally resolved understanding of the climate response to the eruption the robustness of these inferred connections between post-eruption climate response and historical events remains difficult to constrain.

The magnitude and spatial distribution of the post-eruption climate response following large volcanic eruptions is known to show a strong seasonal dependency (Stevenson et al., 2017, Toohey et al., 2011). Asymmetric cooling between hemispheres occurs due to seasonal variation in Brewer-Dobson circulation which modulates hemispheric aerosol distribution (e.g. Toohey et al., 2011). Asymmetric aerosol distribution combined with enhanced land-albedo feedbacks during NH winter can therefore increase the magnitude of temperature anomalies between hemispheres (Stevenson et al., 2017). Hemispheric temperature contrasts can subsequently drive latitudinal shifts in the Inter-Tropical Convergence Zone (ITCZ), an equatorial band of enhanced rainfall and lower pressure, away from the hemisphere of greatest cooling resulting in hydroclimate perturbations (Broccoli et al., 2006). Therefore, depending on if the Mt. Samalas eruption occurred in Summer 1257 or in early 1258, differences in the magnitude and spatial distribution of resulting SAT and precipitation anomalies are expected.

In this study we utilize a multi-proxy to model comparison to place more precise constraints on the year and season of the Mt. Samalas eruption, tested across the whole window of proposed eruption dates. We utilize both model and proxy constraints to assess regionally heterogeneous impacts of the Mt. Samalas eruption, with reference to proposed historical consequences. UK Earth System Model (UKESM1) simulations were run across January and July eruption scenarios and a globally resolved database of proxy records was collated consisting of tree-ring chronologies, historical sources, lake sediments, and ice core records (Supplementary Sheet 1). This constitutes the most complete multi-proxy database for the Mt. Samalas eruption to date. Our study demonstrates the ability of a multi-proxy to model comparison to more precisely constrain the date of the Mt. Samalas eruption, where previous studies have tended to utilize only a single-proxy approach (Stothers, 2000, Bauch, 2019, Büntgen et al., 2022, Stoffel et al., 2015). The multi-proxy to model comparison employed in this study is shown to have significant potential in constraining similar uncertainties in eruption source parameters for other historical eruptions where sufficient coincident proxy records are available.

## 2 Methods

### 100 2.1 Model Simulations Using the UK Earth System Model (UKESM)

The state-of-the-art interactive aerosol-climate model UKESM1 (Sellar et al., 2019) was used, consisting of the physical global climate model HadGEM3-GC3.1 with additional configurations for terrestrial and marine biogeochemistry, land and ocean physics, ocean-sea ice, and dynamic terrestrial vegetation. The model also includes the UK Chemistry and Aerosol (UKCA) interactive stratospheric-tropospheric chemistry and aerosol schemes (Archibald et al., 2020, Mulcahy et al., 2020).

105 The full life cycle of stratospheric sulfur and sulfate aerosol particles is included, from injection of SO<sub>2</sub>, oxidation, particle formation and subsequent growth, to sedimentation and removal.

The model has a horizontal atmospheric resolution of 1.875° by 1.25° and a 1° by 1° resolution in the ocean, giving a vertical resolution of 85 levels in the atmosphere and 75 levels in the ocean. This results in well-resolved ocean and atmosphere dynamics and an internally generated Quasi-Biennial Oscillation (QBO). Coupled ocean-atmosphere simulations were run with greenhouse gases set to a representative pre-industrial (AD 1850) background state. The difference between a preindustrial and bespoke 13th century background state is small compared to model internal variability and thus does not represent a significant limitation of the approach.

115 Eighteen UKESM eruption-perturbed ensemble simulations were run, with nine simulating a January eruption and nine a July eruption, where January and July are winter/summer representatives. Given the preindustrial background the January/July ensemble groupings are not constrained to a specific year and therefore the two ensemble groupings have been used to assess the full range of dates proposed for the Mt. Samalas eruption between the years 1256 and 1258. The ensembles sample a range of initial conditions, with the starting phase of both QBO and the El Niño Southern Oscillation (ENSO) varying between ensembles. For full details of ensemble initial condition classification see Supplementary Document Table S1. Across the eighteen ensembles only the eruption season and initial conditions were varied, with all other eruption source parameters held constant and as listed in Table 1.

119 Tg of SO<sub>2</sub> was taken from the updated database of VSSI estimates (eVolv2k; Toohey and Sigl, 2017), which is within error of the 126 +/- 9.6 Tg estimated by Vidal et al. (2016). In our simulations, the injection height is set at 18-20 km to be consistent with the 1991 Mt. Pinatubo eruption and to allow for lofting of aerosol to higher altitudes in the stratosphere. This height is lower than the estimated 38-40 km column heights (Lavigne et al., 2013, Vidal et al., 2015) however, those column heights refer to the maximum altitude of tephra and ash rather than the height of sulfur injection in the stratosphere or the maximum altitude of the SO<sub>2</sub> plume. A 24-hr eruption duration agrees well with Lavigne et al., (2013) who estimated the eruption duration to be 23.8 +/- 10.3 hrs.

An equivalent control ensemble, with identical starting conditions but no eruption perturbation, was run for each of the individual eruption-perturbed ensemble simulations. Anomalies were calculated with respect to a climatological background constructed from the control ensemble mean.

135

**Table 1: Eruption Source Parameter values used in the ensemble simulations.**

Eruption Source Parameter	Ensemble Value
Volcanic stratospheric sulfur injection (VSSI)	119 Tg of SO <sub>2</sub>
Injection Height	18-20 km
Duration	24hrs
Latitude	8°S

## 2.2 Multi-Proxy Database of Surface Temperature Impacts

The proxy database (See Supplementary Sheets 1 and 2 for full details) was constructed by compiling records indicative of changes to climate (tree-ring chronologies, ice core records, lake sediments and historical sources) that span the range of dates proposed for the eruption with a minimum of annual resolution. Whilst the aim was to create a global database of proxy records, this was significantly impeded by the limited global distribution of all types of proxy records, which show a strong bias to the NH, European, and North American localities. No suitable data was found for this study from Africa or South America.

140

### 2.2.1 Tree-Ring Chronologies

We include 24 region-specific tree-ring studies, distributed predominantly across the NH, although two studies from Australia and New Zealand are included. The parameter used for temperature reconstruction varies between studies, as does the tree species analyzed and season of reconstruction depending on study location (see Supplementary Sheet 1 for details). SAT anomalies for 1258 and 1259 were taken either directly from the referenced study or calculated from reconstructed SAT anomalies using a background climatology which was constructed from the 10-year average prior to the eruption. Where studies reported that frost rings were present, they have also been included in the database.

150

In addition to the 24 region-specific studies, four NH spatially averaged reconstructions have also been incorporated (Wilson et al., 2016, Schneider et al., 2015, Büntgen et al., 2021, Guillet et al., 2017), along with the N-TREND reconstruction which is spatially resolved for the NH (Anchukaitis et al., 2017). For consistency in this study all tree-ring-reconstructed SAT anomalies are calculated from the 10-year average prior to 1257.

