20 **Abstract:** Understanding the near-ground vertical and temporal photochemical O₃
21 formation mechanism is important to mitigate the O₃ pollution. Here, we measured the
22 vertical profiles of O₃ and its precursors at six different heights from 5-335 m using a
23 newly built vertical observation system in Pearl River Delta (PRD) region, China. The
24 net photochemical ozone production rate ($P(O_3)_{net}$) and O₃ formation sensitivities at
25 various heights were diagnosed using an observation-based model coupled with the
26 Master Chemical Mechanism (MCM v3.3.1). Moreover, for the assessment of model
27 performance and the causative factors behind O₃ pollution episodes, the net
28 photochemical ozone production rate ($P(O_3)_{net}$) was measured at 5 m ground level
29 utilizing a custom-built detection system. In total three O₃ pollution episodes and two
30 non-episodes were captured. The identified O₃ pollution episodes were found to be
31 jointly influenced by both photochemical production and physical transport, with local
32 photochemical reactions play a dominate role. The high index of agreement (IOA)
33 calculated from comparing the modelled and measured $P(O_3)_{net}$ values indicated the

34 rationality to investigate the vertical and temporal variability of O₃ formation
35 mechanism using modelling results. However, the measured $P(O_3)_{net}$ values were
36 generally higher than the modelled $P(O_3)_{net}$ values, particularly under high NO_x
37 conditions, which may indicate a potential underestimation of total RO₂ by the model.
38 Throughout the measurement period, the contribution of different reaction pathways to
39 O₃ production remained consistent across various heights, with HO₂+NO as the major
40 O₃ production pathway, followed by RO₂+NO. We saw $P(O_3)_{net}$ decreased with the
41 increase of the measurement height, primarily attributed to the decreased O₃ precursors
42 anthropogenic organic compounds (AVOC) and oxygenated volatile organic
43 compounds (OVOC). O₃ formation regimes were similar at different heights during
44 both episodes and non-episodes, which was located either in volatile organic
45 compounds (VOCs) sensitive regime or in transition regime and more sensitive to
46 VOCs. Diurnally, photochemical O₃ formation typically remained in the VOCs
47 sensitive regime during the morning and noon time, but in the transitional regime and
48 more sensitive to VOCs in the afternoon at around 16:00 LT. The vertical and temporal
49 O₃ formation are most sensitive to AVOC and OVOC, which suggests that targeting
50 VOCs, especially AVOC and OVOC, for control measures is more practical and
51 feasible at the observation site. The vertical temporal analysis of O₃ formation
52 mechanisms near the ground surface in this study provides critical foundational
53 knowledge for formulating effective short-term emergency and long-term strategies to
54 combat O₃ pollution in the PRD region of China.

55 **1. Introduction**

56 Tropospheric ozone (O₃), which have adverse effects on ecosystems, climate change,
57 and human health (Fiore et al., 2009; Anenberg Susan et al., 2012; Seinfeld, 2016), has
58 become an important factor resulting severe regional air pollution in China (Zhu et al.,
59 2020). Tropospheric O₃ mainly comes from the external transport from the stratosphere
60 and the photochemical reactions of O₃ precursors, involving volatile organic
61 compounds (VOCs) and nitrogen oxides (NO_x=NO+NO₂), and the ozone-precursor
62 relationship can be split into a “NO_x-limited” or “VOC-limited” or “mixed-sensitive”
63 regime (Seinfeld and Pandis, 2016; Sillman S., 1999). Local O₃ concentrations can be
64 further affected by meteorological conditions and regional transport of O₃ and O₃
65 precursors (Gong and Liao, 2019; Chang et al., 2019). The Pearl River Delta (PRD) is
66 one of the most rapid economic development and urbanization area in China, which is

67 suffering from severe ground-level O₃ pollution (Lu et al., 2018; Yang et al., 2019).
68 Currently, the relationship between tropospheric ozone pollution and its precursors and
69 meteorological elements in PRD region have been analysed by many scholars (Mao et
70 al., 2022; Li et al., 2022a), which have greatly improved our understanding of the O₃
71 sources and formation processes in PRD region. However, the O₃ distribution is highly
72 variable at different altitudes (Wang et al., 2021), there was a vertical difference in
73 VOCs concentration and sources, and ozone formation sensitivity (Liu et al., 2023;
74 Tang et al., 2017). Using only one height's data for understanding the photochemical
75 reactions in the planetary boundary layer is of great limitation. Thus, diagnosing the O₃
76 formation mechanism at different heights is essential to achieve effective control of O₃
77 pollution.

