20 **Abstract:** Understanding the near-ground vertical and temporal photochemical O₃
21 formation mechanism is important to mitigate O₃ pollution. Here, we measured the
22 vertical profiles of O₃ and its precursors at six different heights ranging from 5 to 335
23 m using a newly built vertical observation system in the Pearl River Delta (PRD) region,
24 China. The net photochemical ozone production rate ($P(O_3)_{net}$) and O₃ formation
25 sensitivities at various heights were diagnosed using an observation-based model
26 coupled with the Master Chemical Mechanism (MCM v3.3.1). Moreover, to assess
27 model performance and identify the causative factors behind O₃ pollution episodes, the
28 $P(O_3)_{net}$ was measured at 5 m ground level utilizing a custom-built detection system. In
29 total three O₃ pollution episodes and two non-episodes were captured. The identified
30 O₃ pollution episodes were found to be jointly influenced by both photochemical

31 production and physical transport, with local photochemical reactions playing a major
32 role. The high index of agreement (IOA) calculated from comparing the modelled and
33 measured $P(O_3)_{net}$ values indicated the rationality to investigate the vertical and
34 temporal variability of O_3 formation mechanisms using modelling results. However,
35 the measured $P(O_3)_{net}$ values were generally higher than the modelled $P(O_3)_{net}$ values,
36 particularly under high NO_x conditions, which may indicate a potential
37 underestimation of total RO_2 by the model. Throughout the measurement period, the
38 contribution of different reaction pathways to O_3 production remained consistent across
39 various heights, with HO_2+NO as the major O_3 production pathway, followed by
40 RO_2+NO . We observed $P(O_3)_{net}$ decreasing with the increase in measurement height,
41 primarily attributed to the decreased O_3 precursors anthropogenic volatile organic
42 compounds (AVOC) and oxygenated volatile organic compounds (OVOC). O_3
43 formation regimes were similar at different heights during both episodes and non-
44 episodes, either located in the volatile organic compounds (VOCs) sensitive regime or
45 in the transition regime and more sensitive to VOCs. Diurnally, photochemical O_3
46 formation typically remained in the VOCs sensitive regime during the morning and
47 noon, but transitioned to the transition regime and more sensitive to VOCs in the
48 afternoon around 16:00 local time (LT). The vertical and temporal O_3 formation is most
49 sensitive to AVOC and OVOC, suggesting that targeting VOCs, especially AVOC and
50 OVOC, for control measures is more practical and feasible at the observation site. The
51 vertical temporal analysis of O_3 formation mechanisms near the ground surface in this
52 study provides critical foundational knowledge for formulating effective short-term
53 emergency and long-term strategies to combat O_3 pollution in the PRD region of China.

54 1. Introduction

55 Tropospheric ozone (O_3), which has adverse effects on ecosystems, climate
56 change, and human health (Fiore et al., 2009; Anenberg Susan et al., 2012; Seinfeld,
57 2016), has become an important factor resulting in severe regional air pollution in China
58 (Zhu et al., 2020). Tropospheric O_3 mainly comes from stratospheric intrusions and the
59 photochemical reactions of O_3 precursors, involving volatile organic compounds
60 (VOCs) and nitrogen oxides ($NO_x=NO+NO_2$). The O_3 -precursor relationship can be
61 split into a “ NO_x -limited” or “VOC-limited” or “mixed-sensitive” regime (Seinfeld and
62 Pandis, 2016; Sillman S., 1999). A “ NO_x -limited” regime has higher VOCs/ NO_x ratios
63 and the O_3 formation is sensitive to NO_x concentration changes, while a “VOCs-limited”

64 regime has lower VOCs/NO_x ratios and the O₃ formation is sensitive to VOCs
65 concentration changes. In a “mixed-sensitive” regime, O₃ formation responds
66 positively to changes in both NO_x and VOC emissions (Wang et al., 2019). Local O₃
67 concentrations can be further influenced by meteorological conditions and the regional
68 transport of O₃ and its precursors (Gong and Liao, 2019; Chang et al., 2019). The Pearl
69 River Delta (PRD) stands out as one of the most rapidly developing economic and
70 urbanized regions in China, which currently is suffering from severe ground-level O₃
71 pollution (Lu et al., 2018; Yang et al., 2019). Currently, many scholars have analyzed
72 the relationship between tropospheric O₃ pollution and its precursors and
73 meteorological elements in the PRD region, results show that the surface O₃ pollution
74 is determined by both local photochemistry and physical transport, with long-range
75 transport contributing 30%-70% to surface O₃ concentrations (Mao et al., 2022; Shen
76 et al., 2021; Li et al., 2012, 2013). However, the distribution of O₃ is highly variable at
77 different altitudes (Wang et al., 2021), due to vertical differences in VOCs
78 concentrations and sources, as well as the sensitivity of O₃ formation (Liu et al., 2023;
79 Tang et al., 2017). Due to the presence of strong vertical mixing driven by the surface
80 heating effect in the daytime boundary layer, the budget of the O₃ at the ground level
81 and also at an arbitrary height in the daytime boundary layer is closely related to the
82 formation and removal of O₃ at other heights (Tang et al., 2017). In addition, the
83 difference in vertical gradients of precursors may drive the vertical change in the
84 photochemical formation regimes of O₃ (Zhao et al., 2019). Using data from only one
85 height to understand the photochemical reactions in the planetary boundary layer is of
86 great limitation. Thus, diagnosing the O₃ formation mechanism at different heights is
87 essential to achieve effective control of O₃ pollution.

88 Currently, remote sensing techniques with high time resolution and real-time
89 response, such as lidar and optical absorption spectroscopy, have been utilized to
90 measure the vertical distribution of O₃ (Luo et al., 2020a; Wang et al., 2021). However,
91 in situ measurements of VOCs at various heights primarily rely on offline methods
92 combined with diverse techniques, including aircraft, tethered balloons, tall buildings
93 and towers, unmanned aerial vehicles (UAVs or drones), and satellite observations
94 (Klein et al., 2019; Li et al., 2022; Geng et al., 2020; Benish et al., 2020; Li et al., 2021;
95 Wang et al., 2019). Owing to the low time resolution of these monitoring techniques,
96 achieving continuous vertical coverage of VOCs and NO_x measurements is challenging.

97 Consequently, the vertical distribution structure of VOCs remains unclear, thus largely
98 hindering our understanding of the vertical and temporal regional O_3 formation
99 mechanism.

100 To fill the gaps in the existing studies, we utilized a newly constructed vertical
101 observation system based on the Shenzhen Meteorological Gradient Tower (SZMGT)
102 (Li et al., 2023). This system measured the vertical profiles of O_3 and its precursors at
103 six different heights from 5 to 335 m. To diagnose the net O_3 production rate, $P(\text{O}_3)_{\text{net}}$,
104 and O_3 formation sensitivities across various heights, we employed an observation-
105 based model coupled with the Master Chemical Mechanism (MCM v3.3.1), referred to
106 as OBM-MCM in the following. Additionally, we employed a novel net photochemical
107 O_3 production rate ($P(\text{O}_3)_{\text{net}}$, NPOPR) detection system to measure the $P(\text{O}_3)_{\text{net}}$ at the 5
108 m ground level to explore potential reasons for O_3 pollution episodes (Hao et al., 2023),
109 i.e., examine the contribution of chemical and physical processes to changes in O_3
110 concentration. Comparisons between the directly measured $P(\text{O}_3)_{\text{net}}$ results and the
111 model-derived data enabled us to evaluate the simulation accuracy and explore potential
112 reasons for discrepancies of the OBM-MCM model concerning photochemical O_3
113 formation. Based on these results, we have extensively discussed the vertical and
114 temporal variability in $P(\text{O}_3)_{\text{net}}$ and O_3 formation sensitivity, while acknowledging
115 potential biases associated to the modelling. The findings of this study offer a new
116 benchmark for understanding the vertical profile of photochemical O_3 formation
117 mechanism, aiding in the identification of the primary driver of ground-level O_3
118 pollution. This identification is crucial as it can provide essential theoretical support for
119 developing short-term effective emergency and long-term control measures targeting
120 O_3 in PRD region of China.

121 **2. Materials and Methods**

122 **2.1 Sampling site**

123 Field measurements were conducted at the Shenzhen Meteorological Gradient
124 Tower (SZMGT) (22.65° N, 113.89° E) from November 13 to December 10, 2021. The
125 SZMGT is 365 m high and is currently the tallest mast tower in Asia and the second
126 tallest of this kind in the world. The main structure of the tower is made of steel, steel
127 stray lines are used for fixing and securing the tower. It is located in the Tiegang
128 Reservoir Water Reserve at Bao'an District of Shenzhen, in the Pearl River Delta (PRD)

129 region of China. The area is surrounded by a high density of vegetation, reservoir
130 features, low-rise buildings, and hills/mountains (Luo et al., 2020b).

131 **2.2 Instrumentation**

132 **2.2.1 The vertical sampling system**

133 A tower-based observation system for traces gases using long perfluoroalkoxy
134 alkane (PFA) tubing (OD: 1/2") was used to sample the O₃ and O₃ precursors at six
135 heights during the campaign, including 5, 40, 70, 120, 220, and 335 m above the ground.
136 All six tubes were continuously drawn using a rotary vane vacuum pump to keep
137 flushing with ambient air to reduce tube delay of the organic compounds, with the flow
138 rate controlled by critical orifices (orifice diameter: 0.063"). A Teflon solenoid valve
139 group was used to switch the air samples at specified time intervals so that the
140 subsamples from these six heights could be sequentially drawn by instruments (see Fig.
141 S1). Consequently, the flow rates of the air sample streams for the six tubes varied
142 between 12.0 and 15.0 SLPM without subsampling and were less than 20 SLPM with
143 subsampling. The residence time of the sample gas in the longest tube (~ 400 m) is less
144 than 180 s at a flow rate of 13 SLPM. The impacts of long tubing on measurements of
145 various of trace gases, including O₃, NO_x, and a set of organic compounds, were
146 systematically investigated using a combination of laboratory tests, field experiments,
147 and modelling techniques. Field observations proved that this observation system is
148 suitable for analyzing spatio-temporal variations of atmospheric trace gases, with many
149 trace gases could be well measured. More details about the establishment and the
150 characterization of this observation system are described elsewhere (Li et al., 2023).