155

## 2.2.2 Ice Core Records

We include two ice core records of SAT derived from annually resolved  $\delta^{18}\text{O}$  isotope series. The first, from Greenland, record is from analysis by Guillet et al., (2017) who utilized three Greenland ice cores at GRIP, CRETE, and DYE3 (Vinther et al., 2010) to calculate an average SAT anomaly for 1258. The second, from Svalbard, is also derived from annually  
160 resolved isotope records and calibrated against instrumental measurements (Divine et al., 2017). Additional ice core records were investigated to expand this analysis such as the Illimani Ice Core in Bolivia and the Belukha Ice Core in Altai, Siberia; however, both records lacked the annual resolution required to constrain abrupt temperature changes associated with volcanic eruptions.

## 2.2.3 Lake Sediments

165 Two lake sediment records are also included from the Gulf of Alaska (Loso, 2008) and Baffin Island (Moore et al., 2001). Both studies measure sediment varve thickness, which varies annually, to calculate yearly summer SAT anomalies. Variations in varve thickness result from strong seasonal fluctuations in runoff and sediment fluxes during the summer melt season. Both studies demonstrate significant correlation between varve thickness and instrumentally measured June-July-August (JJA) Summer temperatures.

## 170 2.2.4 Historical Sources

Historical sources consist predominantly of medieval chronicles which refer to abnormal and/or extreme weather events in the years 1258-59. Analysis of medieval chronicles and economic records for the years 1258-59 by Guillet et al., (2017) form the basis of historical constraints in Europe. Additional chronicles include references from the Russian Annals in the Altai Mountains (Borisenkov and Pasetsky, 1988, Guillet et al., 2017), the Chronicle of Novgorod from Central Russia  
175 (Stothers, 2000), the Þorgils Saga Skarða in Iceland (Bierstedt, 2019), and Azuma Kagami from Japan (Farris, 2006). References to abnormally dark lunar eclipses are also included from the Chronicle of the Abbey of St. Edmunds (Stothers, 2000) and the Annales Ianuenses (Guillet et al., 2017). Additional historical sources across Europe, as well as some from the Middle East, report plague, famine, and economic crises for 1258-60 (Stothers, 2000). These sources have not been incorporated into the database as they refer to social and economic disturbances rather than making direct references to  
180 abnormal climatological phenomena.

## 2.3 Simulated SAT Anomalies

### 2.3.1 Northern Hemisphere Average

Spatially averaged NH summer land SAT anomalies were calculated for the mean of the nine July and January Ensembles respectively. Constraints were applied to model-simulated surface temperature outputs to make them most comparable to  
185 tree-ring reconstructions (Latitudes of 40°N-75°N, land only, June-July-August (JJA) was taken as representative of the

growth season.) Using four NH spatially averaged tree-ring chronologies (Wilson et al., 2016, Schneider et al., 2015, Büntgen et al., 2021, Guillet et al., 2017 – see Supplementary Document, Figure S1 for individual chronology comparison) a mean NH summer SAT anomaly timeseries was also calculated to which the model-simulated anomalies are compared.

### 2.3.2 Spatially Resolved Comparison

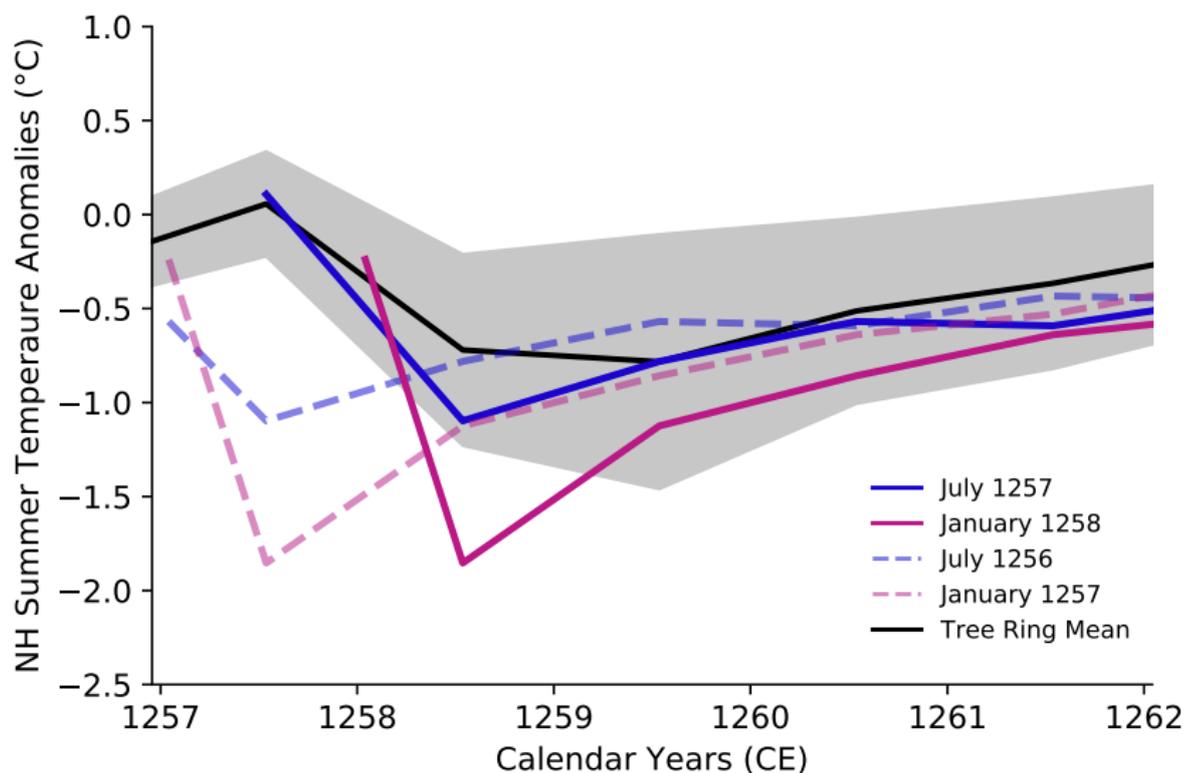

190 Spatially resolved model-simulated summer (JJA) SAT anomalies were calculated globally and for the NH between 1258-1259. This time window was chosen because the July 1257 and January 1258 ensemble simulations show the greatest divergence in SAT anomalies for Summers 1258-59. Model-simulated NH SAT anomalies were re-gridded and masked to facilitate more direct comparison with the N-TREND dataset (Anchukaitis et al., 2017). An analysis of variance (ANOVA) test was performed by eruption season to determine at which grid points the variance in means between the 1258 and 1259  
195 perturbed ensembles exceeded 95% significance relative to the control ensemble simulations, where the null hypothesis was that there was no difference between the mean grid point anomalies for the perturbed 1258 and 1259 ensembles compared to the control ensemble.