78 Currently, high time resolution and real-time response remote sensing (for example,
79 lidar and optical absorption spectroscopy) has been utilized for measuring the vertical
80 distribution of O₃ (Luo et al., 2020a; Wang et al., 2021), however, the in situ
81 measurements of VOCs at different heights are mainly depends on the offline method
82 combined with different techniques, such as aircraft, tethered balloon, high buildings
83 and towers, unmanned aerial vehicles (UAVs or drones), satellite, etc. (Klein et al.,
84 2019; Li et al., 2022b; Geng et al., 2020; Benish et al., 2020; Li et al., 2021; Wang et
85 al., 2019). Owing to the low time resolution of these monitoring techniques, it is
86 difficult to achieve continuous vertical coverage of VOCs and NO_x measurements, the
87 vertical distribution structure of VOCs is still unclear, thus largely hindered our in-
88 depth understanding of the vertical and temporal regional ozone formation mechanism.

89 To fill the gaps in the existing studies, we utilized a newly built vertical
90 observation system based on the Shenzhen Meteorological Gradient Tower (SZMGT)
91 (Li et al., 2023). This system measured the vertical profiles of O₃ and its precursors at
92 six different heights from 5-335 m. To diagnose the $P(\text{O}_3)_{\text{net}}$ and O₃ formation
93 sensitivities across various heights, we employed an observation-based model coupled
94 with the Master Chemical Mechanism (MCM v3.3.1). Additionally, we employed a
95 novel net photochemical ozone production rate ($P(\text{O}_3)_{\text{net}}$, NPOPR) detection system to
96 measure the $P(\text{O}_3)_{\text{net}}$ at the 5 m ground level to explore potential reasons for O₃
97 pollution episodes (Hao et al., 2023), i.e., examine the contribution of chemical and
98 physical processes to changes in O₃ concentration. Comparisons between the directly

99 measured $P(\text{O}_3)_{\text{net}}$ results and the model-derived data enabled us to evaluate the
100 simulation accuracy and explore potential reasons for discrepancies of the OBM-MCM
101 model concerning photochemical O_3 formation. Based on these results, we extensively
102 discussed the vertical and temporal variability in $P(\text{O}_3)_{\text{net}}$ and O_3 formation sensitivity,
103 while acknowledging potential biases associated modelling. The findings of this study
104 offer a new benchmark for understanding the vertical profile of photochemical O_3
105 formation mechanism, aiding in the identification of the primary driver of ground-level
106 O_3 pollution. This identification is crucial as it can provide essential theoretical support
107 for developing short-term effective emergency and long-term control measures
108 targeting O_3 in PRD region in China.

109 **2. Materials and Methods**

110 **2.1 Sampling site**

111 Field measurements were conducted at Shenzhen Meteorological Gradient Tower
112 (SZMGT) (22.65°N , 113.89°E) from 13 November to 10 December, 2021. SZMGT is
113 currently the tallest mast tower in Aisa and the second tallest of this kind in the world,
114 which is located in the Tiegang Reservoir Water Reserve at Bao'an District of Shenzhen,
115 in Pearl River Delta (PRD) region of China. High density of vegetation, reservoir
116 features, low-rise buildings, and hills/mountains are surrounded (Luo et al., 2020b).

