Abstract: Understanding the near-ground vertical and temporal photochemical O_3 formation mechanism is important to mitigate O_3 pollution. Here, we measured the vertical profiles of O_3 and its precursors at six different heights ranging from 5 to 335 m using a newly built vertical observation system in the Pearl River Delta (PRD) region, China. The net photochemical ozone production rate ($P(O_3)_{net}$) and O_3 formation sensitivities at various heights were diagnosed using an observation-based model coupled with the Master Chemical Mechanism (MCM v3.3.1). Moreover, to assess model performance and identify the causative factors behind O_3 pollution episodes, the $P(O_3)_{net}$ was measured at 5 m ground level utilizing a custom-built detection system. In total three O_3 pollution episodes and two non-episodes were captured. The identified

O$_3$ pollution episodes were found to be jointly influenced by both photochemical production and physical transport, with local photochemical reactions playing a major role. The high index of agreement (IOA) calculated from comparing the modelled and measured $P(O_3)_{net}$ values indicated the rationality to investigate the vertical and temporal variability of O$_3$ formation mechanisms using modelling results. However, the measured $P(O_3)_{net}$ values were generally higher than the modelled $P(O_3)_{net}$ values, particularly under high NOx conditions, which may indicate a potential underestimation of total RO$_2$ by the model. Throughout the measurement period, the contribution of different reaction pathways to O$_3$ production remained consistent across various heights, with HO$_2$+NO as the major O$_3$ production pathway, followed by RO$_2$+NO. We observed $P(O_3)_{net}$ decreasing with the increase in measurement height, primarily attributed to the decreased O$_3$ precursors anthropogenic volatile organic compounds (AVOC) and oxygenated volatile organic compounds (OVOC). O$_3$ formation regimes were similar at different heights during both episodes and non-episodes, either located in the volatile organic compounds (VOCs) sensitive regime or in the transition regime and more sensitive to VOCs. Diurnally, photochemical O$_3$ formation typically remained in the VOCs sensitive regime during the morning and noon, but transitioned to the transition regime and more sensitive to VOCs in the afternoon around 16:00 local time (LT). The vertical and temporal O$_3$ formation is most sensitive to OVOC, suggesting that targeting specific VOCs for control measures is more practical and feasible at the observation site. The vertical temporal analysis of O$_3$ formation mechanisms near the ground surface in this study provides critical foundational knowledge for formulating effective short-term emergency and long-term strategies to combat O$_3$ pollution in the PRD region of China.

1. Introduction

Tropospheric ozone (O$_3$), which has adverse effects on ecosystems, climate change, and human health (Fiore et al., 2009; Anenberg Susan et al., 2012; Seinfeld, 2016), has become an important factor resulting in severe regional air pollution in China (Zhu et al., 2020). Tropospheric O$_3$ mainly comes from stratospheric intrusions and the photochemical reactions of O$_3$ precursors, involving volatile organic compounds (VOCs) and nitrogen oxides (NOx=NO+NO$_2$). The O$_3$-precursor relationship can be split into a "NOx-limited" or "VOC-limited" or "mixed-sensitive" regime (Seinfeld and Pandis, 2016; Sillman S., 1999). A "NOx-limited" regime has higher VOCs/NOx ratios

64   and the O_3 formation is sensitive to NOx concentration changes, while a "VOCs-limited"
65   regime has lower VOCs/NOx ratios and the O_3 formation decreases with increasing
66   NO_X and increases with increasing VOCs. In a "mixed-sensitive" regime, O_3 formation
67   responds positively to changes in both NOx and VOC emissions (Wang et al., 2019).
68   Local O_3 concentrations can be further influenced by meteorological conditions and the
69   regional transport of O_3 and its precursors (Gong and Liao, 2019; Chang et al., 2019).
70   The Pearl River Delta (PRD) stands out as one of the most rapidly developing economic
71   and urbanized regions in China, which currently is suffering from severe ground-level
72   O_3 pollution (Lu et al., 2018; Yang et al., 2019). Currently, many scholars have
73   analyzed the relationship between tropospheric O_3 pollution and its precursors and
74   meteorological elements in the PRD region, results show that the surface O_3 pollution
75   is determined by both local photochemistry and physical transport, with long-range
76   transport contributing 30%-70% to surface O_3 concentrations (Mao et al., 2022; Shen
77   et al., 2021; Li et al., 2012, 2013). However, the distribution of O_3 is highly variable at
78   different altitudes (Wang et al., 2021), due to vertical differences in VOC
79   concentrations and sources, as well as the sensitivity of O_3 formation (Liu et al., 2023;
80   Tang et al., 2017). Due to the presence of strong vertical mixing driven by the surface
81   heating effect in the daytime boundary layer, the budget of the O_3 at the ground level
82   and also at an arbitrary height in the daytime boundary layer is closely related to the
83   formation and removal of O_3 at other heights (Tang et al., 2017). In addition, the
84   difference in vertical gradients of precursors may drive the vertical change in the
85   photochemical formation regimes of O_3 (Zhao et al., 2019). Using data from only one
86   height to understand the photochemical reactions in the planetary boundary layer is of
87   great limitation. Thus, diagnosing the O_3 formation mechanism at different heights is
88   essential to achieve effective control of O_3 pollution.

89   Currently, remote sensing techniques with high time resolution and real-time
90   response, such as lidar and optical absorption spectroscopy, have been utilized to
91   measure the vertical distribution of O_3 (Luo et al., 2020a; Wang et al., 2021). However,
92   in situ measurements of VOCs at various heights primarily rely on offline methods
93   combined with diverse techniques, including aircraft, tethered balloons, tall buildings
94   and towers, unmanned aerial vehicles (UAVs or drones), and satellite observations
95   (Klein et al., 2019; Li et al., 2022; Geng et al., 2020; Benish et al., 2020; Li et al., 2021;
96   Wang et al., 2019). Owing to the low time resolution of these monitoring techniques,

97   achieving continuous vertical coverage of VOCs and NOx measurements is challenging.

98   Consequently, the vertical distribution structure of VOCs remains unclear, thus largely

99   hindering our understanding of the vertical and temporal regional O_3 formation

100   mechanism.

101   To fill the gaps in the existing studies, we utilized a newly constructed vertical

102   observation system based on the Shenzhen Meteorological Gradient Tower (SZMGT)

103   (Li et al., 2023). This system measured the vertical profiles of O_3 and its precursors at

104   six different heights from 5 to 335 m. To diagnose the net O_3 production rate, $P(O_3)_{net}$,

105   and O_3 formation sensitivities across various heights, we employed an observation-

106   based model coupled with the Master Chemical Mechanism (MCM v3.3.1), referred to

107   as OBM-MCM in the following. Additionally, we employed a novel net photochemical

108   O_3 production rate ($P(O_3)_{net}$, NPOPR) detection system to measure the $P(O_3)_{net}$ at the 5

109   m ground level to explore potential reasons for O_3 pollution episodes (Hao et al., 2023),

110   i.e., examine the contribution of chemical and physical processes to changes in O_3

111   concentration. Comparisons between the directly measured $P(O_3)_{net}$ results and the

112   model-derived data enabled us to evaluate the simulation accuracy and explore potential

113   reasons for discrepancies of the OBM-MCM model concerning photochemical O_3

114   formation. Based on these results, we have extensively discussed the vertical and

115   temporal variability in $P(O_3)_{net}$ and O_3 formation sensitivity, while acknowledging

116   potential biases associated to the modelling. The findings of this study offer a new

117   benchmark for understanding the vertical profile of photochemical O_3 formation

118   mechanism, aiding in the identification of the primary driver of ground-level O_3

119   pollution. This identification is crucial as it can provide essential theoretical support for

120   developing short-term effective emergency and long-term control measures targeting

121   O_3 in PRD region of China.

122   **2. Materials and Methods**

123   **2.1 Sampling site**

124   Field measurements were conducted at the Shenzhen Meteorological Gradient

125   Tower (SZMGT) (22.65° N,113.89° E) from November 13 to December 10, 2021. The

126   SZMGT is 365 m high and is currently the tallest mast tower in Asia and the second

127   tallest of this kind in the world. The main structure of the tower is made of steel, steel

128   stray lines are used for fixing and securing the tower. It is located in the Tiegang

129 Reservior Water Reserve at Bao'an District of Shenzhen, in the Pearl River Delta (PRD)

130 region of China. The area is surrounded by a high density of vegetation, reservoir

131 features, low-rise buildings, and hills/mountains (Luo et al., 2020b).

132 **2.2 Instrumentation**

133 ### 2.2.1 The vertical sampling system

134 A tower-based observation system for traces gases using long perfluoroalkoxy

135 alkane (PFA) tubing (OD: 1/2") was used to sample the O_3 and O_3 precursors at six

136 heights during the campaign, including 5, 40, 70, 120, 220, and 335 m above the ground.

137 All six tubes were continuously drawn using a rotary vane vacuum pump to keep

138 flushing with ambient air to reduce tube delay of the organic compounds, with the flow

139 rate controlled by critical orifices (orifice diameter: 0.063"). A Teflon solenoid valve

140 group was used to switch the air samples at specified time intervals so that the

141 subsamples from these six heights could be sequentially drawn by instruments (see Fig.

142 S1). Consequently, the flow rates of the air sample streams for the six tubes varied

143 between 12.0 and 15.0 SLPM without subsampling and were less than 20 SLPM with

144 subsampling. The residence time of the sample gas in the longest tube (~ 400 m) is less

145 than 180 s at a flow rate of 13 SLPM. The impacts of long tubing on measurements of

146 various of trace gases, including O_3, NOx, and a set of organic compounds, were

147 systematically investigated using a combination of laboratory tests, field experiments,

148 and modelling techniques. Field observations proved that this observation system is

149 suitable for analyzing spatio-temporal variations of atmospheric trace gases, with many

150 trace gases could be well measured. More details about the establishment and the

151 characterization of this observation system are described elsewhere (Li et al., 2023).