## 3. Results

### 3.1 Multi-Proxy to Model Comparison

#### 200 3.1.1 Northern Hemisphere

Figure 1 shows that the July 1257 ensemble mean (solid blue line) is the only eruption scenario to lie consistently within  $2\sigma$  of the tree-ring mean (grey band around the black line), with good agreement with tree-ring-reconstructed anomalies for both the timing and magnitude of peak cooling across the whole period (1257-1262). The January 1258 eruption ensemble mean (solid pink line) also results in peak cooling occurring in Summer 1258 although the magnitude of model-simulated cooling  
205 is much greater (by over  $1^{\circ}\text{C}$ ) than the peak tree-ring reconstructed cooling. Across individual January 1258 eruption ensembles (shown in Supplementary Document, Figure S2) only two lie within  $2\sigma$  of the tree-ring mean for the whole period. By contrast for the individual July 1257 eruption ensembles seven lie within  $2\sigma$  of the tree-ring mean for the whole period (Supplementary Document, Figure S3). Both July 1256 (dashed blue line) and January 1257 (dashed pink line) eruption scenarios result in peak cooling occurring a year early relative to the tree-ring-reconstructed mean and across both  
210 scenarios no individual ensemble members lie within  $2\sigma$  of the tree-ring mean for 1257-1260.

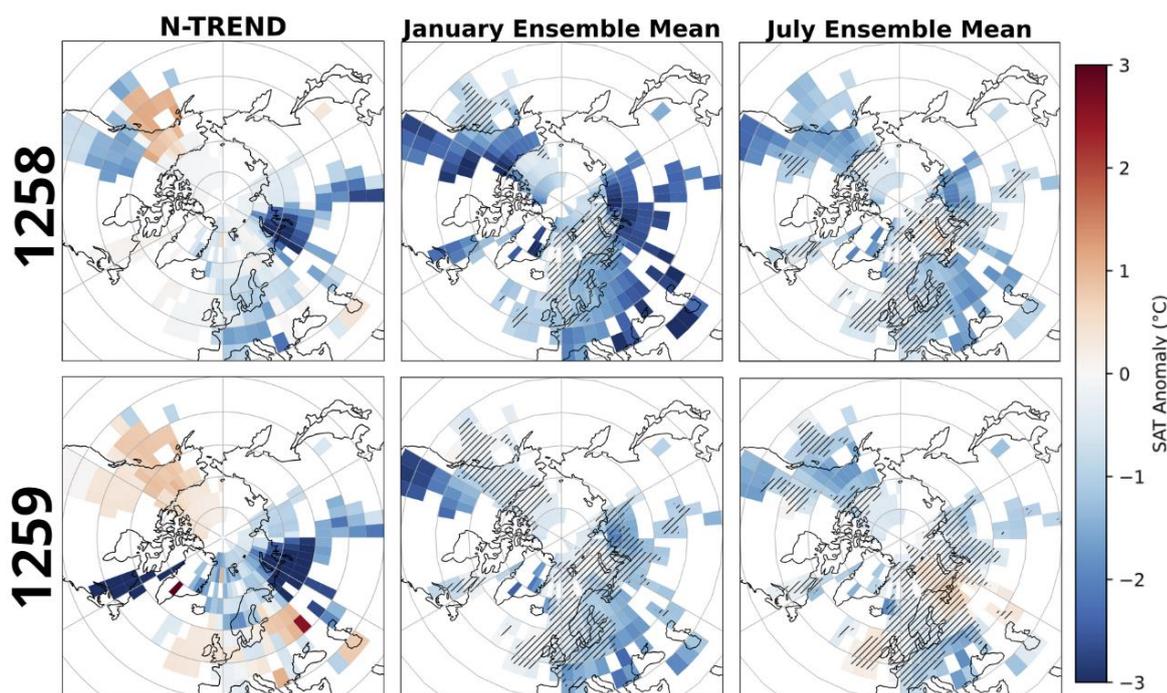

**Figure 1. NH Summer June-July-August Surface temperature anomalies. Blue: July ensemble mean. Pink: January ensemble mean. Solid and dashed lines indicate different eruption years. Black line shows the mean of the tree-ring-reconstructed summer surface air temperature anomalies and grey band shows  $2\sigma$  around the tree-ring mean. Tree-Ring data: Wilson et al., (2016), Schneider et al., (2015), Büntgen et al., (2021), Guillet et al., (2017). See Supplementary Sheet 2 for details of each tree-ring study.**

When compared to the N-TREND spatially resolved tree-ring reconstructed anomalies (first column in Figure 2) the July 1257 ensemble mean (third column in Figure 2) results in more consistent agreement with the magnitude and spatial distribution of SAT anomalies across the NH for Summers 1258 and 1259. For Summer 1258 the mean grid point difference between N-TREND reconstructions and the July 1257 Ensemble mean is  $+0.19$  ( $\sigma = 1.08$ ) whilst the difference with the January 1258 Ensemble mean is  $+0.78$  ( $\sigma = 0.99$ ), with the January 1258 ensemble mean (second column in Figure 2) tending to overpredict summer SAT anomalies relative to N-TREND reconstructions. Across the US West Coast and Central and Northern Europe N-TREND reconstructions suggest cooling of  $-1^{\circ}\text{C}$  to  $-2^{\circ}\text{C}$  whereas model-simulated anomalies for the January 1258 ensemble mean are on the order of  $-2^{\circ}\text{C}$  to  $-3^{\circ}\text{C}$ . By contrast the July 1257 ensemble mean shows widespread but more moderate negative SAT anomalies of  $-1^{\circ}\text{C}$  to  $-2^{\circ}\text{C}$  across the NH for Summer 1258 and thus achieves better agreement with N-TREND reconstructions. Nonetheless, model-simulated anomalies for the July 1257 mean suggest cooling

of up to  $-2^{\circ}\text{C}$  in Central and Northwest Asia which is an underprediction relative to N-TREND tree-ring reconstructions which suggest cooling of up to  $-3^{\circ}\text{C}$  in Summer 1258.

230

235

**Figure 2. Spatially resolved N-TREND-Model comparison for June-July-August average 1258-59 for the Northern Hemisphere (40-90°N). N-TREND data from Anchukaitis et al., (2017). First column shows N-TREND reconstructed summer surface temperature anomalies. Second column shows model-simulated summer surface temperature anomalies for the January 1258 ensemble mean and third column shows the same for the July 1257 ensemble mean. Hashed areas show regions of less than 95% significance as determined using a grid box ANOVA analysis.**

240

Greater regional variability is seen in N-TREND SAT anomalies for summer 1259. N-TREND reconstructions suggest negative SAT anomalies in Northern Eurasia and Quebec of up to  $-3^{\circ}\text{C}$  and between  $-1^{\circ}\text{C}$  to  $-2^{\circ}\text{C}$  in Northern Europe and Central Asia. Positive SAT anomalies of up to  $+1^{\circ}\text{C}$  are seen in Alaska and Western Europe. The January 1258 ensemble mean shows continued widespread negative anomalies of  $-1^{\circ}\text{C}$  to  $-3^{\circ}\text{C}$  across the whole NH and thus does not achieve consistent agreement with reconstructed anomalies across North and Western Europe, US West Coast or Alaska. By contrast, the July 1257 ensemble mean shows moderate positive SAT anomalies in Northern and Western Europe of up to  $+0.5^{\circ}\text{C}$  although still somewhat under predicts the magnitude of cooling in Central and Northern Asia and the US East coast relative to N-TREND reconstructions.