117 **2.2 Instrumentation**

118 **2.2.1 The vertical sampling system**

119 A tower-based observation system for traces gases was used to sample the O_3 and O_3
120 precursors at 6 heights, including 5, 40, 70, 120, 220, and 335 m above the ground
121 during the campaign. This system was established using long perfluoroalkoxy alkane
122 (PFA) tubing. The impacts of long tubing on measurements of various of trace gases,
123 including O_3 , NO_x , and a set of organic compounds were systematically investigated
124 using a combination of laboratory tests, field experiments, and modelling techniques.
125 Field observations proved that this observation system is suitable for analyzing spatio-
126 temporal variations of atmospheric trace gases, with many trace gases could be well
127 measured. More details about the establish and the characterization about this
128 observation system are described elsewhere (Li et al., 2023).

129 **2.2.2 $P(\text{O}_3)_{\text{net}}$ measurement**

130 During the campaign, the $P(\text{O}_3)_{\text{net}}$ at the 5 m ground level was measured using the self-

131 developed NPOPR detection system, which was built based on the dual-channel
132 reaction chambers technique. The improvement, characterization, and the
133 photochemical O₃ formation mechanism in the reaction and reference chambers of the
134 NPOPR detection system are described in our previous study (Hao et al., 2023). Briefly,
135 the NPOPR detection system consists of reaction and reference chambers with the same
136 geometry and made of quartz glass, the length and inner diameter of the quartz glass
137 cylinder are 700 mm and 190.5 mm, respectively, which resulted in an inner volume of
138 ~ 20 L. The outer surface of the reference chamber was covered with an Ultem film
139 (SH2CLAR, 3 M, Japan) for ultraviolet (UV) protection, which can block sunlight with
140 wavelengths < 390 nm thus preventing photochemical reactions inside. During the
141 experiment, both the reaction and reference chambers were placed outdoors and directly
142 exposed to sunlight to simulate real ambient photochemical reactions. Ambient air was
143 introduced into the reaction and reference chambers at the same flow rate, and a Teflon
144 filter was mounted before the chamber inlet to remove fine particles. To correct the
145 effects of fresh NO titration to O₃, we use O_x (=O₃+NO₂) instead of O₃ to quantify the
146 O₃ generated by photochemical reactions (Pan et al., 2015; Tan et al., 2018). A stream
147 of air from the two chambers was alternately introduced into an NO-reaction chamber
148 every 2 min to convert O₃ in the air to NO₂ in the presence of high concentrations of
149 NO (O₃+NO=NO₂), and the O_x concentrations from the outlet NO-reaction chamber,
150 i.e., the total NO₂ concentrations including the inherent NO₂ in the ambient and that
151 converted from O₃, were measured by a Cavity Attenuated Phase Shift (CAPS) NO₂
152 Monitor (Aerodyne research, Inc., Billerica MA, USA) to avoid other nitrogen oxide
153 interferences to the NO₂ measurement (such as alkyl nitrates, peroxyacyl nitrates,
154 peroxyacetic acid, nitrogen pentoxide, etc.). $P(O_3)_{net}$ was obtained by dividing the
155 difference between the O_x concentrations in the reaction and reference chambers (ΔO_x)
156 by the mean residence time of air in the reaction chamber (τ):

$$157 \quad P(O_3)_{net} = P(O_x)_{net} = \frac{\Delta O_x}{\tau} = \frac{[O_x]_{reaction} - [O_x]_{reference}}{\tau} \quad (1)$$

158 A schematic of the NPOPR detection system is shown in Fig. S1. The mean
159 residence time is 0.063 h at the air flow rate of 5 L min⁻¹, which was obtained by
160 introducing a short pulse of NO₂ gas (obtained by mixing 0.2 L min⁻¹ of 2.08 ppmv
161 NO₂ standard gas with 5.2 L min⁻¹ ultrapure air) into the reaction chamber at $\tau = 0$, the
162 time profile of NO₂ mixing ratios ($C(\tau)$) at the exit of the chamber was measured using

163 the CAPS-NO₂ monitor. The pulse width of the introduced NO₂ gas was approximately
164 20 s and sufficiently shorter than $\langle\tau\rangle$. $C(\tau)$ was then normalized and converted to a
165 probability density function ($E(\tau)$) (Sadanaga et al., 2017):

$$166 \quad E\langle\tau\rangle = \frac{C(\tau)}{\int_0^{\infty} C(\tau) d\tau} \quad (2)$$