152 ### 2.2.2 P(O$_3$)$_{net}$ measurement

153 During the campaign, the $P(O_3)_{net}$ at the 5 m ground level was measured using the

154 home-made NPOPR detection system, which was built based on the dual-channel

155 reaction chambers technique. The improvement, characterization, and the

156 photochemical O_3 formation mechanism in the reaction and reference chambers of the

157 NPOPR detection system are described in our previous study (Hao et al., 2023). Briefly,

158 the NPOPR detection system consists of reaction and reference chambers with the same

159 geometry and made of quartz glass. The length and inner diameter of the quartz glass

160 cylinder are 700 mm and 190.5 mm, respectively, which resulted in an inner volume of

161 ~ 20 L. The outer surface of the reference chamber was covered with an Ultem film

162 (SH2CLAR, 3 M, Japan) for ultraviolet (UV) protection, which can block sunlight with

163 wavelengths < 390 nm, thus preventing photochemical reactions inside. During the

164 experiment, both the reaction and reference chambers were placed outdoors and directly

165 exposed to sunlight to simulate real ambient photochemical reactions. Ambient air was

166 introduced into the reaction and reference chambers at the same flow rate, and a Teflon

167 filter was mounted before the chamber inlet to remove fine particles. To correct for the

168 effect of fresh NO titration to O_3, we use O_X (=O_3+NO_2) instead of O_3 to quantify the

169 O_3 generated by photochemical reactions (Pan et al., 2015; Tan et al., 2018). A stream

170 of air from the two chambers was alternately introduced into an NO-reaction chamber

171 every 2 min to convert O_3 in the air to NO_2 in the presence of high concentrations of

172 NO (O_3+NO→NO_2), and the Ox concentrations from the outlet NO-reaction chamber,

173 i.e., the total NO_2 concentrations including the inherent NO_2 in the ambient and that

174 converted from O_3, were measured by a Cavity Attenuated Phase Shift (CAPS) NO_2

175 Monitor (Aerodyne research, Inc., Billerica MA, USA) to avoid other nitrogen oxide

176 interferences to the NO_2 measurement (such as alkyl nitrates, peroxyacyl nitrates,

177 peroxynitric acid, nitrogen pentoxide, etc.). $P(O_3)_{net}$ was obtained by dividing the

178 difference between the Ox concentrations in the reaction and reference chambers (ΔOx)

179 by the mean residence time of air in the reaction chamber $\langle\tau\rangle$:

180 $$P(O_3)_{net} = P(O_X)_{net} = \frac{\Delta O_X}{\tau} = \frac{[O_X]_{reaction} - [O_X]_{reference}}{\tau} \tag{1}$$

181 A schematic of the NPOPR detection system is shown in Fig. S2. The pulse

182 experiments were performed to quantify the residence time in the chambers (Hao et al.,

183 2023).

184 [Ox] values plugged in Eq. (1) to derive $P(O_3)_{net}$ are measured values corrected

185 for wall losses of Ox and the light-enhanced loss of O_3 (d[O_3]) in the reaction and

186 reference chambers during daytime (Hao et al., 2013):

187 $$\gamma = \frac{d[O_3] \times D}{\omega \times [O_3] \times \tau} \tag{2}$$

188 where γ is the light-enhanced loss coefficient of O_3, which is derived from $J(O^1D)$

189 according to the relationship obtained from the outdoor experiments (for more details,

190 see supplementary materials: Sect. S3). d[O_3] represents the difference between the O_3

191   mixing ratios at the inlet and outlet of the reaction and reference chambers, D is the

192   diameter of the chambers, ω is the average velocity of O_3 molecules, $[O_3]$ is the injected

193   O_3 mixing ratio at the inlet of the reaction and reference chambers, and τ is the average

194   residence time of the air in the reaction and reference chambers. When quantifying the

195   light-enhanced O_3 loss ($d[O_3]$) during the ambient air measurement, we first calculate

196   γ using the measured $J(O^1D)$ and the γ -$J(O^1D)$ equations listed in Fig. S8 in the

197   reaction and reference chambers, then use the measured $[O_3]$ and Eq. (2) to calculate

198     $d[O_3]$. The results show that such kind of correction can increase the measured $P(O_3)_{net}$

199   by 10% (25% percentile) to 24% (75% percentile), with a median of 17%.

200   The limit of detection (LOD) of the NPOPR detection system is 2.3 ppbv h^{-1} at the

201   sampling air flow rate of 5 L min^{-1}, which is obtained as three times the measurement

202   error of $P(O_3)_{net}$ (Hao et al., 2013). The measurement error of $P(O_3)_{net}$ is determined by

203   the estimation error of Ox in the reaction and reference chambers, which includes the

204   measurement error associated with the O_X of the CAPS-NO_2 monitor and the error due

205   to the light-enhanced loss of O_3. This collective measurement error is referred to as the

206   measurement precision of the NPOPR detection system, with further details provided

207   in the supplementary materials, specifically in Sect. S4. The measurement accuracy of

208   the NPOPR detection system is determined as 13.9 %, representing the maximum

209   systematic error resulting from photochemical O_3 production in the reference chamber.

210   Our earlier research indicated that the modelled $P(O_3)_{net}$ in the reaction chamber is

211   similar to that modelled in ambient air, with the modelled $P(O_3)_{net}$ in the reference

212   chamber accounting for 0-13.9% of that in the reaction chamber (Hao et al., 2023). This

213   is due to the UV protection Ultem film covered on the reference chamber, which only

214   filtered out the sunlight with wavelengths < 390 nm, allowing photochemical O_3

215   production to persist at the sunlight wavelength between 390 nm and 790 nm. Here, we

216   have utilized the same modelling approach described in Hao et al. (2013) to quantify

217   the $P(O_3)_{net}$ in the reference chamber and corrected for the bias introduced by the

218   measurement accuracy.

219   **2.2.3 VOCs measurement**

220   VOCs were measured using a high-resolution proton transfer reaction time-of-

221   flight mass spectrometer (PTR-TOF-MS, Ionicon Analytik, Austria) (Wang et al.,

222   2020a; Wu et al., 2020) and an off-line gas chromatography mass spectrometry flame

223 ionization detector (GC-MS-FID) (Wuhan Tianlong, Co. Ltd, China) (Yuan et al.,
224 2012). The concentrations of oxygenated VOCs (OVOC), including formaldehyde
225 (HCHO) and acetaldehyde (CH_3CHO), were measured via PTR-TOF-MS, and the non-
226 methane hydrocarbons (NMHC) were measured via GC-MS-FID. PTR-TOF-MS was
227 run with both hydronium ion (H_3O^+) (Yuan et al., 2017; Wu et al., 2020) and nitric
228 oxide ion (NO^+) (Wang et al., 2020) modes. The measurement error of PTR-TOF-MS
229 was lower than 20%, more details of the PTR-TOF-MS technique can be found in our
230 previous publication (Yuan et al., 2017). The H_3O^+ and NO^+ modes were automatically
231 switched with 20 min H_3O^+ mode and 10 min NO^+ mode. The background signal of
232 each mode was measured every 30 min for at least 2 min by automatically switching
233 the ambient measurement to a custom-built platinum catalytic converter heated to 365
234 ^{o}C. Operating the PTR-ToF-MS instrument in NO^+ mode primarily detects higher
235 alkanes, which are known significantly contribute to the formation of secondary organic
236 aerosols (SOA) but negligible contributions to photochemical O_3 formation (Wang et
237 al., 2020). Eventually, we only used VOCs measured during the H_3O^+ mode, which was
238 operated at a drift tube pressure of 3.8 mbar, a temperature of 120 ^{o}C, and a voltage of
239 760 V, resulting in an E/N (E refers to the electric field and N refers to the number
240 density of the buffer gas in the drift tube) value of ~ 120 Td (townsend). 3035 ions with
241 m/z up to 510 were obtained at time resolutions of 10 s. A gas standard with 35 VOC
242 species was used for calibrations of the PTR-ToF-MS once per day. Raw data from
243 PTR-TOF-MS were analyzed using Tofware software (Tofwerk AG, v3.0.3). Due to
244 the humidity dependencies of various VOCs signals of the PTR-ToF-MS observed in
245 laboratory studies, such as formaldehyde, benzene, methanol, ethanol, and furan (Wu
246 et al., 2020), we determined their humidity-dependence curves. During data analysis,
247 we removed the impacts of ambient humidity change on the measured signals of the
248 PTR-ToF-MS according to these humidity-dependence curves. For the off-line GC-
249 MS-FID measurement, whole-air samples were collected using 3.2 L electro-polished
250 stainless-steel canisters (Entech, USA) at 5 and 120 m at time intervals of two hours.
251 Two automatic canister samplers connected to 12 canisters were used to collect the
252 whole-air samples, with each of canister collecting the sample for 10 min. The canisters
253 were analyzed within one week (Zhu et al., 2018). The concentrations of 56 NMHC
254 species in the canister were analyzed by GC-MS/FID which was calibrated daily using
255 the mixture of a photochemical assessment monitoring stations (PAMS) standard gas
256 and pure N_2. In addition, the mixture of PAMS standard gas and pure N_2 with species

257 concentrations of 1 ppbv was injected into the analytical system every 10 samples to
258 check the operational stability of the instrument. Pure N_2 was injected into the analytical
259 system at the start and end of each day's analysis to provide reference blank
260 measurements. A full list of all 56 non-methane hydrocarbons (NMHCs) can be found
261 in the supplementary material (Table S2).