245

Notably neither the July 1257 or January 1258 ensemble mean achieves agreement with positive SAT anomalies reconstructed in Alaska for Summers 1258 and 1259. Across individual ensembles (See Supplementary Document, Figures S4-S7) only 1 July and 4 January ensembles show positive SAT anomalies in this region. Of these ensembles three are classified as having warm phase ENSO initial conditions. N-TREND reconstructions show moderate SAT anomalies in Alaska from 1255-56, with strong positive SAT anomalies first appearing in reconstructions for Summer 1257 (shown in Supplementary Document, Figure S8).

### 3.1.2 Globally Resolved Multi-Proxy Constraints

Multi-proxy-reconstructed SAT anomalies are shown in Figure 3 (top row) along with model-simulated SAT anomalies for a July 1257 eruption (second row) and a January 1258 eruption (third row) across Summers (JJA) 1258 (left) and 1259 (right). Overall, the July 1257 ensemble mean shows more consistent agreement with proxy SAT constraints across Europe, Asia, and North America, whilst the January 1258 ensemble mean tends to overpredict the magnitude of negative SAT anomalies relative to quantitative proxy constraints.

#### 260 Summer 1258

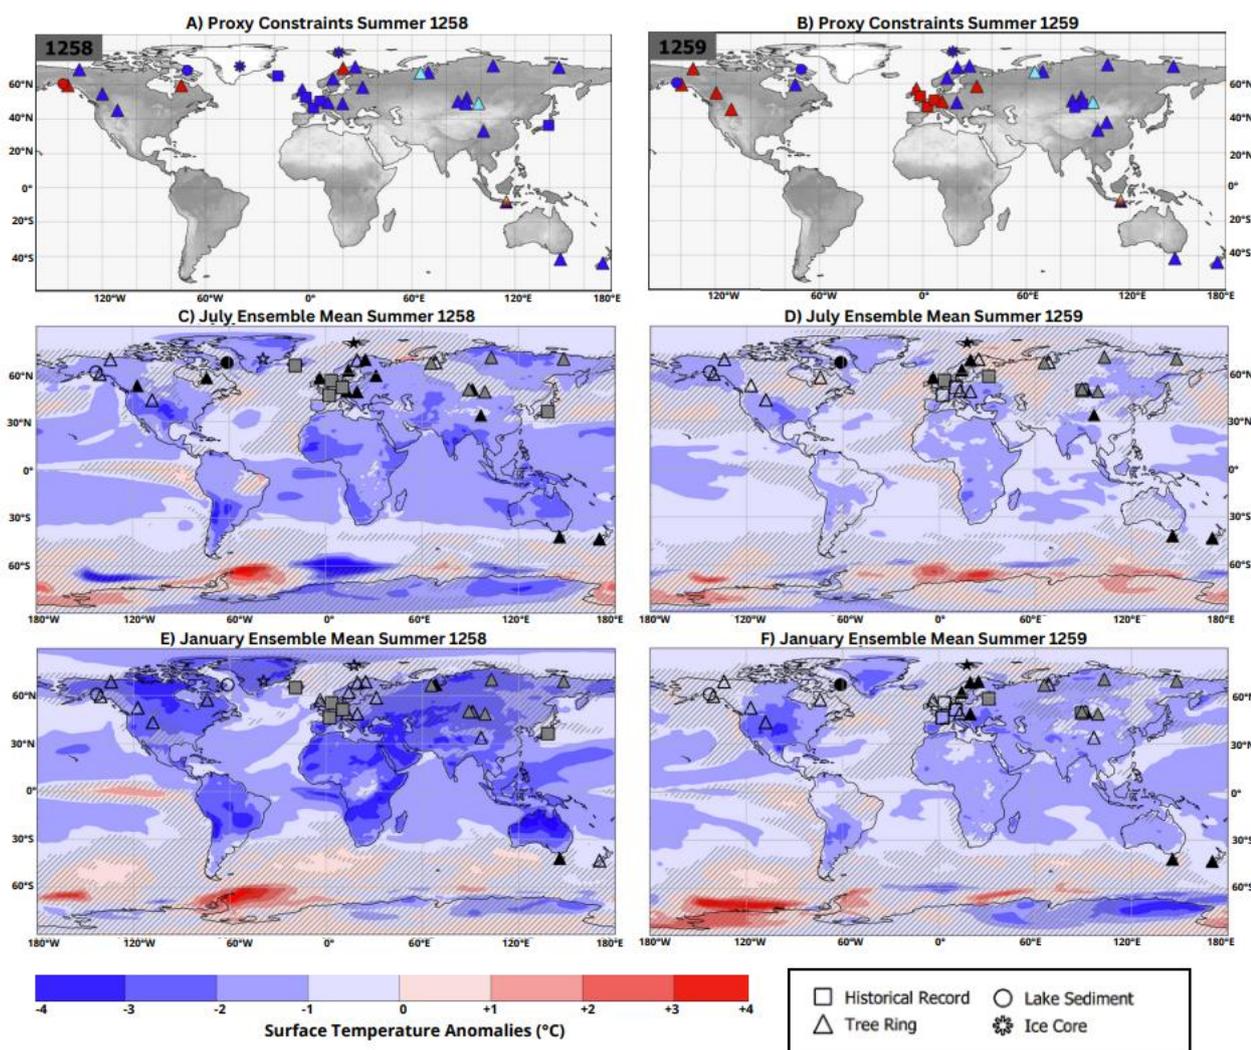

For Summer 1258 large negative SAT anomalies are well constrained across Central Asia, with tree-ring reconstructions suggesting cooling in the region of up to  $-0.4^{\circ}\text{C}$  in Tibet and  $-1.1^{\circ}\text{C}$  in Mongolia (Xu et al., 2019, Davi et al., 2015, Davi et al., 2021) as well as the presence of frost rings late in the 1258 growth season (D'Arrigo et al., 2001). In Japan the Mirror of the East refers to persistent cold and wet conditions. Negative SAT anomalies are constrained across northern Russia, with cooling up to  $-2.7^{\circ}\text{C}$  (Briffa et al., 2013), and frost rings also present in the Polar Urals, Siberia (Hantemirov et al., 2004). Both January 1258 and July 1257 model ensembles suggest strong cooling across Central and Northern Asia, however, only the July 1257 ensemble mean lies consistently within  $\pm 1^{\circ}\text{C}$  of the proxy constraints whilst anomalies of up to  $-4^{\circ}\text{C}$  for the January 1258 ensemble mean are an overprediction relative to proxy constraints (see filled symbols on Figures 3C and 3E).