151 **2.2.2 P(O₃)_{net} measurement**

152 During the campaign, the $P(O_3)_{net}$ at the 5 m ground level was measured using the
153 **home-made** NPOPR detection system, which was built based on the dual-channel
154 reaction chambers technique. The improvement, characterization, and the
155 photochemical O₃ formation mechanism in the reaction and reference chambers of the
156 NPOPR detection system are described in our previous study (Hao et al., 2023). Briefly,
157 the NPOPR detection system consists of reaction and reference chambers with the same
158 geometry and made of quartz glass. The length and inner diameter of the quartz glass
159 cylinder are 700 mm and 190.5 mm, respectively, which resulted in an inner volume of
160 ~ 20 L. The outer surface of the reference chamber was covered with an Ultem film

161 (SH2CLAR, 3 M, Japan) for ultraviolet (UV) protection, which can block sunlight with
 162 wavelengths < 390 nm, thus preventing photochemical reactions inside. During the
 163 experiment, both the reaction and reference chambers were placed outdoors and directly
 164 exposed to sunlight to simulate real ambient photochemical reactions. Ambient air was
 165 introduced into the reaction and reference chambers at the same flow rate, and a Teflon
 166 filter was mounted before the chamber inlet to remove fine particles. To correct for the
 167 effect of fresh NO titration to O₃, we use O_x (=O₃+NO₂) instead of O₃ to quantify the
 168 O₃ generated by photochemical reactions (Pan et al., 2015; Tan et al., 2018). A stream
 169 of air from the two chambers was alternately introduced into an NO-reaction chamber
 170 every 2 min to convert O₃ in the air to NO₂ in the presence of high concentrations of
 171 NO (O₃+NO→NO₂), and the O_x concentrations from the outlet NO-reaction chamber,
 172 i.e., the total NO₂ concentrations including the inherent NO₂ in the ambient and that
 173 converted from O₃, were measured by a Cavity Attenuated Phase Shift (CAPS) NO₂
 174 Monitor (Aerodyne research, Inc., Billerica MA, USA) to avoid other nitrogen oxide
 175 interferences to the NO₂ measurement (such as alkyl nitrates, peroxyacyl nitrates,
 176 peroxyntiric acid, nitrogen pentoxide, etc.). $P(O_3)_{net}$ was obtained by dividing the
 177 difference between the O_x concentrations in the reaction and reference chambers (ΔO_x)
 178 by the mean residence time of air in the reaction chamber (τ):

$$179 \quad P(O_3)_{net} = P(O_x)_{net} = \frac{\Delta O_x}{\tau} = \frac{[O_x]_{reaction} - [O_x]_{reference}}{\tau} \quad (1)$$

180 A schematic of the NPOPR detection system is shown in Fig. S2. The pulse
 181 experiments were performed to quantify the residence time in the chambers (Hao et al.,
 182 2023).

183 [O_x] values plugged in Eq. (1) to derive $P(O_3)_{net}$ are measured values corrected
 184 for wall losses of O_x and the light-enhanced loss of O₃ ($d[O_3]$) in the reaction and
 185 reference chambers during daytime (Hao et al., 2013):

$$186 \quad \gamma = \frac{d[O_3] \times D}{\omega \times [O_3] \times \tau} \quad (2)$$

187 where γ is the light-enhanced loss coefficient of O₃, which is derived from $J(O^1D)$
 188 according to the relationship obtained from the outdoor experiments (for more details,
 189 see supplementary materials: Sect. S3). $d[O_3]$ represents the difference between the O₃
 190 mixing ratios at the inlet and outlet of the reaction and reference chambers, D is the

191 diameter of the chambers, ω is the average velocity of O_3 molecules, $[O_3]$ is the injected
192 O_3 mixing ratio at the inlet of the reaction and reference chambers, and τ is the average
193 residence time of the air in the reaction and reference chambers. When quantifying the
194 light-enhanced O_3 loss ($d[O_3]$) during the ambient air measurement, we first calculate
195 γ using the measured $J(O^1D)$ and the $\gamma - J(O^1D)$ equations listed in Fig. S8 in the
196 reaction and reference chambers, then use the measured $[O_3]$ and Eq. (2) to calculate
197 $d[O_3]$. The results show that such kind of correction can increase the measured $P(O_3)_{net}$
198 by 10% (25% percentile) to 24% (75% percentile), with a median of 17%.

199 The limit of detection (LOD) of the NPOPR detection system is 2.3 ppbv h^{-1} at the
200 sampling air flow rate of 5 L min^{-1} , which is obtained as three times the measurement error of
201 $P(O_3)_{net}$ (Hao et al., 2013). The measurement error of $P(O_3)_{net}$ is determined by the estimation
202 error of O_x in the reaction and reference chambers, which includes the measurement error
203 associated with the O_x of the CAPS- NO_2 monitor and the error due to the light-enhanced loss
204 of O_3 . This collective measurement error is referred to as the measurement precision of the
205 NPOPR detection system, with further details provided in the supplementary materials,
206 specifically in Sect. S4. The measurement accuracy of the NPOPR detection system is
207 determined as 13.9 %, representing the maximum systematic error resulting from
208 photochemical O_3 production in the reference chamber. Our earlier research indicated that the
209 modelled $P(O_3)_{net}$ in the reaction chamber is similar to that modelled in ambient air, with the
210 modelled $P(O_3)_{net}$ in the reference chamber accounting for 0-13.9% of that in the reaction
211 chamber (Hao et al., 2023). This is due to the UV protection Ultem film covered on the
212 reference chamber, which only filtered out the sunlight with wavelengths < 390 nm, allowing
213 photochemical O_3 production persist at the sunlight wavelength between 390 nm and 790 nm.
214 Here, we have utilized the same modelling approach described in Hao et al. (2013) to quantify
215 the $P(O_3)_{net}$ in the reference chamber and corrected for the bias introduced by the measurement
216 accuracy.

217 2.2.3 VOCs measurement

218 VOCs were measured using a high-resolution proton transfer reaction time-of-
219 flight mass spectrometer (PTR-TOF-MS, Ionicon Analytik, Austria) (Wang et al.,
220 2020a; Wu et al., 2020) and an off-line gas chromatography mass spectrometry flame
221 ionization detector (GC-MS-FID) (Wuhan Tianlong, Co. Ltd, China) (Yuan et al.,
222 2012). The concentrations of oxygenated VOCs (OVOC), including formaldehyde
223 (HCHO) and acetaldehyde (CH_3CHO), were measured via PTR-TOF-MS, and the non-
224 methane hydrocarbons (NMHC) were measured via GC-MS-FID. PTR-TOF-MS was

225 run with both hydronium ion (H_3O^+) (Yuan et al., 2017; Wu et al., 2020) and nitric
226 oxide ion (NO^+) (Wang et al., 2020) modes. The measurement error of PTR-TOF-MS
227 was lower than 20%, more details of the PTR-TOF-MS technique can be found in our
228 previous publication (Yuan et al., 2017). The H_3O^+ and NO^+ modes were automatically
229 switched with 20 min H_3O^+ mode and 10 min NO^+ mode. The background signal of
230 each mode was measured every 30 min for at least 2 min by automatically switching the
231 ambient measurement to a custom-built platinum catalytic converter heated to 365 °C.
232 Operating the PTR-ToF-MS instrument in NO^+ mode primarily detects higher alkanes,
233 which are known significantly contribute to the formation of secondary organic aerosols
234 (SOA) but negligible contributions to photochemical O_3 formation (Wang et al., 2020).
235 Eventually, we only used VOCs measured during the H_3O^+ mode, which was operated
236 at a drift tube pressure of 3.8 mbar, a temperature of 120 °C, and a voltage of 760 V,
237 resulting in an E/N (E refers to the electric field and N refers to the number density of
238 the buffer gas in the drift tube) value of ~ 120 Td (townsend). 3035 ions with m/z up to
239 510 were obtained at time resolutions of 10 s. A gas standard with 35 VOC species was
240 used for calibrations of the PTR-ToF-MS once per day. Raw data from PTR-TOF-MS
241 were analyzed using Tofware software (Tofwerk AG, v3.0.3). Due to the humidity
242 dependencies of various VOCs signals of the PTR-ToF-MS observed in laboratory
243 studies, such as formaldehyde, benzene, methanol, ethanol, and furan (Wu et al., 2020),
244 we determined their humidity-dependence curves. During data analysis, we removed
245 the impacts of ambient humidity change on the measured signals of the PTR-ToF-MS
246 according to these humidity-dependence curves. For the off-line GC-MS-FID
247 measurement, whole-air samples were collected using 3.2 L electro-polished stainless-
248 steel canisters (Entech, USA) at 5 and 120 m at time intervals of two hours. Two
249 automatic canister samplers connected to 12 canisters were used to collect the whole-
250 air samples, with each of canister collecting the sample for 10 min. The canisters were
251 analyzed within one week (Zhu et al., 2018). The concentrations of 56 NMHC species
252 in the canister analyzed by GC-MS/FID were calibrated daily using the mixture of a
253 photochemical assessment monitoring stations (PAMS) standard gas and pure N_2 . In
254 addition, the mixture of PAMS standard gas and pure N_2 with species concentrations
255 of 1 ppbv was injected into the analytical system every 10 samples to check the
256 operational stability of the instrument. Pure N_2 was injected into the analytical system
257 at the start and end of each day's analysis to provide reference blank measurements. A
258 full list of all 56 non-methane hydrocarbons (NMHCs) can be found in the

259 supplementary material (Table S2).