2.2.4 Other parameters

263 The photolysis frequencies of different species were measured using the actinic
264 flux spectrometer (PFS-100, Focused Photonics Inc, China). O_3, CO, and NO_X
265 concentrations were measured by a 2B O_3 monitor based on dual-channel UV-
266 absorption (Model 205, 2B Technologies, USA), a gas filter correlation (GFC) CO
267 analyzer (Model 48i, Thermo Fisher Scientific, USA), and a chemiluminescence NOx
268 monitor (Model 42i, Thermo Fisher Scientific, USA), respectively. According to our
269 test (Zhou et al., 2025), a 5% overestimation could be caused in the NO_2 measurement
270 using the chemiluminescence technique compared to the CAPS technique, due to some
271 NO_Z species (i.e., HNO_3, peroxyacetyl nitrate (PANs), HONO, etc.)(Dunlea et al.,
272 2007), this will result in a decrease of the modelled $P(O_3)_{net}$ by < 4%, which is
273 negligible compared to the bias caused by the $P(O_3)_{net}$ in the reference chamber (~ 14%)
274 (Zhou et al., 2023).Temperature (*T*), relative humidity (RH), and pressure (*P*) were
275 measured by a portable weather station (Met Pak, Gill Instruments Ltd, UK).

2.3 Data analysis

2.3.1 Observation-based chemical box model

278 We investigated the detailed photochemical O_3 formation mechanism during the
279 observation period based on the field observed data. The specific tropospheric O_3
280 photochemical formation process involves the photolysis of NO_2 at < 420 nm
281 (Sadanaga et al., 2017). Simultaneously, RO_X (RO_X=OH+HO_2 +RO_2) radical cycles
282 provide HO_2 and RO_2 to oxidize NO to NO_2, resulting in the accumulation of O_3 (Shen
283 et al., 2021; Cazorla and Brune, 2010; Sadanaga et al., 2017). Therefore, the ROx
284 radicals and the O_3, OH, NO_3 oxidants play important roles in photochemical O_3
285 formation. A zero-dimensional box model based on the Framework for 0-D
286 Atmospheric Modelling (F0AM) v3.2 (Wolfe et al., 2016) coupled with the MCM
287 v3.3.1 was used to simulate the $P(O_3)_{net}$. MCM v3.1.1 contains a total of 143 VOCs,
288 more than 6700 species, involving more than 17000 reactions (Jenkin et al., 2015).

289 $P(O_3)_{net}$ and O_3 concentrations were simulated by constraining T, RH, P, organic and

290 inorganic substances in gases, including 12 OVOCs (methanol, ethanol, formaldehyde,

291 acetaldehyde, acrolein, acetone, hydroxyacetone, phenol, m-cresol, methyl vinyl ketone,

292 methacrylaldehyde, methyl ethyl ketone), 56 NMHCs (toluene, benzene, isoprene,

293 styrene, etc. as listed in Table S2), inorganic gaseous pollutants (O_3, NO, NO_2, and CO),

294 and photolysis rate values ($J(O^1D)$, $J(NO_2)$, $J(H_2O_2)$, $J(HONO)$, $J(HCHO\_M)$,

295 $J(HCHO\_R)$, $J(NO_3\_M)$, $J(NO_3\_R)$, etc.). The VOCs, NOx, T, RH and P were

296 constrained throughout the modelling period, while O_3 was not constrained after

297 providing initial concentration values. To avoid the build-up of long-lived species to

298 unreasonable levels, we also considered the physical dilution process by setting a

299 constant dilution factor of 1/43200 s^{-1} throughout the modelling period (Liu et al., 2021;

300 Decker et al., 2019). Additionally, the dry deposition rate of O_3 was set to 0.42 cm s^{-1},

301 and the background of O_3, CO, and CH_4 were set to 30, 70, and 1800 ppbv, respectively,

302 based on the findings of Wang et al. (2011), Wang et al. (2022a), and WMO greenhouse

303 gas bulletin (2022). The model was run in a time-dependent mode with a resolution of

304 5 min, and it was run for spin-up time of 72 h to establish steady-state concentrations

305 for secondary pollutants that were not constrained during the simulation. $P(O_3)_{net}$ can

306 be expressed by the difference between O_3 production rate ($P(O_3)$) and O_3 destruction

307 rate ($D(O_3)$), where $P(O_3)$ and $D(O_3)$ can be calculated as Eq. (3)-(4):

308 $$P(O_3) = k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_{2,i}+NO}[RO_{2i}][NO]\varphi_i \qquad (3)$$

309 $$D(O_3) = k_{O(^1D)+H_2O}[O(^1D)][H_2O] + k_{OH+O_3}[OH][O_3] + k_{HO_2+O_3}[HO_2][O_3]$$

310 $$+ k_{O_3+alkenes}[O_3][alkenes] + k_{OH+NO_2}[OH][NO_2] +$$

311 $$k_{RO_{2,i}+NO_2}[RO_{2i}][NO_2] \qquad (4)$$

312   where k_{M+N} represents the bimolecular reaction rate constant of M and N, the

313 subscript 'i' refers to different types of RO$_2$, and φ_i is the yield of NO$_2$ of the reaction

314 RO$_{2i}$+NO. The relevant reaction rates of $P(O_3)$ and $D(O_3)$ and the mean measured

315 concentrations of each VOC category at 5 m ground during O_3 episodes and non-

316 episodes used in the model are listed in Tables S1 and S2.

317   **2.3.2 Derive contribution of chemical and physical processes to O3**

318   **changes on the ground level**

319   It is known that chemical and physical processes jointly influence the O_3

10

320 concentration changes near the ground surface (Xue et al., 2014; Tan et al., 2019). The

321 direct measurement of $P(O_3)_{net}$ gave us a chance to identify the contribution of chemical

322 and physical processes to the variation of observed O_3 concentrations using the

323 following equation:

324 $$\frac{dO_X}{dt} = P(O_X)_{net} + R(O_X)_{trans} \tag{5}$$

325 Where $\frac{dO_X}{dt}$ is the change rate of the observed O_x mixing ratio change (ppbv h^{-1}),

326 $P(Ox)_{net}$ denotes the net photochemical O_3 production rate (ppbv h^{-1}), which was equal

327 to $P(O_3)_{net}$ and measured directly by the NPOPR system. $R(O_X)_{trans}$ represents O_3

328 mixing ratio change due to physical transportation (ppbv h^{-1}), including the horizontal

329 and vertical transport, dry deposition and the atmospheric mixing (Liu et al., 2022). To

330 correct the effects of NO titration to O_3, we have replaced O_3 with O_X ($=O_3+NO_2$)

331 during the calculation in this study (Pan et al., 2015).

2.3.3 Model performance

333 In order to judge the reliability of the model simulation, we calculated the index

334 of agreement (IOA) based on the measured and modelled $P(O_3)_{net}$ and O_3 at 5 m above

335 the ground level using the following equation (Liu et al., 2019):

336 $$IOA = 1 - \frac{\sum_{i=1}^{n}(O_i - S_i)^2}{\sum_{i=1}^{n}(|O_i - \bar{O}| - |S_i - \bar{O}|)^2} \tag{6}$$

337 Where S_i and O_i represents the simulated and observed $P(O_3)_{net}$ or O_3 values at the

338 same time, respectively, $\bar{O}$ is the averaged observed value, and n is the data number.

339 Furthermore, we also judged the model simulation performance using statistical

340 measures, including the normalized mean bias (NMB) and normalized mean error

341 (NME), which are defined as:

342 $$NMB = \frac{\sum_{i=1}^{n}(S_i - O_i)}{\sum_{i=1}^{n} O_i} \cdot 100 \% \tag{7}$$

343 $$NME = \frac{\sum_{i=1}^{n}|S_i - O_i|}{\sum_{i=1}^{n} O_i} \cdot 100 \% \tag{8}$$

344 Where S_i and O_i have the same meaning as Eq. (6), and n is the total number of

345 such data pairs of interest. The results will be discussed in Sect. 3.2.2.

2.3.4 OH reactivity

347   In order to investigate the influence of the photochemical reactions of different

348   VOCs to photochemical O_3 formation, we calculated the OH reactivities of different

349   VOCs, which is the sum of concentrations of OH reactants multiplied by their reaction

350   rate coefficients, as shown below:

351      $k_{OH} = k_i \times [VOCs]_i$ (9)

352   where k_{OH} represents the total OH reactivity of a group of VOCs species, k_i

353   represents the rate constants between OH radicals and different VOCs species i,

354    $[VOCs]_i$ represents the concentration of species i. In this study, we summarized the OH

355   reactivities of different kinds of VOCs groups together to investigate their influence on

356   the vertical gradient $P(O_3)_{net}$ in Sect. 3.2.3.

357   **2.3.5 O_3 formation potential**

358   The O_3 formation potential is calculated using the product of the VOC concentration

359   and the maximum incremental reactivity (MIR) coefficient (dimensionless, gram of O_3

360   produced per gram of VOCs) (Carter et al., 2012):

361      $OFP_i = \sum_i [VOC]_i \times MIR_i$ (10)

362   Where OFP_i is the O_3 formation potential of species i, $[VOC]_i$ is the mass

363   concentration or emission of species i, and MIR_i denotes the maximum increment

364   reactivity of species i (g O_3/g VOCs).