167 The expected $\langle\tau\rangle$ value was then calculated using Eq. (3):

$$168 \quad \langle\tau\rangle = \int_0^{\infty} \tau E\langle\tau\rangle d\tau = \int_0^{\infty} \frac{\tau C(\tau)}{\int_0^{\infty} C(\tau) d\tau} d\tau \quad (3)$$

169 We further quantified and corrected the wall losses of Ox and the light-enhanced
170 loss of O₃ ($d[\text{O}_3]$) in the reaction and reference chambers during daytime:

$$171 \quad \gamma = \frac{d[\text{O}_3] \times D}{\omega \times [\text{O}_3] \times \tau} \quad (4)$$

172 where γ is the light-enhanced loss coefficient of O₃, $[\text{O}_3]$ represents the difference
173 between the O₃ mixing ratios at the inlet and outlet of the reaction and reference
174 chambers, D is the diameter of the chambers, ω is the average velocity of O₃ molecules,
175 $[\text{O}_3]$ is the injected O₃ mixing ratio at the inlet of the reaction and reference chambers,
176 and τ is the average residence time of the air in the reaction and reference chambers. γ
177 is calculated as a function of $J(\text{O}^1\text{D})$. The relationship of γ with $J(\text{O}^1\text{D})$ is obtained from
178 the laboratory calibration tests in our previous study (Hao et al., 2013).

179 The limit of detection (LOD) of the NPOPR detection system is 2.3 ppbv h⁻¹ at the
180 sampling air flow rate of 5 L min⁻¹, which is obtained as three times the measurement
181 error of $P(\text{O}_3)_{\text{net}}$. The measurement error of $P(\text{O}_3)_{\text{net}}$ is mainly determined by the
182 measurement precision of Ox by the CAPS NO₂ monitor, the light-enhanced loss of O₃,
183 the chamber Ox losses, and the residence time, as demonstrated in our previous study
184 (Hao et al., 2013). The measurement accuracy of NPOPR detection system is
185 determined as 13.9 %, which is the maximum systematic error caused by the
186 photochemical O₃ productions in the reference chamber. As the UV protection Ultem
187 film covered on the reference chamber can only filtered out the sunlight with
188 wavelengths < 390 nm, the photochemical O₃ productions at the sunlight wavelength
189 between 390 nm and 790 nm still exists in the reference chamber. The photochemical
190 reactions in the reaction and reference chambers have been thoroughly studied in our

191 previous studies (Hao et al., 2023), and we found that while the modelled $P(\text{O}_3)_{\text{net}}$ in
192 the reaction chamber is similar with that modelled in the ambient air, the modelled
193 $P(\text{O}_3)_{\text{net}}$ in the reference chamber accounted 0-13.9% of that in the reaction chamber.
194 Therefore, we corrected the measured $P(\text{O}_3)_{\text{net}}$ using the quantified $P(\text{O}_3)_{\text{net}}$ in the
195 reference chamber.