260 **2.2.4 Other parameters**

261 The photolysis frequencies of different species were measured using the actinic
262 flux spectrometer (PFS-100, Focused Photonics Inc, China). O₃, CO, and NO_x
263 concentrations were measured by a 2B O₃ monitor based on dual-channel UV-
264 absorption (Model 205, 2B Technologies, USA), a gas filter correlation (GFC) CO
265 analyzer (Model 48i, Thermo Fisher Scientific, USA), and a chemiluminescence NO_x
266 monitor (Model 42i, Thermo Fisher Scientific, USA), respectively. According to our
267 test (Zhou et al., 2025), a 5% overestimation could be caused in the NO₂ measurement
268 using the chemiluminescence technique compared to the CAPS technique, due to some
269 NO_z species (i.e., HNO₃, peroxyacetyl nitrate (PANs), HONO, etc.)(Dunlea et al.,
270 2007), this will result in a decrease of the modelled $P(O_3)_{net}$ by < 4%, which is
271 negligible compared to the bias caused by the $P(O_3)_{net}$ in the reference chamber (~ 14%)
272 (Zhou et al., 2023). Temperature (T), relative humidity (RH), and pressure (P) were
273 measured by a portable weather station (Met Pak, Gill Instruments Ltd, UK).

274 **2.3 Data analysis**

275 **2.3.1 Observation-based chemical box model**

276 We investigated the detailed photochemical O₃ formation mechanism during the
277 observation period based on the field observed data. The specific tropospheric O₃
278 photochemical formation process involves the photolysis of NO₂ at < 420 nm
279 (Sadanaga et al., 2017). Simultaneously, RO_x (RO_x=OH+HO₂ +RO₂) radical recycles
280 provide HO₂ and RO₂ to oxidize NO to NO₂, resulting in the accumulation of O₃ (Shen
281 et al., 2021; Cazorla and Brune, 2010; Sadanaga et al., 2017). Therefore, the RO_x
282 radicals and the O₃, OH, NO₃ oxidants play important roles in photochemical O₃
283 formation. A zero-dimensional box model based on the Framework for 0-D
284 Atmospheric Modelling (F0AM) v3.2 (Wolfe et al., 2016) coupled with the MCM
285 v3.3.1 was used to simulate the $P(O_3)_{net}$. MCM v3.1.1 contains a total of 143 VOCs,
286 more than 6700 species, involving more than 17000 reactions (Jenkin et al., 2015).
287 $P(O_3)_{net}$ and O₃ concentrations were simulated by constraining T , RH, P , organic and
288 inorganic substances in gases, including 12 OVOCs (methanol, ethanol, formaldehyde,
289 acetaldehyde, acrolein, acetone, hydroxyacetone, phenol, *m*-cresol, methyl vinyl ketone,
290 methacrylaldehyde, methyl ethyl ketone), 56 NMHCs (toluene, benzene, isoprene,

291 styrene, etc. as listed in Table S2), inorganic gaseous pollutants (O₃, NO, NO₂, and CO),
 292 and photolysis rate values ($J(\text{O}^1\text{D})$, $J(\text{NO}_2)$, $J(\text{H}_2\text{O}_2)$, $J(\text{HONO})$, $J(\text{HCHO}_M)$,
 293 $J(\text{HCHO}_R)$, $J(\text{NO}_3_M)$, $J(\text{NO}_3_R)$, etc.). The VOCs, NO_x, T , RH and P were
 294 constrained throughout the modelling period, while O₃ was not constrained after
 295 providing initial concentration values. To avoid the build-up of long-lived species to
 296 unreasonable levels, we also considered the physical dilution process by setting a
 297 constant dilution factor of $1/43200 \text{ s}^{-1}$ throughout the modelling period (Liu et al., 2021;
 298 Decker et al., 2019). Additionally, the dry deposition rate of O₃ was set to 0.42 cm s^{-1} ,
 299 and the background of O₃, CO, and CH₄ were set to 30, 70, and 1800 ppbv, respectively,
 300 based on the findings of Wang et al. (2011), Wang et al. (2022a), and WMO greenhouse
 301 gas bulletin (2022). The modelling was run in a time-dependent mode with a resolution
 302 of 5 min, and it was run for spin-up time of 72 h to establish steady-state concentrations
 303 for secondary pollutants that were not constrained during the simulation. $P(\text{O}_3)_{\text{net}}$ can
 304 be expressed by the difference between O₃ production rate ($P(\text{O}_3)$) and O₃ destruction
 305 rate ($D(\text{O}_3)$), where $P(\text{O}_3)$ and $D(\text{O}_3)$ can be calculated as Eq. (3)-(4):

$$306 \quad P(\text{O}_3) = k_{\text{HO}_2+\text{NO}}[\text{HO}_2][\text{NO}] + \sum_i k_{\text{RO}_{2,i}+\text{NO}}[\text{RO}_{2,i}][\text{NO}]\varphi_i \quad (3)$$

$$307 \quad D(\text{O}_3) = k_{\text{O}^1\text{D}+\text{H}_2\text{O}}[\text{O}^1\text{D}][\text{H}_2\text{O}] + k_{\text{OH}+\text{O}_3}[\text{OH}][\text{O}_3] + k_{\text{HO}_2+\text{O}_3}[\text{HO}_2][\text{O}_3]$$

$$308 \quad + k_{\text{O}_3+\text{alkenes}}[\text{O}_3][\text{alkenes}] + k_{\text{OH}+\text{NO}_2}[\text{OH}][\text{NO}_2] +$$

$$309 \quad k_{\text{RO}_{2,i}+\text{NO}_2}[\text{RO}_{2,i}][\text{NO}_2] \quad (4)$$

310 where $k_{\text{M+N}}$ represents the bimolecular reaction rate constant of M and N, the
 311 subscript ‘ i ’ refers to different types of RO₂, and φ_i is the yield of NO₂ of the reaction
 312 RO_{2*i*}+NO. The relevant reaction rates of $P(\text{O}_3)$ and $D(\text{O}_3)$ and the mean measured
 313 concentrations of each VOC category at 5 m ground during O₃ episodes and non-
 314 episodes used in the model are listed in Tables S1 and S2.

315 **2.3.2 Derive contribution of chemical and physical processes to O₃** 316 **changes on the ground level**

317 It is known that chemical and physical processes jointly influence the O₃
 318 concentration changes near the ground surface (Xue et al., 2014; Tan et al., 2019). The
 319 direct measurement of $P(\text{O}_3)_{\text{net}}$ gave us a chance to identify the contribution of chemical
 320 and physical processes to the variation of observed O₃ concentrations using the
 321 following equation:

322
$$\frac{dO_X}{dt} = P(O_X)_{\text{net}} + R(O_X)_{\text{trans}} \quad (5)$$

323 Where $\frac{dO_X}{dt}$ is the change rate of the observed O_X mixing ratio change (ppbv h^{-1}),
 324 $P(O_X)_{\text{net}}$ denotes the net photochemical O_3 production rate (ppbv h^{-1}), which was equal
 325 to $P(O_3)_{\text{net}}$ and measured directly by the NPOPR system. $R(O_X)_{\text{trans}}$ represents O_3
 326 mixing ratio change due to physical transportation (ppbv h^{-1}), including the horizontal
 327 and vertical transport, dry deposition and the atmospheric mixing (Liu et al., 2022). To
 328 correct the effects of NO titration to O_3 , we have replaced O_3 with $O_X (=O_3+NO_2)$
 329 during the calculation in this study (Pan et al., 2015).

330 **2.3.3 Model performance**

331 In order to judge the reliability of the model simulation, we calculated the index
 332 of agreement (IOA) based on the measured and modelled $P(O_3)_{\text{net}}$ and O_3 at 5 m above
 333 the ground level using the following equation (Liu et al., 2019):

334
$$IOA = 1 - \frac{\sum_{i=1}^n (O_i - S_i)^2}{\sum_{i=1}^n (|O_i - \bar{O}| + |S_i - \bar{O}|)^2} \quad (6)$$

335 Where S_i and O_i represents the simulated and observed $P(O_3)_{\text{net}}$ or O_3 values at the
 336 same time, respectively, \bar{O} is the averaged observed value, and n is the data number.
 337 Furthermore, we also judged the model simulation performance using statistical
 338 measures, including the normalized mean bias (NMB) and normalized mean error
 339 (NME), which are defined as:

340
$$NMB = \frac{\sum_{i=1}^n (S_i - O_i)}{\sum_{i=1}^n O_i} \cdot 100 \% \quad (7)$$

341
$$NME = \frac{\sum_{i=1}^n |S_i - O_i|}{\sum_{i=1}^n O_i} \cdot 100 \% \quad (8)$$

342 Where S_i and O_i have the same meaning as Eq. (6), and n is the total number of
 343 such data pairs of interest. The results will be discussed in Sect. 3.2.2.

344 **2.3.4 OH reactivity**

345 In order to investigate the influence of the photochemical reactions of different
 346 VOCs to photochemical O_3 formation, we calculated the OH reactivities of different
 347 VOCs, which is the sum of concentrations of OH reactants multiplied by their reaction
 348 rate coefficients, as shown below:

349 $k_{OH} = k_i \times [VOCs]_i$ (9)

350 where k_{OH} represents the total OH reactivity of a group of VOCs species, k_i
351 represents the rate constants between OH radicals and different VOCs species i ,
352 $[VOCs]_i$ represents the concentration of species i . In this study, we summarized the OH
353 reactivities of different kinds of VOCs groups together to investigate their influence on
354 the vertical gradient $P(O_3)_{net}$ in Sect. 3.2.3.

355 **2.3.5 O₃ formation potential**

356 The O₃ formation potential is calculated using the product of the VOCs concentration
357 and the maximum incremental reactivity (MIR) coefficient (dimensionless, gram of O₃
358 produced per gram of VOCs) (Carter et al., 2012):

359 $OFP_i = \sum_i [VOC]_i \times MIR_i$ (10)

360 Where OFP_i is the O₃ formation potential of species i , $[VOC]_i$ is the mass
361 concentration or emission of species i , and MIR_i denotes the maximum increment
362 reactivity of species i (g O₃/g VOCs).

363 **2.3.6 O₃ formation regime**

364 The sensitivity of photochemical O₃ production to its precursors was diagnosed by
365 calculating the relative incremental reactivity (RIR) using the OBM-MCM model. RIR
366 is defined as the percent change in O₃ photochemical production per percent change in
367 the concentration of its single precursor/precursor group (Cardelino and Chameides,
368 1995). Therefore, the RIR for precursor (group) X can be expressed as:

369 $RIR = \frac{\Delta P(O_3)/P(O_3)}{\Delta X/X}$ (11)

370 where the $\Delta X/X$ represent the percent change in different O₃ precursors or
371 precursor groups. We classified the measured VOCs into anthropogenic organic
372 compounds (AVOC), biogenic organic compounds (BVOC), and OVOC group, and
373 investigated the O₃ formation sensitivity to these different types of VOCs.