365   **2.3.6 O_3 formation regime**

366   The sensitivity of photochemical O_3 production to its precursors was diagnosed by

367   calculating the relative incremental reactivity (RIR) using the OBM-MCM model. RIR

368   is defined as the percent change in O_3 photochemical production per percent change in

369   the concentration of its single precursor/precursor group (Cardelino and Chameides,

370   1995). Therefore, the RIR for precursor (group) X can be expressed as:

371 $RIR = \dfrac{\Delta P(O_3)/P(O_3)}{\Delta X/X}$ (11)

372   where the $\Delta X/X$ represent the percent change in different O_3 precursors or

373   precursor groups. We classified the measured VOCs into anthropogenic organic

374   compounds (AVOC), biogenic organic compounds (BVOC), and OVOC group, and

375   investigated the O_3 formation sensitivity to these different types of VOCs.

3. Results and discussions

3.1 Vertical and temporal profile of O_3 and its precursors

3.1.1 O_3 and its precursors at 5 m ground level

Figure 1 shows the time series of the major trace gases, photolysis rate constants, and meteorological parameters at 5 m ground-level during the observation period at SZMGT. Over the 1-month field observation period, a total of 3 O_3 pollution episodes (referred to episodes hereafter) and 2 non-O_3 pollution episodes (referred to non-episodes hereafter) were captured. O_3 pollution episodes were defined as the days during which the hourly average O_3 concentration at ground-level (5 m) exceed the Grade II standard (102 ppbv, GB 3095-2012, China; Ambient Air Quality Standards, 2012), while the remaining days were defined as non-episodes. Episode days (marked as gray columns in Fig. 1) included November 13-18 (episode I), November 26 (episode II), and December 7-9 (episode III), while the non-episode days included November 22-25 (non-episode I), November 26-27 and 30 (non-episode II). The corresponding daytime mean values (6:00-18:00 LT) during all episode days and non-episode days are shown in Table 1. During the daytime of episode days (episodes I, II, and III), the mean concentrations of O_3 were 70.1±28.6, 59.5±32.4, and 71.3±31.0, respectively. The mean T and RH were 22.3±2.5 ℃ and 56.2±14.5 % for episode I, 20.4±3.2 ℃ and 52.2±16.7 % for episode II, and 20.6±3.4 ℃ and 58.2±17.2 % for episode III. During non-episode days, the mean concentrations of O_3 were 45.3±16.2 and 63.7±21.3 ppbv for non-episode I and II, respectively. The corresponding mean T and RH were 18.4±4.3 ℃ and 69.5±15.4 % for non-episode I, and 21.3±2.7 ℃ and 51.8 ±13.7 % for non-episode II. These observations indicate that the T and RH during episode days were not significantly different from those during non-episode days. This phenomenon contrasts with previous studies in the PRD area, where O_3 pollution episodes were generally associated with high T and low RH (Mousavinezhad et al., 2021; Hong et al., 2022).

403
Figure 1. Time series of major trace gases, photolysis rate constants, and meteorological parameters at 5 m ground level during the observation period. The gray columns show the typical O_3 episodes that occurred.

Table 1. Daytime major trace gases concentrations (units: ppbv), $P(O_3)_{net}$ (units: ppbv h^{-1}), and meteorological parameters during different episodes and non-episodes during the observation period (from 13 November to 9 December 2021) at SZMGT.

| Parameters	Mean±SD				
	Episode I	Episode II	Episode III	Non-episode I	Non-episode II

wind direction (°)	115.5±48.7	128.6±35.3	144.8±57.1	115.0±57.6	115.3±36.2

410   * All values here were calculated as the mean average values during daytime (6:00-18:00 LT).

411   The mean concentrations of O_3 precursors, including CO, NO, NO_2, and the total

14

VOCs measured by PTR-TOF-MS (shown as TVOC in Fig. 1 and Table 1), did not exhibit notable discrepancies between episodes and non-episodes. This suggests that their concentrations during O_3 pollution episodes can vary, being either higher or lower than those observed during non-episodes (as shown in Table 1). For example, though there are days with very high hourly average O_3 concentrations which define O_3 pollution episodes-where levels exceed the Grade II standard of 102 ppbv-the overall average O_3 concentrations for episode II is not higher than that of non-episode II. This suggests that despite the occurrence of peak hourly levels, the average concentration for episode II remains lower, highlighting the fluctuating pattern of O_3 levels during these episodes. Further comparison of the daytime mean O_3 formation potential (OFP) and the measured $P(O_3)_{net}$ during episodes and non-episodes showed no significant differences, ranging from 5.1×10^{-4} to 1.0×10^{-3} g m^{-3} and 14.3 to 21.5 ppb h^{-1}, respectively, during non-episodes, whereas they are ranged from 4.1×10^{-4} to 4.7×10^{-4} g m^{-3} and 5.6 to 18.9 ppb h^{-1} respectively, during episodes. Although OFP was always higher during episodes than during non-episodes, the mean $P(O_3)_{net}$ values during episodes I and III were even lower than during non-episodes II. The higher O_3 concentrations may be due to the more stable weather conditions during episodes I and III (with lower wind speed), which benefits the accumulation of O_3 formed by local photochemical O_3 formation. While for non-episode II, even it processes higher $P(O_3)_{net}$, the outflow of O_3 from the observation site by physical processes may be higher due to the higher wind speed. These findings indicate that the O_3 pollution episodes stem from either substantially elevated local photochemical O_3 formation (i.e., episode II), or the accumulation of O_3 formed by moderate local photochemical O_3 formation under stable weather conditions (i.e., episodes I and II). Notably, when local photochemical reactions contribute intensely to the formation of O_3, favorable weather conditions facilitating O_3 outflow diminish the likelihood of O_3 pollution occurrences (i.e., non-episode II). These results indicate that O_3 pollution episodes are jointly affected by the photochemical reactions and physical transport processes, which we will discuss in more detail in Sect. 3.2.1.
Figure 2. Time series of vertical profiles for O₃, NOx, Ox, and TVOC during the observation period. The contour plots are made using the measured values from six heights.

Figure 3. Average vertical profiles of O₃, NO, Ox, NOx, and TVOC during both daytime and nighttime, and OFP of different VOCs types during daytime at six heights (5, 40, 70, 120, 220, and 335 m), including episodes and non-episodes throughout the observation period. The error bars indicate the standard deviation calculated from the measured values during these periods.

3.1.2 Vertical profiles of O₃ and its precursors at 5-335 m level

Figure 2 shows the contour plots illustrating the vertical profiles of O₃, NOx, Ox(=O₃+NO₂), and TVOC. From Fig. 2, minimal vertical gradients were observed during daytime in the concentration of all species–O₃, NOx, Ox, and TVOC–due to the rapid vertical mixing effects. However, distinct vertical gradients were observed during nighttime owing to the stability of the nocturnal residual layer. Elevated concentrations of O₃ and Ox were identified at higher altitudes, whereas higher NOx concentrations predominantly occurred at ground level. We further elucidated the vertical distribution patterns of different pollutants as well as the OFP of different VOCs groups during local daytime (6:00-18:00 LT) and nighttime (19:00-5:00 LT) for both episodes and non-episodes, as shown in Fig. 3.

17

463 The vertical profiles of averaged concentrations of various pollutants exhibit
464 similar trends during both episodes and non-episodes, with O_3 showing an increasing
465 trend from 5 m above ground level to 355 m, aligning with findings from previous
466 studies (Zhang et al., 2019; Wang et al., 2021). Given that NOx has a significant
467 titration effect on O_3, the lower O_3 concentration at ground level may be attributed to
468 the increase in NOx concentration (Zhang et al., 2022) and also the dry deposition near
469 the ground (Li et al., 2022). NO and NOx showed an opposite trend compared to O_3.
470 These two factors jointly effected the Ox changing trend with heights, and consequently,
471 the gradients of Ox concentrations showed a weaker increasing trend from the 5 m
472 ground level to 355 m height compared to O_3. This observation demonstrated a more
473 pronounced NO titration effect at the 5 m ground level compared to the effect at 355 m
474 height. However, the TVOC showed variable trends with increased height for daytime
475 and nighttime during episodes and non-episodes. During daytime, TVOC initially
476 decreased from 5 m to 40 m, and then continuously increased from 40 m to 355 m
477 during episodes, while continuously slightly decreased from 5 m to 335 m during non-
478 episodes. During nighttime, TVOC concentrations first increased from 5 m to 40 m and
479 then continuously decreased from 40 m to 335 m during both episodes and non-episodes.
480 We further plotted the OFP of different VOCs categories at various altitudes, including
481 OVOCs, aromatics, alkyne, alkene, and alkane, and found that the total OFP was
482 highest at 5 m ground level and exhibited higher levels during episodes compared to
483 non-episode periods. Subsequently, there was a significant decrease at 40 m height
484 during both episodes and non-episodes. However, there was a sharp increase observed
485 at 70 m, 120 m, and 220 m during episodes, contrasting with a gradual rise during non-
486 episode periods, which eventually reach a peak at 220 m during non-episodes. A
487 consistent decrease of OFP from 220 m to 335 m was observed during both episodes
488 and non-episodes. The OFP was primarily attributed to OVOCs among different VOCs
489 categories at different altitudes throughout both episodes and non-episodes, followed
490 by aromatics and alkane during episodes and non-episodes, respectively.

491 In conclusion, our daytime observations revealed minimal vertical gradients in the
492 concentrations of O_3, NOx, Ox, and TVOC, attributed to the rapid vertical mixing
493 effects driven by surface heating effects (Tang et al., 2017). This suggests that ground-
494 level O_3 concentrations would be representative of the entire vertical column.
495 Nonetheless, the OFP varies for different VOCs profiles at various heights, and the

496 vertical mixing effects facilitates the downward transport of O_3 photochemically
497 formed from higher altitudes to the near-ground layer. Consequently, a box model
498 constraining to ground-level NOx and VOCs concentrations may not accurately reflect
499 the in situ O_3 production in the vertical atmospheric column.