196 **2.2.3 VOCs measurement**

197 VOCs were measured using a high-resolution proton transfer reaction time-of-flight
198 mass spectrometry (PTR-TOF-MS, Ionicon Analytik, Austria) (Wang et al., 2020a; Wu
199 et al., 2020) and an off-line gas chromatography mass spectrometry flame ionization
200 detector (GC-MS-FID) (Wuhan Tianlong, Co. Ltd, China) (Yuan et al., 2012). The
201 concentrations of oxygenated VOCs (OVOC), including formaldehyde (HCHO) and
202 acetaldehyde (CH_3CHO), were measured via PTR-TOF-MS, and the non-methane
203 hydrocarbons (NMHC) were measured via GC-MS-FID. PTR-TOF-MS was running
204 with both hydronium ion (H_3O^+) (Yuan et al., 2017; Wu et al., 2020) and nitric oxide
205 ion (NO^+) (Wang et al., 2020) modes. The measurement error of PTR-TOF-MS was
206 lower than 20%, more details of the PTR-TOF-MS technique can be found in our
207 previous publication (Yuan et al., 2017). The H_3O^+ and NO^+ modes were automatically
208 switched with 20 min H_3O^+ mode and 10 min NO^+ mode. The background signal of
209 each mode was determined at the last 2 min, by automatically switching ambient
210 measurement to a custom-built platinum catalytic converter heated to 365 °C.
211 Eventually, we only used VOCs measured during H_3O^+ mode, which was operated with
212 a drift tube pressure of 3.8 mbar, temperature of 120 °C, and voltage of 760 V, 3035
213 ions with m/z up to 510 were obtained at time resolutions of 10 s. A gas standard with
214 35 VOC species was used for calibrations of the PTR-ToF-MS once per day. Raw data
215 from PTR-TOF-MS were analyzed using Tofware software (Tofwerk AG, v3.0.3). Due
216 to the humidity dependencies of various VOCs signals of the PTR-ToF-MS observed
217 in laboratory study, we have determined their humidity-dependence curves, such as
218 formaldehyde, benzene, methanol, ethanol, and furan (Wu et al., 2020). During the data
219 analysis, we removed the impacts of ambient humidity change on the measured signals
220 of the PTR-ToF-MS according to these humidity-dependence curves.

221 **2.2.4 Other parameters**

222 The photolysis frequencies of different species were measured using the actinic flux

223 spectrometer (PFS-100, Focused Photonics Inc, China). O₃ and NO_x concentrations
224 were measured by a 2B O₃ monitor based on dual-channel UV-absorption (Model 205,
225 2B Technologies, USA) and a chemiluminescence NO_x monitor (Model 42i, Thermo
226 Fisher Scientific, USA), respectively. Temperature (*T*), relative humidity (RH), and
227 pressure (*P*) were measured by a portable weather station (Met Pak, Gill Instruments
228 Ltd, UK).

229 **2.3 Data analysis**

230 **2.3.1 Observation-based chemical box model**

231 We investigated the detailed photochemical O₃ formation mechanism during the
232 observation period based on the field observed data. The specific tropospheric O₃
233 photochemical formation process is the photolysis of NO₂ at 424 nm, simultaneously,
234 there are RO_x (RO_x=OH+HO₂+RO₂) radical recycles provide HO₂ and RO₂ to oxidize
235 NO to NO₂ resulting in the accumulation of O₃ (Shen et al., 2021; Cazorla and Brune,
236 2010; Sadanaga et al., 2017), therefore, the RO_x radicals and the O₃, OH, NO₃ oxidants
237 play important roles in photochemical O₃ formation. A zero-dimensional box model
238 based on the Framework for 0-D Atmospheric Modelling (F0AM) v3.2 (Wolfe et al.,
239 2016) coupled with the MCM v3.3.1 was used to simulate the $P(O_3)_{net}$. MCM v3.1.1
240 contains a total of 143 VOCs, more than 6700 species, involving more than 17000
241 reactions (Jenkin et al., 2015). Through the constraint *T*, RH, *P*, organic and inorganic
242 substances in gases to simulate $P(O_3)_{net}$, including 12 OVOCs (methanol, ethanol,
243 formaldehyde, acetaldehyde, acrolein, acetone, hydroxyacetone, phenol, *m*-cresol,
244 methyl vinyl ketone, methacrylaldehyde, methyl ethyl ketone), 47 non-methane
245 hydrocarbons (toluene, benzene, isoprene, styrene, etc.), conventional pollutants (O₃,
246 NO, NO₂, and CO), and photolysis rate values ($J(O^1D)$, $J(NO_2)$, $J(H_2O_2)$, $J(HONO)$,
247 $J(HCHO_M)$, $J(HCHO_R)$, $J(NO_3_M)$, $J(NO_3_R)$, etc.). $P(O_3)_{net}$ can be expressed by
248 the difference between ozone production rate ($P(O_3)$) and ozone destruction rate
249 ($D(O_3)$), $P(O_3)$, and $D(O_3)$ can be calculated as Eq. (5)-(6).