374 **3. Results and discussions**

375 **3.1 Vertical and temporal profile of O₃ and its precursors**

376 **3.1.1 O₃ and its precursors at 5 m ground level**

377 Figure 1 shows the time series of the major trace gases, photolysis rate constants,

378 and meteorological parameters at 5 m ground-level during the observation period at
379 SZMGT. Over the 1-month field observation period, a total of 3 O₃ pollution episodes
380 (referred to episodes hereafter) and 2 non-O₃ pollution episodes (referred to non-
381 episodes hereafter) were captured. O₃ pollution episodes were defined as the days
382 during which the hourly average O₃ concentration at ground-level (5 m) exceed the
383 Grade II standard (102 ppbv, GB 3095-2012, China; Ambient Air Quality Standards,
384 2012), while the remaining days were defined as non-episodes. Episode days (marked
385 as gray columns in Fig. 1) included November 13-18 (episode I), November 26 (episode
386 II), and December 7-9 (episode III), while the non-episode days included November
387 22-25 (non-episode I), November 26-27 and 30 (non-episode II). The corresponding
388 daytime mean values (6:00-18:00 LT) during all episode days and non-episode days are
389 shown in Table 1. During the daytime of episode days (episodes I, II, and III), the mean
390 concentrations of O₃ were 70.1 ± 28.6 , 59.5 ± 32.4 , and 71.3 ± 31.0 , respectively. The
391 mean *T* and RH were 22.3 ± 2.5 °C and 56.2 ± 14.5 % for episode I, 20.4 ± 3.2 °C and
392 52.2 ± 16.7 % for episode II, and 20.6 ± 3.4 °C and 58.2 ± 17.2 % for episode III. During
393 non-episode days, the mean concentrations of O₃ were 45.3 ± 16.2 and 63.7 ± 21.3 ppbv
394 for non-episode I and II, respectively. The corresponding mean *T* and RH were
395 18.4 ± 4.3 °C and 69.5 ± 15.4 % for non-episode I, and 21.3 ± 2.7 °C and 51.8 ± 13.7 % for
396 non-episode II. These observations indicate that the *T* and RH during episode days were
397 not significantly different from those during non-episode days. This phenomenon
398 contrasts with previous studies in the PRD area, where O₃ pollution episodes were
399 generally associated with high *T* and low RH (Mousavinezhad et al., 2021; Hong et al.,
400 2022).

401

402 **Figure 1. Time series of major trace gases, photolysis rate constants, and meteorological**
 403 **parameters at 5 m ground level during the observation period. The gray columns show the**
 404 **typical O₃ episodes that occurred.**

405 **Table 1. Daytime major trace gases concentrations (units: ppbv), $P(O_3)_{net}$ (units: ppbv h⁻¹),**
 406 **and meteorological parameters during different episodes and non-episodes during the**
 407 **observation period (from 13 November to 9 December 2021) at SZMGT.**

Parameters	Mean±SD				
	Episode I	Episode II	Episode III	Non-episode I	Non-episode II

408

* All values here were calculated as the mean average values during daytime (6:00-18:00 LT).

409

The mean concentrations of O₃ precursors, including CO, NO, NO₂, and the total

410 VOCs measured by PTR-TOF-MS (shown as TVOC in Fig. 1 and Table 1), did not
411 exhibit notable discrepancies between episodes and non-episodes. This suggests that
412 their concentrations during O₃ pollution episodes can vary, being either higher or lower
413 than those observed during non-episodes (as shown in Table 1). For example, through
414 there are days with very high hourly average O₃ concentrations which define O₃
415 pollution episodes-where levels exceed the Grade II standard of 102 ppbv-the
416 overall average O₃ concentrations for episode II is not higher than that of non-episode
417 II. This suggests that despite the occurrence of peak hourly levels, the average
418 concentration for episode II remains lower, highlighting the fluctuating pattern of
419 O₃ levels during these episodes. Further comparison of the daytime mean O₃
420 formation potential (OFP) and the measured $P(O_3)_{net}$ during episodes and non-episodes
421 showed no significant differences, ranging from 5.1×10^{-4} to 1.0×10^{-3} g m⁻³ and 14.3 to
422 21.5 ppb h⁻¹, respectively, during non-episodes, whereas they are ranged from 4.1×10^{-4}
423 to 4.7×10^{-4} g m⁻³ and 5.6 to 18.9 ppb h⁻¹ respectively, during episodes. Although OFP
424 was always higher during episodes than during non-episodes, the mean $P(O_3)_{net}$ values
425 during episodes I and III were even lower than during non-episodes II. The higher O₃
426 concentrations may be due to the more stable weather conditions during episodes I and
427 III (with lower wind speed), which benefits the accumulation of O₃ formed by local
428 photochemical O₃ formation. While for non-episode II, even it processes higher $P(O_3)_{net}$,
429 the outflow of O₃ from the observation site by physical processes may be higher due to
430 the higher wind speed. These findings indicate that the O₃ pollution episodes stem from
431 either substantially elevated local photochemical O₃ formation (i.e., episode II), or the
432 accumulation of O₃ formed by moderate local photochemical O₃ formation under stable
433 weather conditions (i.e., episodes I and II). Notably, when local photochemical
434 reactions contribute intensely to the formation of O₃, favorable weather conditions
435 facilitating O₃ outflow diminish the likelihood of O₃ pollution occurrences (i.e., non-
436 episode II). These results indicate that O₃ pollution episodes are jointly affected by the
437 photochemical reactions and physical transport processes, which we will discuss in
438 more detail in Sect. 3.2.1.

 442 **observation period. The contour plots are made using the measured values from six heights.**

443

444

445 **Figure 3. Average vertical profiles of O₃, NO, Ox, NO_x, and TVOC during both daytime**
 446 **and nighttime, and OFP of different VOCs types during daytime at six heights (5, 40, 70, 120,**
 447 **220, and 335 m), including episodes and non-episodes throughout the observation period. The**
 448 **error bars indicate the standard deviation calculated from the measured values during these**
 449 **periods.**

450 3.1.2 Vertical profiles of O₃ and its precursors at 5-335 m level

451 Figure 2 shows the contour plots illustrating the vertical profiles of O₃, NO_x,
 452 Ox(=O₃+NO₂), and TVOC. From Fig. 2, minimal vertical gradients were observed
 453 during daytime in the concentration of all species—O₃, NO_x, Ox, and TVOC—due to the
 454 rapid vertical mixing effects. However, distinct vertical gradients were observed during
 455 nighttime owing to the stability of the nocturnal residual layer. Elevated concentrations
 456 of O₃ and Ox were identified at higher altitudes, whereas higher NO_x concentrations
 457 predominantly occurred at ground level. We further elucidated the vertical distribution
 458 patterns of different pollutants as well as the OFP of different VOCs groups during
 459 local daytime (6:00-18:00 LT) and nighttime (19:00-5:00 LT) for both episodes and
 460 non-episodes, as shown in Fig. 3.

461 The vertical profiles of averaged concentrations of various pollutants exhibit
462 similar trends during both episodes and non-episodes, with O₃ showing an increasing
463 trend from 5 m above ground level to 355 m, aligning with findings from previous
464 studies (Zhang et al., 2019; Wang et al., 2021). Given that NO_x has a significant
465 titration effect on O₃, the lower O₃ concentration at ground level may be attributed to
466 the increase in NO_x concentration (Zhang et al., 2022) and also the dry deposition near
467 the ground (Li et al., 2022). NO and NO_x showed an opposite trend compared to O₃.
468 These two factors jointly effected the Ox changing trend with heights, and consequently,
469 the gradients of Ox concentrations showed a weaker increasing trend from the 5 m
470 ground level to 355 m height compared to O₃. This observation demonstrated a more
471 pronounced NO titration effect at the 5 m ground level compared to the effect at 355 m
472 height. However, the TVOC showed variable trends with increased height for daytime
473 and nighttime during episodes and non-episodes. During daytime, TVOC initially
474 decreased from 5 m to 40 m, and then continuously increased from 40 m to 355 m
475 during episodes, while continuously slightly decreased from 5 m to 335 m during non-
476 episodes. During nighttime, TVOC concentrations first increased from 5 m to 40 m and
477 then continuously decreased from 40 m to 335 m during both episodes and non-episodes.
478 We further plotted the OFP of different VOCs groups at various altitudes, and found
479 that the total OFP was highest at 5 m ground level and exhibited higher levels during
480 episodes compared to non-episode periods. Subsequently, there was a significant
481 decrease at 40 m height during both episodes and non-episodes. However, there was a
482 sharp increase observed at 70 m, 120 m, and 220 m during episodes, contrasting with a
483 gradual rise during non-episode periods, which eventually reach a peak at 220 m during
484 non-episodes. A consistent decrease of OFP from 220 m to 335 m was observed during
485 both episodes and non-episodes. The OFP was primarily attributed to OVOCs at
486 different altitudes throughout both episodes and non-episodes, followed by aromatics
487 and alkane during episodes and non-episodes, respectively.

488 In conclusion, our daytime observations revealed minimal vertical gradients in the
489 concentrations of O₃, NO_x, Ox, and TVOC, attributed to the rapid vertical mixing
490 effects driven by surface heating effects (Tang et al., 2017). This suggests that ground-
491 level O₃ concentrations would be representative of the entire vertical column.
492 Nonetheless, the OFP varies for different VOCs profiles at various heights, and the
493 vertical mixing effects facilitates the downward transport of O₃ photochemically

494 formed from higher altitudes to the near-ground layer. Consequently, a box model
495 constraining to ground-level NO_x and VOCs concentrations may not accurately reflect
496 the in situ O₃ production in the vertical atmospheric column.