3.2 O_3 pollution episodes formation mechanism at near-ground surface

501 In this section, we first explore the possible reason for O_3 pollution episodes on
502 the 5 m ground level, aiming to identify the contribution of chemical and physical
503 processes to change in O_3 concentrations (Sect. 3.2.1). Subsequently, we assessed the
504 modelling performance and investigated the potential reasons for the modelling bias in
505 photochemical O_3 formation by comparing the measured $P(O_3)_{net}$ with the modelled
506 $P(O_3)_{net}$ (Sect. 3.2.2). To gain insights into the photochemical O_3 formation mechanism
507 at different heights and understand their role in overall O_3 pollution, we further discuss
508 the chemical budget of O_3 at different heights (Sect. 3.2.3), the vertical and temporal
509 variability of $P(O_3)_{net}$ and O_3 formation regime (Sect. 3.2.4), along with potential bias
510 within the modelling approach (Sect. 3.2.5).

**3.2.1   Contribution of chemical and physical processes to O_3 changes on
the ground level**

513 As concluded in Sect. 3.1.1, O_3 pollution episodes may be jointly affected by the
514 photochemical reactions and physical transport. In order to identify the main reasons
515 for O_3 pollution on the ground level, we calculated the contribution of chemical and
516 physical processes to O_X concentration changes at 5 m ground level separately for all 3
517 episodes and 2 non-episodes. Typically, as dry deposition contributes a relatively small
518 portion and can often be considered negligible, making vertical and horizontal transport
519 the main contributors to physical processes (Tan et al., 2019).

520

521
Figure 4. Time series of O_X concentration changes (d(O_X)/dt) and contributions from local photochemical production ($P(O_X)_{net}$) and physical transport ($R(O_X)_{tran}$). The shaded areas of d(O_X)/dt, $P(O_X)_{net}$, and $R(O_X)_{tran}$ represent one standard deviation (denoted by σ) of the mean d(O_X)/dt, the uncertainty of measured $P(O_X)_{net}$, and the propagated error of $R(O_X)_{tran}$, respectively.

527

Figure 5. Diurnal variation of the contribution of chemical and physical transport to O_3 changes on the ground level.

530    $R(O_X)_{trans}$ at 5 m ground level was derived from $\frac{dO_X}{dt}$ minus $P(O_X)_{net}$, according to

531   Eq. (5) shown Sect. 2.3.2, their hourly averages and diurnal variations are shown in

532   Figs. 4 and 5, respectively. From these figures, it is evident that the fluctuation of the

533   O_X concentration change rate (d(O_X)/dt) at ground level is typically small and primarily

534   dominated by the physical processes during nighttime. During nighttime, $P(O_X)_{net}$

535   should be zero without sun radiation, the significant $P(O_X)_{net}$ shown in Fig. 5 may be

20

536 due to the measurement uncertainty of $P(O_X)_{net}$, which is determined by the
537 measurement error of O_X of CAPS-NO_2 monitor in the reaction and reference chambers
538 (as discussed in Sect. S4). The measurement uncertainty of $P(O_X)_{net}$ is higher at lower
539 $P(O_X)_{net}$ values (as shown in Fig. 4), which was mainly determined by the instrumental
540 error of O_X measurement and the ambient O_X concentrations during nighttime. It was
541 estimated to be ~ 38 % and can be considered as the measurement precision. Around
542 6:00-7:00 LT, O_3 concentrations increase for all episodes and non-episodes, mainly due
543 to physical transport during episodes I and II and non-episodes I, while photochemical
544 reactions and physical processes are equally important for episodes III and non-episode
545 II. This could be due to short-term strong vertical turbulence in the early morning,
546 which leads to an expansion of the boundary layer height and makes the residual layer
547 "leaky", allowing vertical transport. At the same time, O_3 precursors were also
548 transported down from the residual layer, and with increasing sunlight, these O_3
549 precursors underwent rapid photochemical reactions that competed with the physical
550 processes between 6:00-7:00 LT, leading to a sharp increase in $P(O_X)_{net}$ between 8:00
551 to 12:00 LT. The $P(O_X)_{net}$ peaked around 11:00-14:00 LT and started to decrease
552 around 15:00, eventually approaching zero by around 19:00-20:00 LT. Between 7:00-
553 8:00 LT, $R(O_X)_{tran}>0$ for all episodes and non-episodes, indicating inflow of O_3 from
554 physical transport, increasing surface O_3 concentration by averages of 4.7, 3.9, 2.3, 3.5,
555 and 4.5 ppbv h^{-1} for episodes I, II, III, and non-episodes I and II, respectively. From
556 9:00 to 10:00 LT, $R(O_X)_{tran}>0$ only for episodes I, increasing the O_3 concentration by
557 1.5 ppbv h^{-1}, indicating inflow of O_3 from physical transport; on the contrary,
558 $R(O_X)_{tran}<0$ for episodes II and III, and non-episodes I and II, indicating outflow of O_3
559 from physical transport, decreasing the O_3 concentration by 3.1, 0.1, 3.0, and 16.9 ppbv
560 h^{-1}, respectively. After 10:00 LT, $R(O_X)_{tran}<0$ for all episodes and non-episodes,
561 indicating outflow of O_3 from the observation sites, possibly due to accumulated
562 photochemically formed O_3 increasing the concentration at the observation site,
563 diffusing upward or to surrounding areas.

564 In conclusion, the observed daytime O_3 concentration changes during all episodes
565 and non-episodes were influenced by both photochemical production and physical
566 transport. In the early morning, the increase in O_3 concentrations can be attributed to
567 photochemical reactions, physical processes, and possibly reduced NO titration effects
568 as the boundary layer height increases. Around noon, O_3 concentrations stabilize,

21

569 suggesting a balance between photochemical reactions and physical transport affecting

570 O_3 concentration changes. In the afternoon, O_3 concentrations decrease due to the

571 transport of photochemically formed O_3 from the observation site to upwards or the

572 surrounding areas. Our findings indicate that local photochemical reactions dominate

573 O_3 pollution. For example, O_3 pollution episodes recorded during the observation

574 period manifest under specific conditions: ① high photochemical O_3 production (i.e.,

575 episode II); ② moderate photochemical O_3 productions coupled with O_3 accumulation

576 under stable weather conditions (i.e., episodes I and III). In contrast, non-episodes

577 observed during the observation period occur under different conditions: ① low levels

578 of photochemical O_3 production (i.e., non-episodes I); ②elevated photochemical O_3

579 production, with O_3 transport to surrounding areas under favorable diffusion conditions

580 (i.e., non-episodes II).

581 ### 3.2.2 The model performance

582 In order to test the simulation ability of OBM-MCM model for $P(O_3)_{net}$, we

583 compared the measured and modelled $P(O_3)_{net}$ at 5 m ground level, as depicted in Fig.

584 S3a. The measured and modelled $P(O_3)_{net}$ revealed close alignment during episodes I

585 and III, yet displayed discernible variations during episode II, non-episode I, and non-

586 episode II. Assessment metrics including IOA, NMB, and NME were computed based

587 on the observed and modelled $P(O_3)_{net}$ over the entire measurement period (as described

588 in Sect. 2.3.3). The IOA ranged between 0.87 (25th percentile) and 0.90 (75th percentile)

589 for the measured and modelled $P(O_3)_{net}$ across the measurement period, indicating the

590 acceptable performance of the OBM-MCM model simulation (a higher IOA value

591 signifies a stronger agreement between simulated and observed values). Additionally,

592 comparison of measured and modelled O_3 concentrations at different heights (as shown

593 in Fig. S4) revealed generally higher modelled values during daytime and closer

594 alignment during nighttime at lower heights (i.e., 5 m, 40 m, and 70 m), while

595 discrepancies were observed at higher heights (i.e., 120 m, 220 m, and 335 m). These

596 phenomena may be primarily attributed to uncertainties in assumed physical processes

597 in the modelling, such as vertical and horizontal transport. Previous studies have

598 utilized the comparison of measured and modelled O_3 concentrations to determine the

599 dilution factor in modelling studies, discovering that suitable dilution factors vary by

600 location (Yang et al., 2021). To achieve the best agreement between the modelled O_3

601 concentrations and the observed values, we applied different dilution factors (the

602   lifetime of the species) in the modelling, varying from 6 h to 24 h. We found that the

603   simulated O_3 is closest to the measured O_3 concentrations when the lifetime of the

604   species is set to 12 h. However, given that O_3 concentrations are affected by physical

605   transport processes, the dilution factor might only represent the outflow of O_3 from the

606   observation site. Therefore, there may be limitations in using this method for precise

607   comparisons. We further compared the measured and modelled $P(O_3)_{net}$ under

608   different dilution factors. The modelled $P(O_3)_{net}$ initially increases and then decreases

609   as the dilution factor decreases (equivalent to an increase of species lifetime). However,

610   the influence of varying dilution rates on the modelled $P(O_3)_{net}$ is minimal, constituting

611   less than 30 %, due to the short lifetimes of the HO_2 and RO_2 radicals, which determine

612   the $P(O_3)_{net}$ values (Wang et al., 2021). Notably, the modelled $P(O_3)_{net}$ closely matched

613   the measured values when the species lifetime was set to12 h, as illustrated in Fig. S3b.