270 Across Northern, Central, and Western Europe negative SAT anomalies are constrained by a combination of tree-ring reconstructions, with moderate cooling of up to  $-0.3^{\circ}\text{C}$  in Europe (Büntgen et al., 2011), and a multitude of medieval chronicles across France, Germany, and England which refer to cold and wet conditions (Guillet et al., 2017). The July 1257 ensemble shows SAT anomalies of up to  $-1^{\circ}\text{C}$  in good agreement with proxy constraints on the magnitude of cooling (see filled triangles across Europe in Figure 3C), whereas the January 1258 ensemble mean shows cooling between  $-2^{\circ}\text{C}$  and  $-3^{\circ}\text{C}$ . The Porgils Saga Skarða in Iceland also refers to abnormally cold and wet weather during 1258 (Bierstedt, 2019) with ice core reconstructions in Greenland supporting moderate negative SAT anomalies of around  $-0.1^{\circ}\text{C}$  (Guillet et al., 2017). January 1258 and July 1257 ensemble means suggest cooling of up to  $-3^{\circ}\text{C}$  and  $-2^{\circ}\text{C}$  respectively and so both overpredict the magnitude of cooling across Greenland.

280 SAT anomalies are more variable across North America with reconstructions in Eastern Canada showing both positive and  
 negative SAT anomalies of 0.09°C and -1.6°C respectively (Gennaretti et al., 2014, Moore et al., 2001). The July 1257  
 ensemble shows agreement with both proxy constraints suggesting cooling of up to -2°C on Baffin Island and showing no  
 significant SAT anomaly in the Quebec region, whilst the January 1258 ensemble mean shows cooling of up to -3°C and  
 thus overpredicts cooling in both regions. Tree-ring reconstructions in the Western US and Canadian Rockies suggest  
 285 negative SAT anomalies of up to -0.5°C and -1.6°C (Martin et al., 2020, Luckman et al., 2005). The January 1258 ensemble  
 overpredicts the magnitude of cooling relative to proxy constraints with SAT anomalies of up to -3°C whilst the July 1257  
 ensemble mean shows more moderate anomalies of up to -2°C. Positive SAT anomalies are well constrained by both lake  
 sediment and tree-ring reconstructions in the Gulf of Alaska with warming of up to 0.1°C and 0.9°C (Loso, 2008, Wiles et  
 al., 2014), however, neither January 1258 nor July 1257 ensemble means show positive SAT anomalies in this region.

290

**Figure 3: (a)-(b) Globally resolved multi-proxy database visualized for summers 1258 and 12-59. Symbols denote proxy data type, where blue/red shading denotes absolute negative or positive anomalies, respectively. (c)-(f) Globally resolved surface air temperature anomalies for summers (June-July-August) 1258 (left) and 1259 (right) for July 1257 eruptions (middle) and January 1258 eruptions (bottom) ensemble means. Surface air temperature anomalies were calculated relative to a 10-year background climatology constructed from the control ensemble mean. Hashed lines denote anomalies at <95% significance as determined by a grid point ANOVA analysis. Black filled symbols denote agreement within +/- 1°C between model-simulated anomalies and quantitative proxy records. Grey filled symbols denote agreement with qualitative proxy records.**

300

### Summer 1259

Persistent strong negative SAT anomalies are well constrained for Central Asia with tree-ring reconstructions suggesting continued cooling of up to -2.3°C in Mongolia and -0.3°C in Tibet (Davi et al., 2015, Xu et al., 2019) as well as frost rings present early in the 1259 growth season (Churakova et al., 2019, D'Arrigo et al., 2001). The Russian Chronicle of Novgorod refers to abnormal summer snowfall in the Altai mountains and unusual summer frost days (Stothers, 2000, Borisenkov and Pasetsky, 1988) with tree-ring reconstructions showing continued negative SAT anomalies across Northern Russia of up to -4°C (Briffa et al., 2013). Both January 1258 and July 1257 ensemble means show moderate negative anomalies of between -1°C and -2°C in Central Asia, however, only the January 1258 ensemble mean shows stronger negative SAT anomalies of up to -3°C in Northern Russia whilst anomalies for the July 1257 ensemble mean do not exceed 95% significance. Tree-ring reconstructions show some positive SAT anomalies across Central Europe of up to 0.2°C (Büntgen et al., 2011) and in Western Europe medieval chronicles refer to a hot and dry summer (Guillet et al., 2017). Very moderate SAT anomalies across Europe are only shown by the July 1257 ensemble mean, whilst the January 1258 ensemble continues to show cooling in the region of up to -2°C.