497 **3.2 O₃ pollution episodes formation mechanism at near-ground surface**

498 In this section, we first explored the possible reason for O₃ pollution episodes on
499 the 5 m ground level, aiming to identify the contribution of chemical and physical
500 processes to change in O₃ concentrations (Sect. 3.2.1). Subsequently, we assessed the
501 modelling performance and investigated the potential reasons for the modelling bias in
502 photochemical O₃ formation by comparing the measured $P(\text{O}_3)_{\text{net}}$ with the modelled
503 $P(\text{O}_3)_{\text{net}}$ (Sect. 3.2.2). To gain insights into the photochemical O₃ formation mechanism
504 at different heights and understand their role in overall O₃ pollution, we further
505 discussed the chemical budget of O₃ at different heights (Sect. 3.2.3), the vertical and
506 temporal variability of $P(\text{O}_3)_{\text{net}}$ and O₃ formation regime (Sect. 3.2.4), along with
507 potential bias within the modelling approach (Sect. 3.2.5).

508 **3.2.1 Contribution of chemical and physical processes to O₃ changes on** 509 **the ground level**

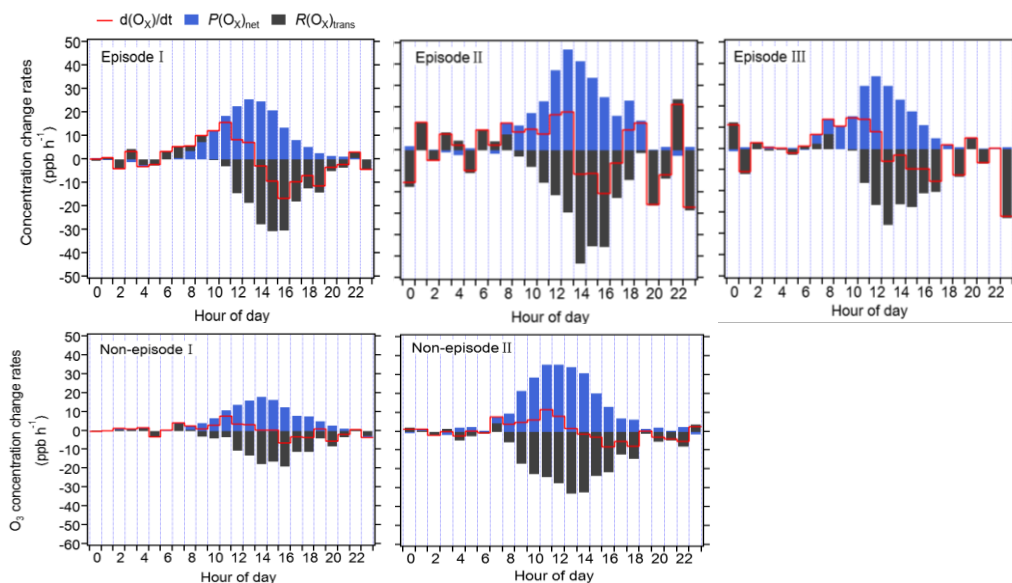

510 As concluded in Sect. 3.1.1, O₃ pollution episodes may be jointly affected by the
511 photochemical reactions and physical transport. In order to identify the main reasons
512 for O₃ pollution on the ground level, we calculated the contribution of chemical and
513 physical processes to O_x concentration changes at 5 m ground level separately for all 3
514 episodes and 2 non-episodes. Typically, as dry deposition contributes a relatively small
515 portion and can often be considered negligible, making vertical and horizontal transport
516 the main contributors to physical processes (Tan et al., 2019).

517

518

519 **Figure 4. Time series of O_X concentration changes ($d(O_X)/dt$) and contributions from**
 520 **local photochemical production ($P(O_X)_{net}$) and physical transport ($R(O_X)_{tran}$). The shaded**
 521 **areas of $d(O_X)/dt$, $P(O_X)_{net}$, and $R(O_X)_{tran}$ represent one standard deviation (denoted by σ) of**
 522 **the mean $d(O_X)/dt$, the uncertainty of measured $P(O_X)_{net}$, and the propagated error of**
 523 **$R(O_X)_{tran}$, respectively.**

524

525 **Figure 5. Diurnal variation of the contribution of chemical and physical transport to**
 526 **O_3 changes on the ground level.**

527 $R(O_X)_{trans}$ at 5 m ground level was derived from $\frac{dO_X}{dt}$ minus $P(O_X)_{net}$, according to
 528 Eq. (5) shown Sect. 2.3.2, their hourly averages and diurnal variations are shown in
 529 Figs. 4 and 5, respectively. From these figures, it is evident that the fluctuation of the
 530 O_X concentration change rate ($d(O_X)/dt$) at ground level is typically small and primarily
 531 dominated by the physical processes during nighttime. During nighttime, $P(O_X)_{net}$
 532 should be zero without sun radiation, the significant $P(O_X)_{net}$ shown in Fig. 5 may be

533 due to the measurement uncertainty of $P(O_X)_{net}$, which is determined by the
534 measurement error of O_X of CAPS- NO_2 monitor and the error caused by the light-
535 enhanced loss of O_3 in the reaction and reference chambers (as discussed in Sect. S4).
536 The measurement uncertainty of $P(O_X)_{net}$ is higher at lower $P(O_X)_{net}$ values (as shown
537 in Fig. 4), which was mainly determined by the instrumental error of O_X measurement
538 and the ambient O_X concentrations during nighttime. It was estimated to be $\sim 38\%$ and
539 can be considered as the measurement precision. Around 6:00-7:00 LT, O_3
540 concentrations increase for all episodes and non-episodes, mainly due to physical
541 transport during episodes I and II and non-episodes I, while photochemical reactions
542 and physical processes are equally important for episodes III and non-episode II. This
543 could be due to short-term strong vertical turbulence in the early morning, which leads
544 to an expansion of the boundary layer height and makes the residual layer “leaky”,
545 allowing vertical transport. At the same time, O_3 precursors were also transported down
546 from the residual layer, and with increasing sunlight, these O_3 precursors underwent
547 rapid photochemical reactions that competed with the physical processes between 6:00-
548 7:00 LT, leading to a sharp increase in $P(O_X)_{net}$ between 8:00 to 12:00 LT. The $P(O_X)_{net}$
549 peaked around 11:00-14:00 LT and started to decrease around 15:00, eventually
550 approaching zero by around 19:00-20:00 LT. Between 7:00-8:00 LT, $R(O_X)_{tran} > 0$ for
551 all episodes and non-episodes, indicating inflow of O_3 from physical transport,
552 increasing surface O_3 concentration by averages of 4.7, 3.9, 2.3, 3.5, and 4.5 ppbv h^{-1}
553 for episodes I, II, III, and non-episodes I and II, respectively. From 9:00 to 10:00 LT,
554 $R(O_X)_{tran} > 0$ only for episodes I, increasing the O_3 concentration by 1.5 ppbv h^{-1} ,
555 indicating inflow of O_3 from physical transport; on the contrary, $R(O_X)_{tran} < 0$ for
556 episodes II and III, and non-episodes I and II, indicating outflow of O_3 from physical
557 transport, decreasing the O_3 concentration by 3.1, 0.1, 3.0, and 16.9 ppbv h^{-1} ,
558 respectively. After 10:00 LT, $R(O_X)_{tran} < 0$ for all episodes and non-episodes, indicating
559 outflow of O_3 from the observation sites, possibly due to accumulated photochemically
560 formed O_3 increasing the concentration at the observation site, diffusing upward or to
561 surrounding areas.

562 In conclusion, the observed daytime O_3 concentration changes during all episodes
563 and non-episodes were influenced by both photochemical production and physical
564 transport. In the early morning, the increase in O_3 concentrations can be attributed to
565 photochemical reactions, physical processes, and possibly reduced NO titration effects

566 as the boundary layer height increases. Around noon, O₃ concentrations stabilize,
567 suggesting a balance between photochemical reactions and physical transport affecting
568 O₃ concentration changes. In the afternoon, O₃ concentrations decrease due to the
569 transport of photochemically formed O₃ from the observation site to upward directions
570 or the surrounding areas. Our findings indicate that local photochemical reactions
571 dominate O₃ pollution. For example, O₃ pollution episodes recorded during the
572 observation period manifest under specific conditions: ① high photochemical O₃
573 production (i.e., episode II); ② moderate photochemical O₃ productions coupled with
574 O₃ accumulation under stable weather conditions (i.e., episodes I and III). In contrast,
575 non-episodes observed during the observation period occur under different conditions:
576 ① low levels of photochemical O₃ production (i.e., non-episodes I); ② elevated
577 photochemical O₃ production, with O₃ transport to surrounding areas under favorable
578 diffusion conditions (i.e., non-episodes II).

579 **3.2.2 The model performance**

580 In order to test the simulation ability of OBM-MCM model for $P(O_3)_{net}$, we
581 compared the measured and modelled $P(O_3)_{net}$ at 5 m ground level, as depicted in Fig.
582 S3a. The measured and modelled $P(O_3)_{net}$ revealed close alignment during episodes I
583 and III, yet displayed discernible variations during episode II, non-episode I, and non-
584 episode II. Assessment metrics including IOA, NMB, and NME were computed based
585 on the observed and modelled $P(O_3)_{net}$ over the entire measurement period (as described
586 in Sect. 2.3.3). The IOA ranged between 0.87 (25th percentile) and 0.90 (75th percentile)
587 for the measured and modelled $P(O_3)_{net}$ across the measurement period, indicating the
588 acceptable performance of the OBM-MCM model simulation (a higher IOA value
589 signifies a stronger agreement between simulated and observed values). Additionally,
590 comparison of measured and modelled O₃ concentrations at different heights (as shown
591 in Fig. S4) revealed generally higher modelled values during daytime and closer
592 alignment during nighttime at lower heights (i.e., 5 m, 40 m, and 70 m), while
593 discrepancies were observed at higher heights (i.e., 120 m, 220 m, and 335 m). These
594 phenomena may be primarily attributed to uncertainties in assumed physical processes
595 in the modelling, such as vertical and horizontal transport. Previous studies have
596 utilized the comparison of measured and modelled O₃ concentrations to determine the
597 dilution factor in modelling studies, discovering that suitable dilution factors vary by
598 location (Yang et al., 2021). To achieve the best agreement between the modelled O₃