614   Consequently, a constant dilution factor of $1/43200$ s^{-1} was applied throughout the

615   observation period. Further investigations revealed an IOA range between 0.80 (25th

616   percentile) and 0.82 (75th percentile) for measured and modelled O_3 concentrations at

617   5 m ground level, which lies in between the IOA result for the modelled and observed

618   O_3 concentrations in previous studies, which range between 0.68 and 0.89 (Wang et al.,

619   2018), signifying the modelling results for O_3 concentrations here are acceptable. The

620   calculated NMB and NME using the modelled and observed $P(O_3)_{net}$ at 5 m ground

621   level during the whole measurement period ranged from -0.42 (25th percentile) to -0.31

622   (75th percentile) and -0.42 (25th percentile) to 0.54 (75th percentile), respectively. These

623   analysis results indicate that the model underestimates the measured $P(O_3)_{net}$ by a factor

624   ranging from 1.42 (25th percentile) to 1.31 (75th percentile), calculated as (1+|NMB|),

625   and the simulation results are reliable (with -1<NME<1).
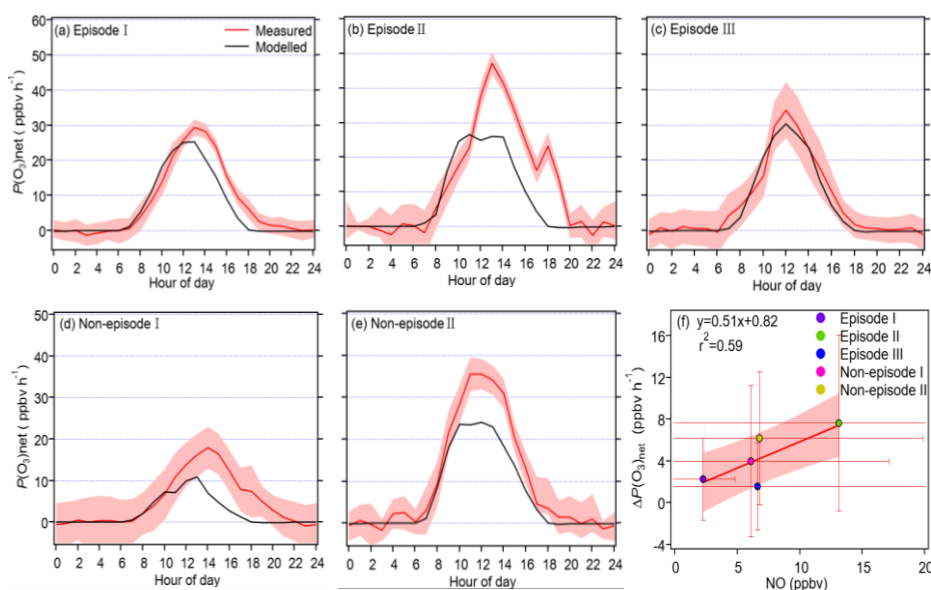

626   The mean diel variation of measured and modelled $P(O_3)_{net}$ during different

627   episodes and non-episodes are shown in Fig. 6a-e. The maximum daily $P(O_3)_{net}$ values

628   were 29.3, 47.2, and 34.2 ppbv h^{-1} for episodes I, II, and III, and 17.9 and 35.5 ppbv h^{-1}

629   [1] for non-episodes I and II, respectively. These values were comparable to or lower than

630   those measured in urban areas of Houston, United States (40-50 and 100 ppbv h^{-1} in

631   autumn and spring, respectively) (Baier et al., 2015; Ren et al., 2013), but higher than

632   those measured in a remote area of Japan (10.5 ppbv h^{-1} in summer) and an urban area

633   of Pennsyvania, United States (~ 8 ppbv h^{-1} in summer) (Sadanaga et al., 2017; Cazorla

634   and Brune, 2020). The averaged diel profiles of measured and simulated $P(O_3)_{net}$

635 exhibited large standard deviations (as depicted in Table 1), representing their day-to-
636 day variation throughout the campaign. The measured $P(O_3)_{net}$ were mostly higher than
637 the modelled $P(O_3)_{net}$, which could be attributed to the underestimation of RO_2 under
638 high NO conditions, leading to substantial disparities between calculated $P(O_3)_{net}$
639 derived from measured and modelled RO_2 concentrations, as highlighted in previous
640 studies (Whalley et al., 2018, 2021; Tan et al., 2017, 2018). The median value of
641 [measured $P(O_3)_{net}$-modelled $P(O_3)_{net}$]/measured $P(O_3)_{net}$ ranged from 22% to 45% for
642 different episodes and non-episodes. To delve deeper, we further investigated the
643 relationship between the daily disparities of measured and modelled $P(O_3)_{net}$ ($\Delta P(O_3)_{net}$
644 = measured $P(O_3)_{net}$-modelled $P(O_3)_{net}$) and average daytime NO concentrations during
645 different episodes and non-episodes, as depicted in Fig. 6f. The observed elevated
646 $\Delta P(O_3)_{net}$ at higher NO concentrations aligns with findings from previous studies,
647 which suggest that multiple factors could contribute to these outcomes. For example,
648 the reaction of OH with unknown VOCs (Tan et al., 2017), the missing RO_2 production
649 from photolysis $ClNO_2$ (Whalley et al., 2018; Tan et al., 2017), and the underestimation
650 of OVOCs photolysis (Wang et al., 2022b) in modelling approaches may lead to the
651 underestimation of RO_2, thus underestimating the modelled $P(O_3)_{net}$. Further analysis
652 showed that the underestimation of $P(O_3)_{net}$ can lead to the NOx-limited regime being
653 shifted to the VOCs-limited regime, thus underestimating the NOx-limited regime
654 (Wang et al., 2022b, 2024). However, the derived IOA, NMB, and NME values from
655 the modelled and observed $P(O_3)_{net}$ (and O_3) at 5 m ground during different episodes
656 and non-episodes indicate that the model proficiently reproduces the genuine $P(O_3)_{net}$
657 at the observation site (as shown in Table S3). Consequently, these results provide
658 confidence in exploring the vertical and temporal variations of $P(O_3)_{net}$ and O_3
659 formation sensitivities utilizing the outcomes from the modelling approach.
660 Nonetheless, it is important to acknowledge and discuss the potential biases caused by
661 the modelling methodology in this study.

662

663

664

Figure 6. (a-e) diurnal variations of the measured and modelled $P(O_3)_{net}$ during the observation period, and (f) the relationship between the average daily differences of measured and modelled $P(O_3)_{net}$ ($\Delta P(O_3)_{net}$) and the average daytime NO concentrations during different episodes and non-episodes.

3.2.3 Vertical and temporal variability of $P(O_3)_{net}$ budget

The detailed $P(O_3)_{net}$ budget at different heights during the observation period from the modelling results are shown in Fig. 7. Across various heights and different episodes and non-episodes, the contributions of different reaction pathways to $P(O_3)$ were almost the same, with HO_2+NO as the major O_3 production pathway, followed by CH_3O_2+NO and other RO_2+NO, where other RO_2+NO encompasses all RO_2 except CH_3O_2. This result aligns with previous studies (Liu et al., 2021; Liu et al., 2022). The major O_3 destruction pathway was $OH+NO_2$ (loss of OH radicals), followed by net RO_2+NO_2 (form peroxyacetyl nitrate, commonly called PAN species) and O_3 photolysis, while other O_3 destruction pathways, including O_3+OH, O_3+HO_2, $C_5H_8+O_3$, $C_3H_6+O_3$, and $C_2H_4+O_3$, together contributed negligibly to O_3 destruction. These $P(O_3)$ and $D(O_3)$ reaction pathways occurred between 6:00-18:00 LT, exhibiting strong diurnal variation characterized by a sharp increase between 6:00-11:00 LT in the morning, peaking between 11:00 and 14:00 LT, and decreasing rapidly after 14:00 LT. These phenomena were in accordance with the concentration changes of the major oxidants (i.e., OH, O_3, and NO_3), as shown in Fig. S5, where OH radicals and O_3 concentrations increased significantly in the morning and reached a peak around noon, followed by sharp afternoon decreases.

25

688   The diurnal changes in the concentrations of different reaction pathways to $P(O_3)$

689   and $D(O_3)$ at 5 m ground level during different episodes and non-episodes are depicted

690   in Fig. S6. We note that the maximum total $P(O_3)$ resulting from diel variations at 5 m

691   ground level for episode I, II, and III were 32.0, 34.9, and 38.3 ppbv h^{-1}, respectively.