$$250 \quad P(O_3) = k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_{2,i}+NO}[RO_{2,i}][NO]\varphi_i \quad (5)$$

$$251 \quad D(O_3) = k_{O(^1D)+H_2O}[O(^1D)][H_2O] + k_{OH+O_3}[OH][O_3] + k_{HO_2+O_3}[HO_2][O_3]$$
$$252 \quad + k_{O_3+alkenes}[O_3][alkenes] + k_{OH+NO_2}[OH][NO_2] + k_{RO_{2,i}+NO_2}[RO_{2,i}][NO_2] \quad (6)$$

253 where k_{M+N} represents the bimolecular reaction rate constant of M and N, the subscript
254 'i' refers to different types of RO₂, and φ_i is the yield of NO₂ of the reaction RO_{2*i*+NO}.

255 The relevant reaction rates of $P(O_3)$ and $D(O_3)$ and the mean measured concentrations
256 of each VOC category at 5 m ground during O_3 episodes and non-episodes used in the
257 model are listed in Tables S1 and S2. A “spin up” for 3 days before the modelling days
258 was applied in the model to get the radical intermediates steady.

259 **2.3.2 Derive contribution of chemical and physical processes to O_3 changes** 260 **on the ground level**

261 It is known that chemical and physical processes jointly influence the O_3 concentration
262 changes near the ground surface (Xue et al., 2014; Tan et al., 2019). The direct
263 measurement of $P(O_3)_{net}$ gave us a chance to identify the contribution of chemical and
264 physical processes to the variation of observed O_3 concentrations using the following
265 equation:

$$266 \quad \frac{dO_x}{dt} = P(O_x)_{net} + R(O_x)_{trans} \quad (7)$$

267 Where $\frac{dO_x}{dt}$ is the change rate of the observed O_x mixing ratio change ($ppbv \text{ h}^{-1}$),
268 $P(O_3)_{net}$ denotes the net photochemical O_3 production rate ($ppbv \text{ h}^{-1}$), which was equal
269 to $P(O_3)_{net}$ and measured directly by NPOPR system, $R(O_x)_{trans}$ represents O_3 mixing
270 ratio change due to the physical transportation ($ppbv \text{ h}^{-1}$), including the horizontal and
271 vertical transport, dry deposition and the atmospheric mixing (Liu et al., 2022). To
272 correct the effects of NO titration to O_3 , we have replaced O_3 with $O_x (=O_3+NO_2)$ during
273 the calculation in this study (Pan et al., 2015).

274 **2.3.3 Model performance**

275 In order to judge the reliability of the model simulation, we calculated the index of
276 agreement (IOA) based on the measured and modelled $P(O_3)_{net}$ at 5 m above the ground
277 level using the following equation (Liu et al., 2019):

$$278 \quad IOA = 1 - \frac{\sum_{i=1}^n (O_i - S_i)^2}{\sum_{i=1}^n (|O_i - \bar{O}| + |S_i - \bar{O}|)^2} \quad (8)$$

279 Where S_i and O_i represents the simulated and observed $P(O_3)_{net}$ or O_3 values at the
280 same time, respectively, \bar{O} is the averaged observed value, and n is the data number.
281 Further, we also judged the model simulation performance using statistical measures,
282 including the correlation coefficient, normalized mean bias (NMB) and normalized
283 mean error (NME), which are defined as:

284
$$NMB = \frac{\sum_{i=1}^n (S_i - O_i)}{\sum_{i=1}^n O_i} \cdot 100 \% \quad (9)$$

285
$$NME = \frac{\sum_{i=1}^n |S_i - O_i|}{\sum_{i=1}^n O_i} \cdot 100 \% \quad (10)$$

286 Where S_i and O_i have the same meaning as Eq. (8), and n is the total number of such
287 data pairs of interest. The results will be discussed in Sect. 3.2.2.