599 concentrations and the observed values, we applied different dilution factors (the
600 lifetime of the species) in the modelling, varying from 6 h to 24 h. We found that the
601 simulated O_3 is closest to the measured O_3 concentrations when the lifetime of the
602 species is set to 12 h. However, given that O_3 concentrations are affected by physical
603 transport processes, the dilution factor might only represent the outflow of O_3 from the
604 observation site. Therefore, there may be limitations in using this method for precise
605 comparisons. We further compared the measured and modelled $P(O_3)_{net}$ under
606 different dilution factors. The modelled $P(O_3)_{net}$ initially increases and then decreases
607 as the dilution factor decreases (equivalent to an increase of species lifetime). However,
608 the influence of varying dilution rates on the modelled $P(O_3)_{net}$ is minimal, constituting
609 less than 30 %, due to the short lifetimes of the HO_2 and RO_2 radicals, which determine
610 the $P(O_3)_{net}$ values (Wang et al., 2021). Notably, the modelled $P(O_3)_{net}$ closely matched
611 the measured values when the species lifetime was set to 12 h, as illustrated in Fig. S3b.
612 Consequently, a constant dilution factor of $1/43200\text{ s}^{-1}$ was applied throughout the
613 observation period. Further investigations revealed an IOA range between 0.80 (25th
614 percentile) and 0.82 (75th percentile) for measured and modelled O_3 concentrations at
615 5 m ground level, which lies in between the IOA result for the modelled and observed
616 O_3 concentrations in previous studies, which range between 0.68 and 0.89 (Wang et al.,
617 2018), signifying the modelling results for O_3 concentrations here are acceptable. The
618 calculated NMB and NME using the modelled and observed $P(O_3)_{net}$ at 5 m ground
619 level during the whole measurement period ranged from -0.42 (25th percentile) to -0.31
620 (75th percentile) and -0.42 (25th percentile) to 0.54 (75th percentile), respectively. These
621 analysis results indicate that the model underestimates the measured $P(O_3)_{net}$ by a factor
622 ranging from 1.42 (25th percentile) to 1.31 (75th percentile), calculated as $(1+|NMB|)$,
623 and the simulation results are reliable (with $-1 < NME < 1$).

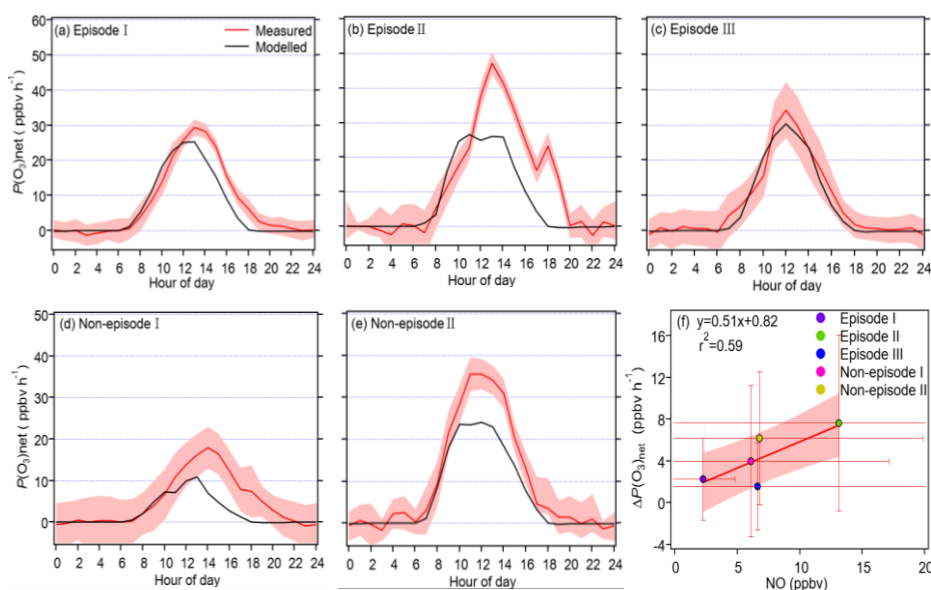

624 The mean diel variation of measured and modelled $P(O_3)_{net}$ during different
625 episodes and non-episodes are shown in Fig. 6a-e. The maximum daily $P(O_3)_{net}$ values
626 were 29.3, 47.2, and 34.2 ppbv h^{-1} for episodes I, II, and III, and 17.9 and 35.5 ppbv h^{-1}
627 for non-episodes I and II, respectively. These values were comparable to or lower than
628 those measured in urban areas of Houston, United States (40-50 and 100 ppbv h^{-1} in
629 autumn and spring, respectively) (Baier et al., 2015; Ren et al., 2013), but higher than
630 those measured in a remote area of Japan (10.5 ppbv h^{-1} in summer) and an urban area
631 of Pennsylvania, United States (~ 8 ppbv h^{-1} in summer) (Sadanaga et al., 2017; Cazorla

632 and Brune, 2020). The averaged diel profiles of measured and simulated $P(O_3)_{net}$
633 exhibited large standard deviations (as depicted in Table 1), representing their day-to-
634 day variation throughout the campaign. The measured $P(O_3)_{net}$ were mostly higher than
635 the modelled $P(O_3)_{net}$, which could be attributed to the underestimation of RO_2 under
636 high NO conditions, leading to substantial disparities between calculated $P(O_3)_{net}$
637 derived from measured and modelled RO_2 concentrations, as highlighted in previous
638 studies (Whalley et al., 2018, 2021; Tan et al., 2017, 2018). The median value of
639 $[\text{measured } P(O_3)_{net} - \text{modelled } P(O_3)_{net}] / \text{measured } P(O_3)_{net}$ ranged from 22% to 45% for
640 different episodes and non-episodes. To delve deeper, we further investigated the
641 relationship between the daily disparities of measured and modelled $P(O_3)_{net}$ ($\Delta P(O_3)_{net}$
642 = measured $P(O_3)_{net}$ - modelled $P(O_3)_{net}$) and average daytime NO concentrations during
643 different episodes and non-episodes, as depicted in Fig. 6f. The observed elevated
644 $\Delta P(O_3)_{net}$ at higher NO concentrations aligns with findings from previous studies,
645 which suggest that multiple factors could contribute to these outcomes. For example,
646 the reaction of OH with unknown VOCs (Tan et al., 2017), the lack of correction for
647 the decomposition of $CH_3O_2NO_2$, the missing RO_2 production from photolysis $ClNO_2$
648 (Whalley et al., 2018; Tan et al., 2017), and the underestimation of OVOCs photolysis
649 (Wang et al., 2022b) in modelling approaches may lead to the underestimation of RO_2 ,
650 thus underestimating the modelled $P(O_3)_{net}$. Further analysis showed that the
651 underestimation of $P(O_3)_{net}$ can lead to the NO_x -limited regime being shifted to the
652 VOCs-limited regime, thus underestimating the NO_x -limited regime (Wang et al.,
653 2022b, 2024). However, the derived IOA, NMB, and NME values from the modelled
654 and observed $P(O_3)_{net}$ (and O_3) at 5 m ground during different episodes and non-
655 episodes indicate that the model proficiently reproduces the genuine $P(O_3)_{net}$ at the
656 observation site (as shown in Table S3). Consequently, these results provide confidence
657 in exploring the vertical and temporal variations of $P(O_3)_{net}$ and O_3 formation
658 sensitivities utilizing the outcomes from the modelling approach. Nonetheless, it is
659 important to acknowledge and discuss the potential biases caused by the modelling
660 methodology in this study.