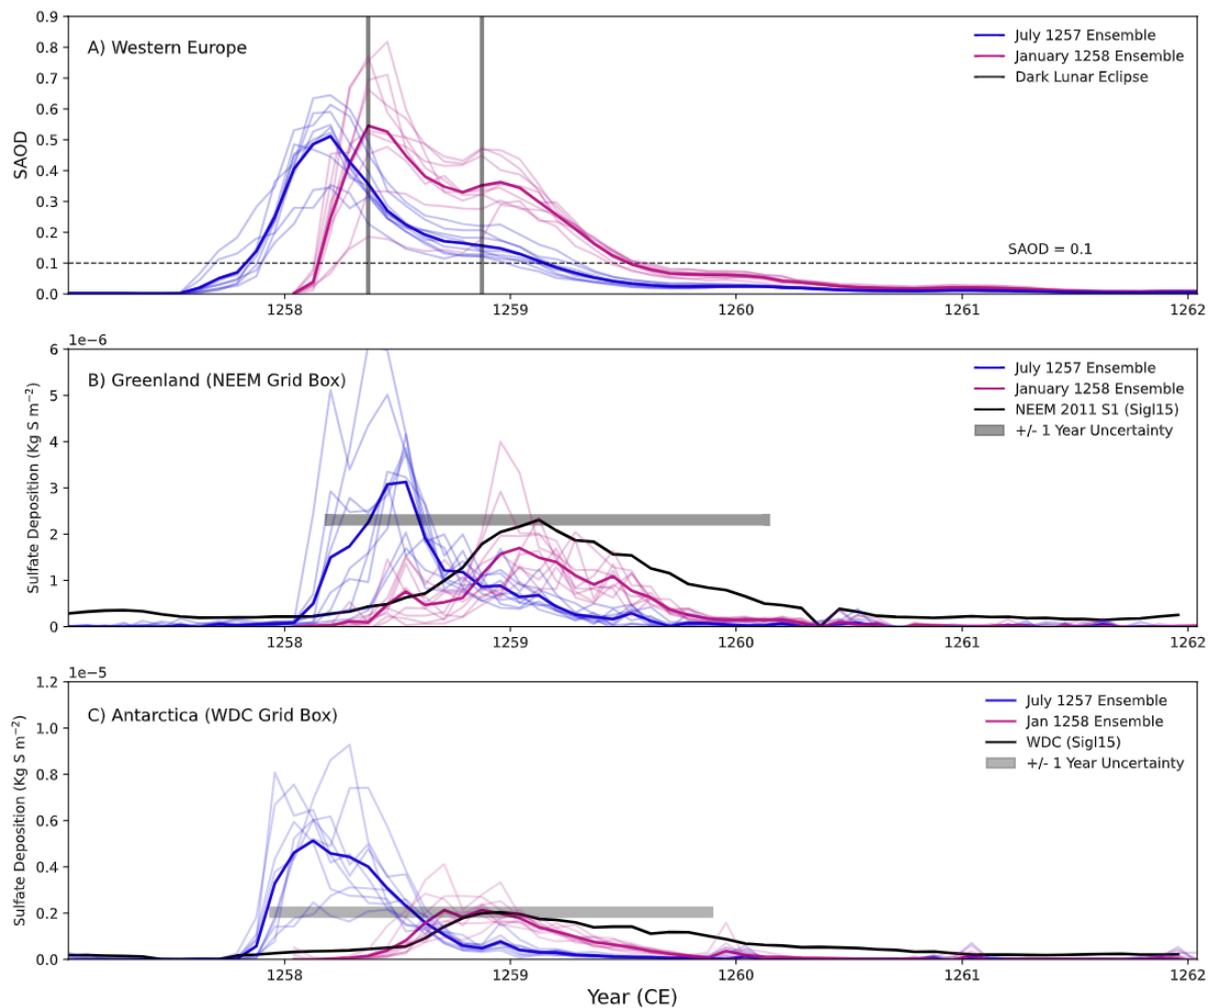

Negative SAT anomalies persist across Eastern North America with cooling of up to -2.6°C and -1.6°C constrained from tree-ring and lake sediment reconstructions respectively (Gennaretti et al., 2014, Moore et al., 2001). Cooling of up to -2°C is shown by both ensemble means across Baffin Island (NE Canada), however, neither ensemble achieves agreement with the stronger cooling signal in Quebec. Along the Western coast of North America tree-ring reconstructions yield positive SAT anomalies of up to +0.8°C in the Missouri River Basin and +0.3°C in the Canadian Rockies (Martin et al., 2020, Luckman et al., 2005). Both ensembles continue to show cooling along the US West Coast although the magnitude is more moderate for the July 1257 ensemble. In the Gulf of Alaska there is some discrepancy as tree-ring reconstructions suggest continued positive SAT anomalies of up to +0.7°C whilst lake sediment reconstructions suggest moderate negative SAT anomalies of up to -0.1°C (Loso, 2008, Wiles et al., 2014). The January 1258 ensemble mean shows no anomalies exceeding 95% significance in Alaska whilst the July 1257 ensemble mean shows continued cooling of up to -2°C and so neither eruption scenario achieves good agreement with proxy constraints.

325

### 3.2 Re-evaluating Evidence for a January 1258 Eruption Date

Two lines of evidence have previously been invoked for a January 1258 eruption date: references in medieval chronicles to a “dark lunar eclipse” in mid-May 1258 (Stothers, 2000) and peak sulfate fall out in Greenland Ice Cores in early 1259 (Zielinski et al., 1994). Figure 4a shows model-simulated Stratospheric Aerosol Optical Depth (SAOD) averaged across western Europe for the years following the eruption. Marked by the grey lines are the dark lunar eclipses of May 1258 and Nov 1258 identified by Stothers (2000) in the Bury Saint Edmunds Abbey chronicle and Guillet et al., (2017) in the Annales Ianuenses respectively, where for the moon to appear dark an SAOD > 0.1 is needed (Stothers, 2000). Whilst a January 1258 eruption scenario does result in a later SAOD peak, both a July 1257 and a January 1258 eruption result in SAOD >> 0.1 during both May and November 1258 and therefore either eruption scenario could account for observations of darkened lunar eclipses.

**Figure 4: A) Model-simulated Stratospheric Aerosol Optical Depth (SAOD) timeseries averaged across Western Europe (Lat: 40-60°N, Longitude: 10W-10°E) for July 1257 (blue line) and Jan 1258 (pink line) eruption scenarios where bold lines are the ensemble means. Vertical grey bars denote historical records of dark lunar eclipses in May 1258 (England) and November 1258 (Genoa). The dashed horizontal line at SAOD = 0.1 denotes the minimum SAOD required for a dark lunar eclipse. B-C) Model-simulated sulfate deposition (kg S m<sup>-2</sup>) over Greenland and Antarctica ice sheets for July 1257 (Blue) and January 1258 (Pink) eruption scenarios. The region of deposition is limited to the single model grid box containing NEEM (Greenland) and WDC (Antarctica) ice core drill sites respectively. Black lines are timeseries from NEEM and WDC ice core records respectively (Sigl et al., 2015) with grey bars showing +/- 1-year uncertainty for the timing of peak deposition.**

Figures 4B and 4C show model-simulated sulfate deposition across Greenland and Antarctic ice sheets at the single grid-boxes containing WDC and NEEM ice cores respectively, for July 1257 and January 1258 eruption scenarios. Additional sulfate deposition timeseries are derived from NEEM and WDC ice cores respectively (Sigl et al 2015). See Supplementary Figure S10 for ice sheet-averaged model-simulated sulfate deposition across Greenland and Antarctica. The July 1257 ensemble shows peak deposition occurring in early to mid-1258, whilst the January 1258 ensemble shows peak deposition in early 1259, which is in better alignment with Greenland and Antarctic ice core records. Nonetheless, the resolution of the ice core age uncertainty (+/- 1 year as shown by the grey shading) of the timing of peak deposition is less than the 6-month offset between model-simulated deposition timeseries, meaning these ice core constraints cannot robustly distinguish the difference in timing of peak deposition between eruption scenarios. Moreover, although the magnitude of deposition for the January 1258 ensemble mean is most comparable to the ice core records, particularly in Antarctica, across both eruption scenarios there are individual ensembles which show agreement with the magnitude of peak deposition within the grid boxes containing the WDC and NEEM ice core records.

## 4. Discussion

### 4.1 Constraining the Eruption Year and Season of the Mt. Samalas eruption

As shown in Figure 1, both July 1256 and January 1257 eruption scenarios result in peak surface cooling occurring a year too early relative to reconstructed SAT anomalies. Thus, an early eruption date such as Spring 1256, as proposed by Bauch (2019), is unfeasible for the Mt. Samalas eruption. Across the two remaining eruption scenarios only the July 1257 eruption ensemble lies consistently within  $2\sigma$  of the tree ring-reconstructed mean between 1258-1262. By contrast, the January 1258 eruption ensemble results in peak cooling being over 1°C greater than tree ring reconstructions for Summer 1258.

When compared with spatially resolved N-TREND reconstructions model-simulated SAT anomalies for the January ensemble mean continue to consistently overpredict the magnitude of cooling for both 1258 and 1259 across the NH. Whilst

the spatial agreement of SAT anomalies for the July 1257 ensemble mean does not precisely replicate those reconstructed  
370 from the N-TREND tree ring record it does show widespread but less extreme negative SAT anomalies across the NH and  
thus achieves better agreement with reconstructed anomalies on a regional basis. This is confirmed by comparison between  
globally resolved model-simulated ensemble mean SAT anomalies and multi-proxy-reconstructed anomalies where the  
January 1258 ensemble mean consistently over predicts the magnitude of cooling in key regions across Europe, Central Asia,  
and the US, whilst the July 1257 ensemble mean results in better agreement across these regions with more moderate  
375 negative SAT anomalies.