692   These values were consistently higher than the maximum total $P(O_3)$ observed for non-

693   episodes I and II, which were 15.6 and 30.7 ppbv h^{-1}, respectively. However, as $P(O_3)_{net}$

694   was determined by both $P(O_3)$ and $D(O_3)$, the maximum total $D(O_3)$ values resulting

695   from diel variations during episodes I, II, III, and non-episode I, II, were 5.0, 5.7, 5.1,

696   2.4, and 5.3 ppbv h^{-1}, respectively. Consequently, the modelled $P(O_3)_{net}$ during episodes

697   does not exhibit a statistically significant difference from that during non-episodes

698   (Mann-Whitney p value=0.12), as shown in Fig. S5, which is in agreement with the

699   measured $P(O_3)_{net}$ (Mann-Whitney p-value=0.28), as depicted in Sect. 3.1.1.
700   The diurnal variation of $P(O_3)_{net}$ during different episodes and non-episodes

701   obtained by OBM-MCM modelling at different heights are shown in Fig. 8. We saw

702   that the $P(O_3)_{net}$ all showed a decreasing trend with the increase of the measurement

703   height during different episodes and non-episodes, but the variation of $P(O_3)_{net}$ along

704   with the measurement height differed for different episodes and non-episodes. For

705   example, the decrement of the averaged $P(O_3)_{net}$ during 6:00-18:00 LT from 5 m to 335

706   m were 1.5 and 0.6 ppbv h^{-1} for episode I and non-episode I, respectively, which was

707   relatively smaller than that during episode II, episode III, and non-episode II, which

708   were 5.3, 5.4, and 4.0 ppbv h^{-1}, respectively. To explore the reason, we plotted the

709   differences of calculated OH reactivities at 5 m and 335 m of different VOCs groups

710   (marked as ΔOH reactivity) as a function of the $P(O_3)_{net}$ change at 5 m and 335 m

711   (marked as $\Delta P(O_3)_{net}$), including nonmethane hydrocarbons (NMHC), anthropogenic

712   volatile organic compounds (AVOC), biogenic volatile organic compounds (BVOC),

713   and oxygenated volatile organic compounds (OVOC) (as shown in Fig.8f). The VOCs

714   species included in each category are listed in Table S2. We found that the OH

715   reactivities of AVOC and OVOC had the highest correlation coefficients (R^2) with the

716    $\Delta P(O_3)_{net}$, which are 0.85 and 0.67, respectively, indicating their predominant influence

717   on the decrement of $P(O_3)_{net}$ from 5 m to 335 m. However, the OH reactivity change

718   from 5 m to 335 m of different groups was quite different. Therefore, we further

719   explored O_3 formation sensitivity to its different VOCs precursors and precursor groups.

720
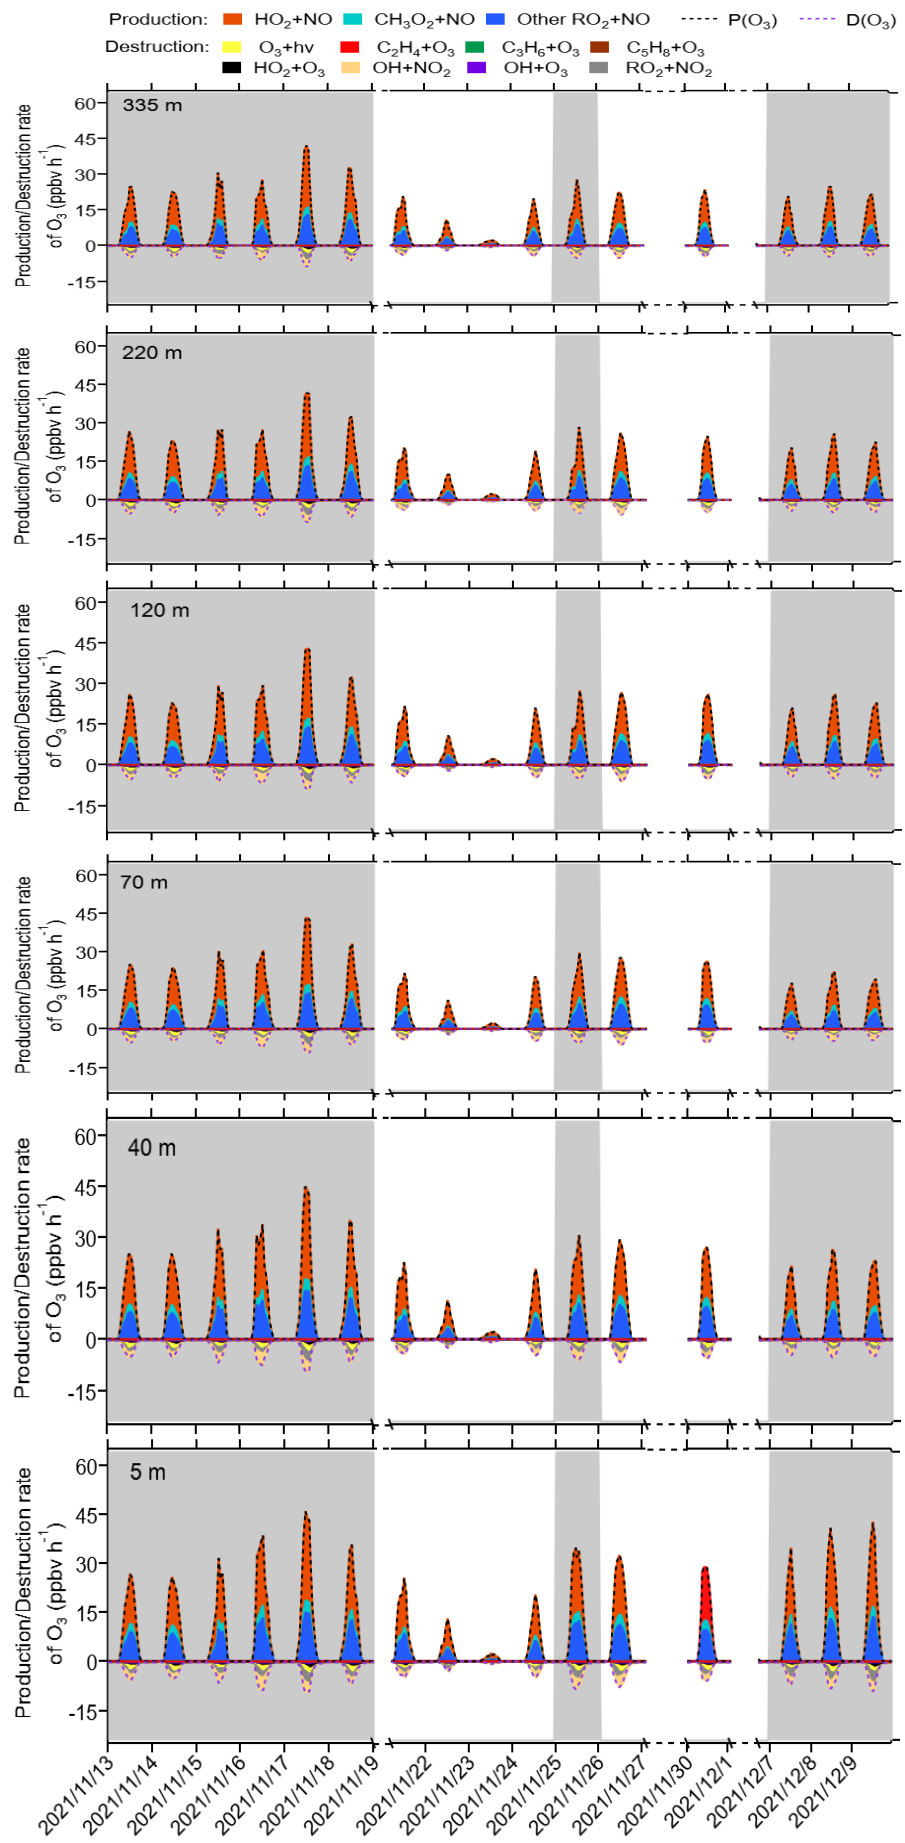

Figure 7. Time series of model-simulated O₃ production and destruction rates during 13

November and 9 December 2021, at different heights at SZMGT, the gray columns show the

typical O₃ episodes that occurred.

Figure 8. (a-e) Diurnal variation of vertical profile of the model-simulated $P(O_3)_{net}$

during different episodes and non-episodes from 13 November to 9 December 2021, and (f)

the relationship between the average daytime differences of modelled $P(O_3)_{net}$ (denoted as

$\Delta P(O_3)_{net}$), and OH reactivity of different precursor groups at 5 m and 335 m (denoted as ΔOH

reactivity).

3.2.4 Vertical distributions of O₃ formation regime

To investigate the reasons behind the variable distribution of $P(O_3)_{net}$ at varying

heights, we clarified the sensitivity of O₃ formation to different O₃ precursors or

precursor groups, including NMHC, AVOC, BVOC, OVOC, CO, and NOx, by

calculating their RIRs during different episodes and non-episodes, as shown in Fig. 9.

The VOCs species, categorized into different precursor groups as listed in Table S2,

indicate that some species depicted in Fig. 9 may appear in multiple categories and

hence could be repeated. We note that AVOC includes both NMHC and OVOC.

Figure 9 demonstrates that the aggregate RIR of OVOC and NMHC is nearly

identical to that of AVOC alone. Recognizing that VOC species within the

OVOC category are primarily originate from anthropogenic sources, but can also

originate from biogenic precursors (Wu et al., 2020; Park et al., 2013), we

acknowledge the possibility of an overestimated RIR for AVOC and due to this overlap. As illustrated in Fig. 9, the RIR values for different O_3-precursors or precursor groups don't exhibit significant variation at different heights during specific episodes or non-episodes, indicating a similar photochemical O_3 formation regime. However, the O_3 formation regimes differ between different episodes or non-episodes. During O_3 polluted episode I, O_3 formation is located in a transition regime and is more sensitive to VOCs emissions. Conversely, during O_3 polluted episodes II and III, and non-episodes I and II, it is located in VOCs sensitive regime. This finding aligns with previous studies suggesting that photochemical O_3 formation in the PRD region is likely VOC-limited or mixed-limited (Hong et al., 2022; Lu et al., 2018). The results suggest complexity of O_3 mitigation at the observation site. For example, during polluted episode I, reducing both VOCs and NOx can mitigate photochemical O_3 formation. However, during other O_3 polluted episodes and non-episodes, reducing VOCs can effectively alleviate photochemical O_3 formation, while reducing NOx might aggravate it. Nevertheless, during all episodes and non-episodes, O_3 formation is most sensitive to AVOC (RIR: 0.83-1.12), followed by OVOC (RIR: 0.59-0.79) at different heights, given that the AVOC includes NMHC and OVOC, there is urgent need to reduce NMHC and OVOC emissions to mitigate O_3 pollution in this area. Additionally, it is evident that OVOCs have a substantially higher RIR than NMHC, therefore, it is more accurate to conclude that the O_3 formation is most sensitive to OVOC rather than AVOC.
Figure 9. RIR values for O_3-precursor or precursor groups at different heights during different classified episodes.