669

3.2.3 Vertical and temporal variability of $P(O_3)_{net}$ budget

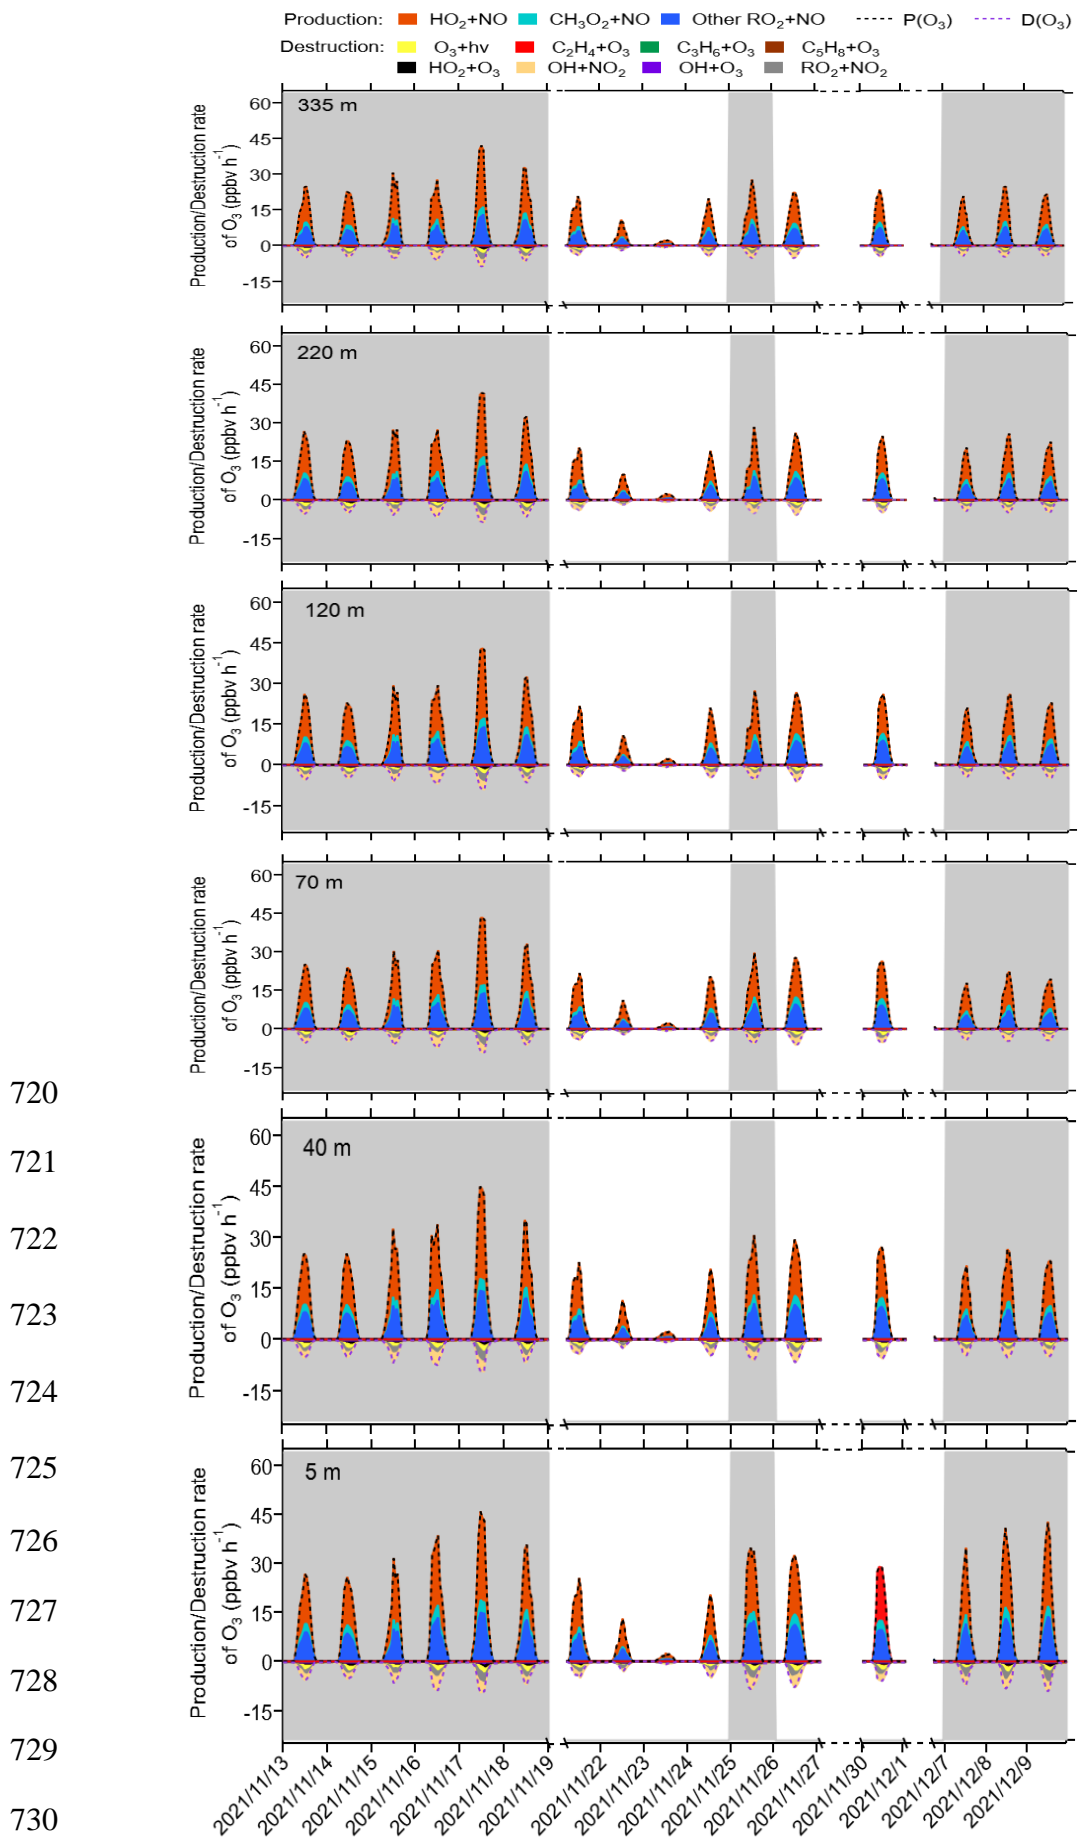

670

671 The detailed $P(O_3)_{net}$ budget at different heights during the observation period
 672 from the modelling results are shown in Fig. 7. Across various heights and different
 673 episodes and non-episodes, the contributions of different reaction pathways to $P(O_3)$
 674 were almost the same, with HO_2+NO as the major O_3 production pathway, followed by
 675 CH_3O_2+NO and other RO_2+NO , where other RO_2+NO encompasses all RO_2 except
 676 CH_3O_2 . This result aligns with previous studies (Liu et al., 2021; Liu et al., 2022). The
 677 major O_3 destruction pathway was $OH+NO_2$ (loss of OH radicals), followed by net
 678 RO_2+NO_2 (form peroxyacetyl nitrate, commonly called PAN species) and O_3
 679 photolysis, while other O_3 destruction pathways, including O_3+OH , O_3+HO_2 , $C_5H_8+O_3$,
 680 $C_3H_6+O_3$, and $C_2H_4+O_3$, together contributed negligibly to O_3 destruction. These $P(O_3)$
 681 and $D(O_3)$ reaction pathways occurred between 6:00-18:00 LT, exhibiting strong
 682 diurnal variation characterized by a sharp increase between 6:00-11:00 LT in the
 683 morning, peaking between 11:00 and 14:00 LT, and decreasing rapidly after 14:00 LT.
 684 These phenomena were in accordance with the concentration changes of the major
 685 oxidants (i.e., OH, O_3 , and NO_3), as shown in Fig. S5, where OH radicals and O_3
 686 concentrations increased significantly in the morning and reached a peak around noon,
 followed by sharp afternoon decreases.

687 The diurnal changes in the concentrations of different reaction pathways to $P(O_3)$
688 and $D(O_3)$ at 5 m ground level during different episodes and non-episodes are depicted
689 in Fig. S6. We note that the maximum total $P(O_3)$ resulting from diel variations at 5 m
690 ground level for episode I, II, and III were 32.0, 34.9, and 38.3 ppbv h⁻¹, respectively.
691 These values were consistently higher than the maximum total $P(O_3)$ observed for non-
692 episodes I and II, which were 15.6 and 30.7 ppbv h⁻¹, respectively. However, as $P(O_3)_{net}$
693 was determined by both $P(O_3)$ and $D(O_3)$, the maximum total $D(O_3)$ values resulting
694 from diel variations during episodes I, II, III, and non-episode I, II, were 5.0, 5.7, 5.1,
695 2.4, and 5.3 ppbv h⁻¹, respectively. Consequently, the modelled $P(O_3)_{net}$ during episodes
696 does not exhibiting a statistically significant difference from that during non-episodes
697 (Mann-Whitney p value=0.12), as shown in Fig. S5, which is in agreement with the
698 measured $P(O_3)_{net}$ (Mann-Whitney p -value=0.28), as depicted in Sect. 3.1.1.

699 The diurnal variation of $P(O_3)_{net}$ during different episodes and non-episodes
700 obtained by OBM-MCM modelling at different heights are shown in Fig. 8. We saw
701 that the $P(O_3)_{net}$ all showed a decreasing trend with the increase of the measurement
702 height during different episodes and non-episodes, but the variation of $P(O_3)_{net}$ along
703 with the measurement height differed for different episodes and non-episodes. For
704 example, the decrement of the averaged $P(O_3)_{net}$ during 6:00-18:00 LT from 5 m to 335
705 m were 1.5 and 0.6 ppbv h⁻¹ for episode I and non-episode I, respectively, which was
706 relatively smaller than that during episode II, episode III, and non-episode II, which
707 were 5.3, 5.4, and 4.0 ppbv h⁻¹, respectively. To explore the reason, we plotted the
708 differences of calculated OH reactivities at 5 m and 335 m of different VOCs groups
709 (marked as ΔOH reactivity) as a function of the $P(O_3)_{net}$ change at 5 m and 335 m
710 (marked as $\Delta P(O_3)_{net}$), including nonmethane hydrocarbons (NMHC), anthropogenic
711 volatile organic compounds (AVOC), biogenic volatile organic compounds (BVOC),
712 and oxygenated volatile organic compounds (OVOC) (as shown in Fig.8f). The VOCs
713 species included in each category are listed in Table S2. We found that the OH
714 reactivities of AVOC and OVOC had the highest correlation coefficients (R^2) with the
715 $\Delta P(O_3)_{net}$, which are 0.85 and 0.67, respectively, indicating their predominant influence
716 on the decrement of $P(O_3)_{net}$ from 5 m to 335 m. However, the OH reactivity change
717 from 5 m to 335 m of different groups was quite different. Therefore, we further
718 explored O_3 formation sensitivity to its different VOCs precursors and precursor groups.

719

 739 **reactivity).**

740 3.2.4 Vertical distributions of O₃ formation regime

741 To investigate the reasons behind the variable distribution of $P(O_3)_{net}$ at varying
 742 heights, we clarified the sensitivity of O₃ formation to different O₃ precursors or
 743 precursor groups, including NMHC, AVOC, BVOC, OVOC, CO, and NO_x, by
 744 calculating their RIRs during different episodes and non-episodes, as shown in Fig. 9.
 745 **The VOCs species, categorized into different precursor groups as listed in Table S2,**
 746 **indicate that some species depicted in Figure 9 may appear in multiple categories and**
 747 **hence could be repeated.** As illustrated in Fig. 9, the RIR values for different O₃-
 748 precursors or precursor groups don't exhibit significant variation at different heights
 749 during specific episodes or non-episodes, indicating a similar photochemical O₃
 750 formation regime. However, the O₃ formation regimes differ between different episodes
 751 or non-episodes. During O₃ polluted episode I, O₃ formation is located in a transition

752 regime and is more sensitive to VOCs emissions. Conversely, during O₃ polluted
 753 episodes II and III, and non-episodes I and II, it is located in VOCs sensitive regime.
 754 This finding aligns with previous studies suggesting that photochemical O₃ formation
 755 in the PRD region is likely VOC-limited or mixed-limited (Hong et al., 2022; Lu et al.,
 756 2018). The results suggest that the complexity of O₃ mitigation at the observation site.
 757 For example, during polluted episode I, reducing both VOCs and NO_x can mitigate
 758 photochemical O₃ formation. However, during other O₃ polluted episodes and non-
 759 episodes, reducing VOCs can effectively alleviate photochemical O₃ formation, while
 760 reducing NO_x might aggravate it. Nevertheless, during all episodes and non-episodes,
 761 O₃ formation is most sensitive to AVOC (RIR: 0.83-1.12), followed by OVOC (RIR:
 762 0.59-0.79) at different heights, indicating the urgent need to reduce AVOC and OVOC
 763 emissions to mitigate O₃ pollution in this area.