A re-evaluation of evidence for a January 1258 eruption finds that a Summer 1257 eruption can satisfy constraints from both  
ice core records and historically documented dark lunar eclipses. Simulated ice sheet sulfate deposition show that for  
eruption scenarios 6 months apart there is a distinguishable off-set in the timing and magnitude of deposition, with the bi-  
380 polar ratio between northern and southern hemisphere ice sheets varying depending on eruption season. Nonetheless, these  
ice core sulfate records currently have insufficient resolution to discriminate between January and July eruption scenarios for  
the Mt. Samalas eruption with implications for VSSI estimates (see Section 4.3).

Overall, the multi-proxy to model comparison utilized in this study provides a clear distinction between July 1257 and  
385 January 1258 eruption scenarios in both the magnitude and spatial distribution of SAT anomalies. The better agreement  
between proxy reconstructions and model-simulated anomalies for a July 1257 eruption provides strong support for a  
Summer 1257 date for the Mt. Samalas eruption.

#### 4.2 Regionally Heterogenous Climate Response

Multi-Proxy SAT reconstructions highlight the regionally heterogenous climate response following the Mt. Samalas  
eruption. The largest negative SAT anomalies occur across Central Asia and Northern Russia, with cooling of  $-2^{\circ}\text{C}$  to  $-4^{\circ}\text{C}$   
390 between 1258 and 1259, making these as some of the most severely impacted regions in the NH. The role of sudden and  
severe cooling associated with the Mt. Samalas eruption in the decline of the Mongol Empire is therefore plausible (Kern et  
al., 2021). Alongside references to extreme and abnormal weather conditions, the Azuma Kagami in Japan also highlights  
the severity of the Shôga famine between 1257-60 (Farris, 2006). Model-simulated cooling of up to  $-1^{\circ}\text{C}$  across Japan  
395 suggest the severity of this famine could have been amplified by the climate response to the Mt. Samalas eruption in 1258-  
59. Similar evidence exists in the Middle East with famine and pestilence reported across Syria, Iraq, and Southern Turkey in  
1258 (Stothers, 2000). A model-simulated July 1257 eruption scenario suggests cooling of up to  $-2^{\circ}\text{C}$  in the region and thus  
supports a possible association with the Mt. Samalas eruption. Reconstructed and model-simulated SAT anomalies suggest  
less severe cooling across Europe for 1258 ( $<-1^{\circ}\text{C}$ ) and relative warming in the region for 1259. Nonetheless, this is still  
400 associated with significant economic and social disturbances, with historical records reporting famine and social unrest  
(Guillet et al., 2017, Stothers, 2000).

Büntgen et al., (2022) find negative TRW growth anomalies along the US West Coast for Summer 1257 and suggest this is evidence for the onset of climate perturbations in the NH before the end of the 1257 growth season and for a Summer 1257 eruption date. Model-simulated anomalies for a July 1257 eruption, however, show no significant anomalies occurring across the US or NH during Summer 1257 (see Supplementary Document, Figure S9). Instead, model-simulated SAT anomalies for a July 1257 eruption only show significant negative SAT anomalies across South America, Africa, and Oceania beginning in Late Summer 1257 with cooling in some regions of up to  $-2^{\circ}\text{C}$ . Such extreme sudden cooling would be expected to have significant, but as yet unknown, consequences for communities and civilizations in the Southern Hemisphere. For example, the first settlement of New Zealand most likely occurred between 1250–1275, with suggestions this may have reflected a climate-induced migration associated at least in part with the impacts of the Mt. Samalas eruption (Anderson, 2016, Bunbury et al., 2022). Apart from recent analysis of the localized impacts and recovery following the Mt. Samalas eruption (Malawani et al., 2022) the general sparsity of currently available proxy data across the SH precludes definitive conclusions as to climate and social response in the SH following the Mt. Samalas eruption.

415

Notably, neither the January 1258 or July 1257 ensemble mean replicates reconstructed positive SAT anomalies in Alaska for Summer 1258 or the wider US west coast for Summer 1259. Across individual eruption ensembles only 5 show positive SAT anomalies in this region and of these ensembles 3 are classified as having warm phase ENSO initial conditions. N-TREND spatially resolved reconstructions show positive SAT anomalies over Alaska from Summer 1257–59, with warm phase El Niño-like conditions during this period being supported by positive tree ring-reconstructed temperature anomalies in Alaska (Guillet et al., 2017) and the muted absolute temperature signal seen in  $\delta^{18}\text{O}$  coral reconstructions from the central tropical Pacific (most likely explained by the superposition of a volcanic cooling signal and a warm El Niño-like signal (Dee et al. 2020, Robock 2020)). The role of volcanic eruptions in perturbing ENSO remains debated (Mann et al. 2005, Stevenson et al. 2018, Dee et al. 2020, Robock 2020) although climate simulations and proxy records suggest an increased probability for the occurrence of an El Niño event in the first or second year after a large volcanic eruption (see McGregor et al 2020 for a full review). El Niño-like warm conditions may therefore have prevailed at the time of the Mt. Samalas eruption with subsequent volcano-ENSO interactions potentially acting to enhance these pre-existing El Niño-like conditions.

425

#### 4.3 Model and Proxy Limitations

The January 1258 ensemble mean consistently over-predicts the magnitude of cooling relative to proxy-reconstructed anomalies by around  $1^{\circ}\text{C}$ . As such a January 1258 eruption data can only be considered feasible if proxy-reconstructions are thought to under-record the magnitude of cooling following large eruptions. The possible effect of chronological errors resulting from missing growth rings due to extreme cooling following large eruptions has been highlighted (Mann et al., 2012), as well as the need to correct tree ring reconstructions for the effect of increased diffuse light due to enhanced

430

435 scattering (Robock, 2005). Lücke et al., (2019) also highlight the importance of accounting for biologically based memory  
effects, which can lead to dampening of volcanic cooling signals especially in ring width-based chronologies. Nonetheless,  
tree-ring data has been shown to record extreme cooling events synchronous with evidence for explosive volcanic eruptions  
over the last two millennia without chronological errors (Stoffel et al., 2015) and in good agreement with instrumental  
observations following large eruptions (Esper et al., 2013), where the inclusion of maximum latewood density (MXD) data  
440 has reduced attenuation of the volcanic cooling signal (Esper et al., 2014, Stoffel et al., 2015).