The RIR tests for different episodes and non-episodes at various hours of the local daytime are illustrated in the Supplement (Fig. S7). The results indicate that the diurnal

779   changes of RIR values for different episodes and non-episodes exhibit remarkable

780   similarities. In the morning, the RIR values for various VOC groups, including AVOC,

781   BVOC, OVOC, and CO, are typically higher than those for NOx. However, they

782   gradually decrease throughout the day until 16:00 LT, then increase and reach a peak

783   at 18:00 LT. Interestingly, the RIR values at this peak are lower than those at 8:00 LT

784   in the morning. Conversely, the RIR values for NOx are usually around zero or below

785   zero during most of the day, gradually increasing around 16:00 LT and peaking at 18:00

786   LT. This suggests a transition in the photochemical O_3 formation regime throughout

787   the day, shifting from a VOC-limited regime in the morning to a transition regime and

788   more sensitive to NOx in the afternoon around 16:00 LT. The diurnal variations of the

789   RIRs of different O_3 precursors or precursor groups offer detailed insights into the

790   dominant factors influencing the photochemical formation of O_3 at different times of a

791   day.

792   Through the sensitivity study, NOx is not found to be the limiting factor affecting

793    $P(O_3)_{net}$, therefore, reactions involving NOx in the ROx radicals cycle, such as

794    $RO_2+NO \rightarrow HO_2$ and $HO_2+NO \rightarrow OH$, should occurred efficiently. Conversely,

795   reactions not involving NOx, such as $OH+VOCs \rightarrow RO_2$, be the limiting steps of the

796   ROx radicals cycling. We further identified and presented the three VOC species with

797   the highest OFP in NMHC and OVOC groups during different episodes and non-

798   episodes in Table S4. Results show that compounds such as toluene, *m/p*-xylene, and

799   n-butane in NMHC group, formaldehyde, hydroxyacetone, and ethanol in OVOC group

800   have identified as the most significant contributors to the total OFP in all episodes and

801   non-episodes. Toluene, *m/p*-xylene, and n-butane are often associated with specific

802   industrial processes (Shi et al., 2022; Liang et al., 2017), while formaldehyde,

803   hydroxyacetone, and acetaldehyde can originate from both the industrial processes and

804   natural sources (Parrish et al., 2012; Fan et al., 2021; Spaulding et al., 2003;

805   Salthammer 2023). Priority should be given to reducing these emission sources in order

806   to mitigate O_3 pollution in the PRD area of China.

807   **4   Conclusions**

808   We carried out a field observation campaign in an urban area in Pearl River Delta

809   (PRD) in China, focusing on investigating the vertical temporal variability of near-

810   surface O_3 production mechanisms by using a newly built vertical observation system

811   and the observation-based model coupled to the Master Chemical Mechanism (OBM-
812   MCM) v3.3.1. In total, three O_3 pollution episodes and two non-episodes occurred
813   during the observation period. To assess the modelling performance for O_3 production
814   rates and sensitivity, as well as to investigate the potential reasons for O_3 pollution
815   episodes at 5 m ground level, a net photochemical O_3 production rate (NPOPR, $P(O_3)_{net}$)
816   detection system based on the current dual-channel reaction chamber technique was
817   employed to directly measure $P(O_3)_{net}$ at 5 m ground-level.

818   The vertical profiles of averaged concentrations of various pollutants exhibit
819   similar trends during both episodes and non-episodes. The O_3, NOx, and Ox
820   concentrations show minimal vertical gradient during the daytime due to rapid vertical
821   mixing effects, but distinct vertical gradients emerge during nighttime owing to the
822   stability of the nocturnal residual layer. Higher concentrations of O_3 and Ox were
823   observed at higher heights, while elevated NO and NOx concentrations were mainly
824   detected at ground level. Given that NO has a significant titration effect on O_3, the lower
825   O_3 concentration at ground level may be attributed to the increase in NOx concentration
826   due to a more pronounced NO titration effect, besides the dry deposition near the
827   ground. However, the TVOC and their OFP exhibited variable trends with increased
828   height during both daytime and nighttime, observed in episodes and non-episodes,
829   which indicates the complexities of O_3 formation mechanisms at different heights
830   throughout the atmospheric column. Total OFP was highest at the 5 m ground level and
831   exhibited higher levels during episodes compared to non-episode periods. The OFP was
832   primarily attributed to OVOCs at different altitudes throughout both episodes and non-
833   episodes.

834   The mean concentrations of O_3 precursors, including CO, NO, NO$_2$, and TVOC,
835   were not consistently elevated during episodes compared to their levels during non-
836   episodes. By considering the observed O_3 concentrations change and the measured
837   $P(O_3)_{net}$ at 5 m ground level, we found that the O_3 pollution episodes were influenced
838   by both photochemical production and physical transport, with local photochemical
839   reactions playing a key role. O_3 pollution episodes recorded during the observation
840   period occurred under specific conditions: ① high photochemical O_3 productions; ②
841   moderate photochemical O_3 productions coupled with O_3 accumulation under stable
842   weather conditions. The index of agreement (IOA) ranged from 0.87 (25th percentile)
843   to 0.90 (75th percentile) for the measured and modelled $P(O_3)_{net}$ across the measurement

844 period, indicating the rationality to investigate the vertical and temporal variability of

845 O_3 formation mechanisms using modelling results. However, the measured $P(O_3)_{net}$

846 generally exceeded the modelled $P(O_3)_{net}$, the differences between measured and

847 modelled $P(O_3)_{net}$ ($\Delta P(O_3)_{net}$) were found to be correlated with NO concentrations.

848 Based on previous studies, this phenomenon could potentially be attributed to the

849 underestimation of RO_2 at high NO conditions, arising from inadequate knowledge

850 concerning photochemical reaction mechanisms. Therefore, the potential biases caused

851 by the modelling methodology were acknowledged and discussed.

852   From the modelling results, the contribution of different reaction pathways to $P(O_3)$

853 was almost the same at varying heights during both episodes and non-episodes, with

854 HO_2+NO as the major O_3 production pathway, followed by other RO_2+NO (comprising

855 all RO_2 except CH_3O_2) and CH_3O_2+NO. The major O_3 destruction pathway was

856 $OH+NO_2$ (loss of OH radicals), followed by net RO_2+NO_2 (forming peroxyacetyl

857 nitrate) and O_3 photolysis. However, other O_3 destruction pathways, including O_3+OH,

858 O_3+HO_2, $C_5H_8+O_3$, $C_3H_6+O_3$, and $C_2H_4+O_3$, collectively contributed negligibly to O_3

859 destruction. Nevertheless, $P(O_3)_{net}$ showed a decreasing trend with the increase of

860 height during different episodes and non-episodes, which was found mainly attributed

861 to the decline in O_3 precursor concentrations, specifically anthropogenic organic

862 compounds (AVOC) and oxygenated volatile organic compounds (OVOC) groups. We

863 observed that modelling biases were correlated with NO concentrations and VOCs

864 categories, impacting $P(O_3)_{net}$ through the regulation of the RO_2 radicals' budget. The

865 median relative difference between measured and modelled $P(O_3)_{net}$ ranged from 22-

866 45 % during different episodes and non-episodes. Therefore, the variation of $P(O_3)_{net}$

867 along with the measurement height might be even larger than our initial assessment.

868   Similar photochemical O_3 formation regimes were observed at different heights

869 during specific episodes or non-episodes, yet they varied between different episodes or

870 non-episodes. O_3 formation was predominantly located at a transition regime and more

871 sensitive to VOCs emissions during O_3-polluted episode I, whereas it shifted to a

872 VOCs-sensitive regime during O_3-polluted episodes II and III, as well as non-episodes

873 I and II. Further analysis revealed a daytime shift in the photochemical O_3 formation

874 regime, transitioning from a VOC-limited regime in the morning to a transition regime

875 more sensitive to NOx round 16:00 LT in the afternoon. However, the underestimation

876 of RO_2 radicals in the modelling, especially at lower heights with higher NO

877 concentrations, could result in an overestimate of the VOCs-limited regime. This study
878 highlights the need for more precise analysis using direct measurement techniques in
879 future studies. Nonetheless, throughout all episodes and non-episodes, O_3 formation is
880 most sensitive to OVOC at various heights, emphasizing the urgent need to reduce
881 emissions of these compounds and their precursors to mitigate O_3 pollution in this area.

882 This is the first measurement report of the vertical-temporal of O_3 formation
883 mechanisms near the ground surface. Together with the deliberation of the possible bias
884 on the vertical-temporal profile of O_3 formation rate and sensitivity using modelling
885 studies, this research provides critical foundational insights. The findings provide us in-
886 depth understanding of near-ground vertical variability in O_3 formation mechanisms,
887 which are influenced by the concentrations of VOCs and NOx, and the distinct OFP
888 associated with different VOCs profiles. During daytime, the vertical mixing of air
889 masses is substantially enhanced due to the effect of surface heating. Consequently,
890 photochemically formed O_3 at higher altitudes can be vertically transported downward
891 to the near-ground layer. Under this condition, control strategies for O_3 precursors
892 based on the O_3 formation mechanisms on the ground-level are insufficient. A more
893 comprehensive approach is necessary to effectively address the complexities of O_3
894 production throughout the atmospheric column. The vertical variability of O_3
895 formation mechanisms should be taken into account when making effective O_3 control
896 strategies in the PRD area of China.