764

765 **Figure 9. RIR values for O₃-precursor or precursor groups at different heights during**
 766 **different classified episodes.**

767 The RIR tests for different episodes and non-episodes at various hours of the local
 768 daytime are illustrated in the Supplement (Fig. S7). The results indicate that the diurnal
 769 changes of RIR values for different episodes and non-episodes exhibit remarkable
 770 similarities. In the morning, the RIR values for various VOC groups, including AVOC,
 771 BVOC, OVOC, and CO, are typically higher than those for NO_x. However, they
 772 gradually decrease throughout the day until 16:00 LT, then increase and reach a peak

773 at 18:00 LT. Interestingly, the RIR values at this peak are lower than those at 8:00 LT
774 in the morning. Conversely, the RIR values for NO_x are usually around zero or below
775 zero during most of the day, gradually increasing around 16:00 LT and peaking at 18:00
776 LT. This suggests a transition in the photochemical O₃ formation regime throughout
777 the day, shifting from a VOC-limited regime in the morning to a transition regime and
778 more sensitive to NO_x in the afternoon around 16:00 LT. The diurnal variations of the
779 RIRs of different O₃ precursors or precursor groups offer detailed insights into the
780 dominant factors influencing the photochemical formation of O₃ at different times of a
781 day.

782 Through the sensitivity study, NO_x is not found to be the limiting factor affecting
783 $P(O_3)_{\text{net}}$, therefore, reactions involving NO_x in the RO_x radicals cycle, such as
784 $RO_2+NO \rightarrow HO_2$ and $HO_2+NO \rightarrow OH$, should occurred efficiently. Conversely,
785 reactions not involving NO_x, such as $OH+VOCs \rightarrow RO_2$, should be the limiting steps of
786 the RO_x radicals cycling. Given that photochemical O₃ formation is most sensitive to
787 AVOC and OVOC groups, we further identified and presented the three VOC species
788 with the highest OFP during different episodes and non-episodes in Table S4. Results
789 show that compounds such as toluene, *m/p*-xylene, and n-butane in AVOC group,
790 formaldehyde, hydroxyacetone, and ethanol in OVOC group have identified as the most
791 significant contributors to the total OFP in all episodes and non-episodes. Toluene, *m/p*-
792 xylene, and n-butane are often associated with specific industrial processes (Shi et al.,
793 2022; Liang et al., 2017), while formaldehyde, hydroxyacetone, and acetaldehyde can
794 originate from both the industrial processes and natural sources (Parrish et al., 2012;
795 Fan et al., 2021; Spaulding et al., 2003; Salthammer 2023). Priority of these emission
796 sources should be given to reducing AVOC and OVOC to mitigate O₃ pollution in the
797 PRD area of China.

798 **4 Conclusions**

799 We carried out a field observation campaign in an urban area in Pearl River Delta
800 (PRD) in China, focusing on investigating the vertical temporal variability of near-
801 surface O₃ production mechanisms by using a newly built vertical observation system
802 and the observation-based model coupled to the Master Chemical Mechanism (OBM-
803 MCM) v3.3.1. In total, three O₃ pollution episodes and two non-episodes occurred
804 during the observation period. To assess the modelling performance for O₃ production

805 rates and sensitivity, as well as to investigate the potential reasons for O₃ pollution
806 episodes at 5 m ground level, a net photochemical O₃ production rate (NPOPR, $P(O_3)_{net}$)
807 detection system based on the current dual-channel reaction chamber technique was
808 employed to directly measure $P(O_3)_{net}$ at 5 m ground-level.

809 The vertical profiles of averaged concentrations of various pollutants exhibit
810 similar trends during both episodes and non-episodes. The O₃, NO_x, and Ox
811 concentrations show minimal vertical gradient during the daytime due to rapid vertical
812 mixing effects, but distinct vertical gradients emerge during nighttime owing to the
813 stability of the nocturnal residual layer. Higher concentrations of O₃ and Ox were
814 observed at higher heights, while elevated NO and NO_x concentrations were mainly
815 detected at ground level. Given that NO has a significant titration effect on O₃, the lower
816 O₃ concentration at ground level may be attributed to the increase in NO_x concentration
817 due to a more pronounced NO titration effect, besides the dry deposition near the
818 ground. However, the TVOC and their OFP exhibited variable trends with increased
819 height during both daytime and nighttime, observed in episodes and non-episodes,
820 which indicates the complexities of O₃ formation mechanisms at different heights
821 throughout the atmospheric column. Total OFP was highest at the 5 m ground level and
822 exhibited higher levels during episodes compared to non-episode periods. The OFP was
823 primarily attributed to OVOCs at different altitudes throughout both episodes and non-
824 episodes.

825 The mean concentrations of O₃ precursors, including CO, NO, NO₂, and TVOC,
826 were not consistently elevated during episodes compared to their levels during non-
827 episodes. By considering the observed O₃ concentrations change and the measured
828 $P(O_3)_{net}$ at 5 m ground level, we found that the O₃ pollution episodes were influenced
829 by both photochemical production and physical transport, with local photochemical
830 reactions playing a key role. O₃ pollution episodes recorded during the observation
831 period occurred under specific conditions: ① high photochemical O₃ productions; ②
832 moderate photochemical O₃ productions coupled with O₃ accumulation under stable
833 weather conditions. The index of agreement (IOA) ranged from 0.87 (25th percentile)
834 to 0.90 (75th percentile) for the measured and modelled $P(O_3)_{net}$ across the measurement
835 period, indicating the rationality to investigate the vertical and temporal variability of
836 O₃ formation mechanisms using modelling results. However, the measured $P(O_3)_{net}$
837 generally exceeded the modelled $P(O_3)_{net}$, the differences between measured and

838 modelled $P(\text{O}_3)_{\text{net}}$ ($\Delta P(\text{O}_3)_{\text{net}}$) were found to be correlated with NO concentrations. Base
839 on previous studies, this phenomenon could potentially be attributed to the
840 underestimation of RO_2 at high NO conditions, arising from inadequate knowledge
841 concerning photochemical reaction mechanisms. Therefore, the potential biases caused
842 by the modelling methodology were acknowledged and discussed.

843 From the modelling results, the contribution of different reaction pathways to $P(\text{O}_3)$
844 was almost the same at varying heights during both episodes and non-episodes, with
845 HO_2+NO as the major O_3 production pathway, followed by other RO_2+NO (comprising
846 all RO_2 except CH_3O_2) and $\text{CH}_3\text{O}_2+\text{NO}$. The major O_3 destruction pathway was
847 $\text{OH}+\text{NO}_2$ (loss of OH radicals), followed by net RO_2+NO_2 (forming peroxyacetyl
848 nitrate) and O_3 photolysis. However, other O_3 destruction pathways, including O_3+OH ,
849 O_3+HO_2 , $\text{C}_5\text{H}_8+\text{O}_3$, $\text{C}_3\text{H}_6+\text{O}_3$, and $\text{C}_2\text{H}_4+\text{O}_3$, collectively contributed negligibly to O_3
850 destruction. Nevertheless, $P(\text{O}_3)_{\text{net}}$ showed a decreasing trend with the increase of
851 height during different episodes and non-episodes, which was found mainly attributed
852 to the decline in O_3 precursor concentrations, specifically anthropogenic organic
853 compounds (AVOC) and oxygenated volatile organic compounds (OVOC) groups. We
854 observed that modelling biases were correlated with NO concentrations and VOCs
855 categories, impacting $P(\text{O}_3)_{\text{net}}$ through the regulation of the RO_2 radicals' budget. The
856 median relative difference between measured and modelled $P(\text{O}_3)_{\text{net}}$ ranged from 22-
857 45 % during different episodes and non-episodes. Therefore, the variation of $P(\text{O}_3)_{\text{net}}$
858 along with the measurement height might be even larger than our initial assessment.

859 Similar photochemical O_3 formation regimes were observed at different heights
860 during specific episodes or non-episodes, yet they varied between different episodes or
861 non-episodes. O_3 formation was predominantly located at a transition regime and more
862 sensitive to VOCs emissions during O_3 -polluted episode I, whereas it shifted to a
863 VOCs-sensitive regime during O_3 -polluted episodes II and III, as well as non-episodes
864 I and II. Further analysis revealed a daytime shift in the photochemical O_3 formation
865 regime, transitioning from a VOC-limited regime in the morning to a transition regime
866 more sensitive to NO_x round 16:00 LT in the afternoon. However, the underestimation
867 of RO_2 radicals in the modelling, especially at lower heights with higher NO
868 concentrations, could result in an overestimate of the VOCs-limited regime. This study
869 highlights the need for more precise analysis using direct measurement techniques in
870 future studies. Nonetheless, throughout all episodes and non-episodes, O_3 formation is

871 most sensitive to AVOC, followed by OVOC at various heights, emphasizing the urgent
872 need to reduce emissions of these compounds to mitigate O₃ pollution in this area.

873 This is the first measurement report of the vertical-temporal of O₃ formation
874 mechanisms near the ground surface. Together with the deliberation of the possible bias
875 on the vertical-temporal profile of O₃ formation rate and sensitivity using modelling
876 studies, this research provides critical foundational insights. The findings provide us in-
877 depth understanding of near-ground vertical variability in O₃ formation mechanisms,
878 which are influenced by the concentrations of VOCs and NO_x, and the distinct OFP
879 associated with different VOCs profiles. During daytime, the vertical mixing of air
880 masses is substantially enhanced due to the effect of surface heating. Consequently,
881 photochemically formed O₃ at higher altitudes can be vertically transported downward
882 to the near-ground layer. Under this condition, control strategies for O₃ precursors
883 based on the O₃ formation mechanisms on the ground-level are insufficient. A more
884 comprehensive approach is necessary to effectively address the complexities of O₃
885 production throughout the atmospheric column. The vertical variability of O₃
886 formation mechanisms should be taken into account when making effective O₃ control
887 strategies in the PRD area of China.