Alternatively, model-simulated anomalies may be overpredicting the magnitude of cooling following large volcanic  
eruptions. Timmreck et al., (2009) highlighted the strong dependence of model-simulated post-eruption climate responses  
following large volcanic eruptions on the aerosol particle size distribution due to self-limiting effects of larger particles  
445 (Pinto et al., 1989). Particle characteristics are difficult to constrain retrospectively for historic eruptions such as Mt. Samalas  
and thus represent one of the most significant uncertainties with modelling historic eruptions, nonetheless, processes such as  
particle coagulation are accounted for by the aerosol microphysics scheme applied in model simulations for this study. There  
is also uncertainty as to the VSSI, which could have been overestimated in our simulations. Injection height was also held  
constant, also a key parameter in modulating the post-eruption climate response (Robock, 2000, Stoffel et al., 2015). The  
450 values chosen for the SO<sub>2</sub> emission and injection height are consistent with current best estimates for the Mt. Samalas  
eruption although there remains uncertainty as to their exact values. Stoffel et al., (2015) found that increasing plume height  
from 22-26 km to 33-36 km increased the magnitude of the peak post-eruption NH JJA temperature anomaly to -4°C for a  
January eruption and -1°C and -2°C for May and July eruption scenarios respectively. A higher plume height than the 20km  
used in our study would therefore likely further enforce our central conclusion that better agreement between proxy and  
455 model temperature anomalies is achieved for a summer 1257 eruption date, whilst a greater plume height for a January 1258  
eruption would only further overpredict the magnitude of post-eruption cooling.

Proxy records able to reconstruct hydroclimate anomalies (such as stalagmite and tree ring records) were investigated as  
additional constraints in our study (See Supplementary Figures S11 and S12), although most lacked the annual resolution  
460 required for direct comparison to model outputs. Previous studies utilizing tree-ring reconstructed hydroclimate anomalies  
have suggested moderately wetter conditions in the SH during 1258, potentially indicative of a southward ITCZ shift  
(Tejedor et al., 2021, Büntgen et al., 2022). Nonetheless, without a greater distribution of annually resolved proxy records  
able to reconstruct tropical hydroclimate anomalies, definitive conclusions as to the ITCZ and global hydroclimate response  
following the Mt. Samalas eruption remain elusive.

465 Model-simulated ice sheet sulfate deposition (Fig. 4) shows a clear distinction between January and July eruption scenarios  
in both the timing and hemispheric distribution of deposition. For the same stratospheric SO<sub>2</sub> injection, an eruption during  
NH summer results in more pronounced asymmetric polar deposition, with the magnitude of peak deposition in Antarctica

(see Supplementary Figure S10) being nearly a factor of 3x greater than for an eruption during the SH summer, likely due to  
470 the stronger branch of the Brewer-Dobson circulation and seasonal effects on aerosol transport and depositional processes.  
This highlights that for a given deposition there is the potential for non-unique VSSI estimates depending on the season of  
eruption. As such, this represents an uncertainty when reconstructing VSSI from ice core sulfate deposition for eruptions  
such as Mt. Samalas where the season of eruption is unconstrained (Marshall et al., 2021). Moreover, the +/-1 year age  
475 uncertainty of the NEEM and WDC ice core records (Sigl et al., 2015) meant they were unable to clearly distinguish  
between January and July eruption scenarios thus suggests that, at least until higher temporal resolution is possible in ice  
core records, they are an unsuitable tool to constrain eruption season for Common Era eruptions such as Mt. Samalas.

## 5 Conclusions

We have utilized eighteen aerosol-climate UKESM1 ensemble simulations for the 1257 Mt. Samalas eruption in  
combination with the most complete globally resolved multi-proxy database to date for the Mt. Samalas eruption. This  
480 allowed more precise constraints on the year and season as well as the regionally heterogeneous climate response following  
the Mt. Samalas eruption. Comparison with NH averaged and spatially resolved tree ring reconstructions showed that a  
Summer 1257 eruption scenario agrees best with reconstructed SAT anomalies, with a January 1258 eruption consistently  
over predicting the magnitude of cooling relative to reconstructions. The regionally variable SAT response following the  
eruption is revealed by multi-proxy reconstructions which lend support to inferred social, economic and historical  
485 consequences across Europe and Asia following the eruption. Model-simulated SAT anomalies also suggest the onset of  
sudden a severe cooling across the SH, with the potential for significant social and economic consequences in impacted  
communities across South America, Africa, and Oceania. The spatial distribution of SAT anomalies shows some sensitivity  
to initial atmospheric-ocean conditions, with positive SAT anomalies in Alaska being potentially indicative of warm El  
Niño-like conditions at the time of the eruption, with potential ENSO-Volcano interactions enhancing these conditions  
490 further.

Overall, the proxy to model comparison employed in this study has been shown as an effective approach to constrain  
uncertain eruption source parameters. This framework therefore has significant potential in similar applications to constrain  
unknown initial conditions and regional climatic impacts for other historic eruptions with sufficient concurrent proxy  
495 evidence. A greater global distribution of proxy evidence, especially in the Southern Hemisphere where all types of proxy  
evidence are sparse, will strengthen this proxy-model framework approach for future analysis. The incorporation of  
hydroclimate anomalies in particular has the potential to add further independent constraints, although relies on the  
development of higher resolution records, especially at low latitude sites. A re-evaluation of the application of the use of ice  
core sulfate records to estimate eruption season and VSSI also highlights current limitations in the approach. This is due to  
500 insufficient seasonal resolution in ice core records and seasonal effects on global aerosol distribution which in our

simulations results in different deposition signatures (e.g. in the timing, peak deposition, and total magnitude) for each season for the same VSSI.

505 Finally, both proxy-reconstructed and model-simulated temperature anomalies highlight the severity of the global climate response following a large tropical explosive eruption, with historical records confirming widespread and severe economic and social consequences. This adds further weight to recent calls (Cassidy and Mani, 2022) for increased global preparedness for the next large magnitude explosive volcanic eruption, given profound global consequences that would be expected, as clearly demonstrated by the Mt. Samalas eruption.

#### 510 **Data Availability**

Summary model output is currently being uploaded to the CEDA archive.

#### **Supplement**

The supplement related to this article is available online at:

515

#### **Author Contributions**

LW, LM, and AS jointly conceived the project methodology. LM ran the UKESM model simulations. LW performed the analysis, visualisation, and writing of the manuscript with supervision from LM and AS. All authors jointly reviewed and edited the paper.

520

#### **Competing Interests**

The authors declare that they have no conflict of interest.

#### 525 **Acknowledgements**

This research formed part of LWs MSci Thesis at the University of Cambridge. LW would like to thank O. Shorttle and E. Harper for their additional supervision and encouragement throughout this project, as well as Newnham College for supporting the presentation of this work through a travel bursary. LM and AS acknowledge support from NERC grant NE/S000887/1 (VOL-CLIM), and AS additionally acknowledges funding from NERC grant NE/S00436X/1 (V-PLUS). The authors would also like to thank M. Sigl and K. Anchukaitis for providing ice core and tree ring data sets utilized in this project, and N.L Abraham for technical modelling support. This work used the ARCHER UK National Supercomputing Service (<http://www.archer.ac.uk>) and JASMIN, the UK collaborative data analysis facility.