288 **2.3.4 OH reactivity**

289 In order to investigate the influence of the photochemical reactions of different VOCs
290 to photochemical O_3 formation, we calculated the OH reactivities of different VOCs,
291 i.e., the sum of concentrations of OH reactants multiplied by their reaction rate
292 coefficients, as shown below:

293
$$k_{OH} = k_i \times [VOCs]_i \quad (11)$$

294 where k_{OH} represents the total OH reactivity of a group of VOCs species, k_i represents
295 the rate constants between OH radicals and different VOCs species i , $[VOCs]_i$ represent
296 the concentration of species i . In this study, we summarized the OH reactivities of
297 different kinds of VOCs groups together to investigate their influence to the gradient
298 $P(O_3)_{net}$ change with heights in Sect. 3.2.3.

299 **2.3.5 Ozone formation regime**

300 The sensitivity of photochemical O_3 production to its precursors was diagnosed by
301 calculating the relative incremental reactivity (RIR) using the OBM-MCM model. RIR
302 is defined as the O_3 photochemical production percent change due to per percent change
303 in its single precursor/precursor group concentrations (Cardelino and Chameides, 1995).
304 Therefore, the RIR for precursor (group) X can be expressed as:

305
$$RIR = \frac{\Delta P(O_3)/P(O_3)}{\Delta X/X} \quad (12)$$

306 where the $\Delta X/X$ represent the percent change in different O_3 precursor or
307 precursor groups. We classified the measured VOCs into anthropogenic organic
308 compounds (AVOC), biogenic organic compounds (BVOC), and OVOC group, and
309 investigated the O_3 formation sensitivity to these different types of VOCs.

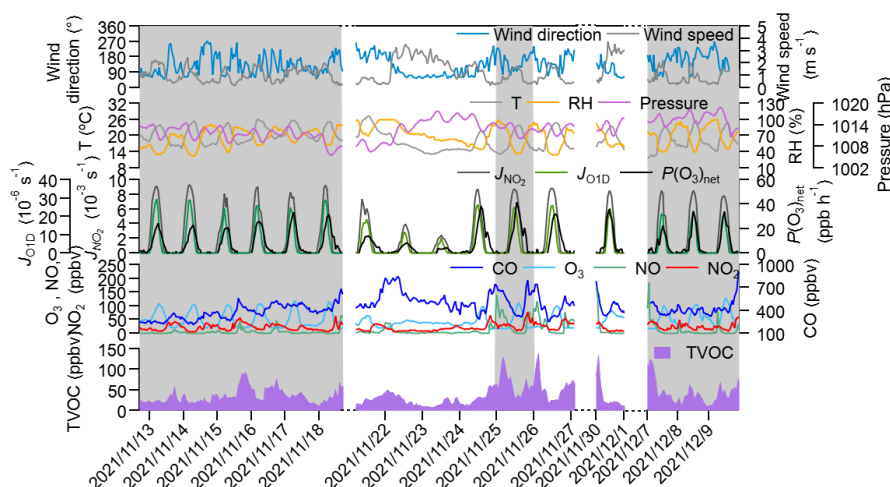

310 **3. Results and discussions**

311 **3.1 Vertical and temporal profile of ozone and its precursors**

312 **3.1.1 Ozone and its precursors at 5 m ground level**

313 Figure 1 shows the time series of the major trace gases, photolysis rate constants, and
314 meteorological parameters at 5 m ground-level during the observation period at
315 SZMGT. During the 1-month field observation period, in total 3 O₃ pollution episodes
316 (referred to episodes hereafter) and 2 non-O₃ pollution episodes (referred to non-
317 episodes hereafter) were captured, the O₃ pollution episodes were defined as the days
318 during which the hourly average ozone concentration on the ground-level (5 m) exceed
319 the Grade II standard (102 ppbv, GB 3095-2012, China; Ambient air quality standards,
320 2012), the rest days were defined as non-episodes. Episode days (marked as gray
321 columns in Fig. 1) including 13-18 November (episode I), 26 November (episode II),
322 and 7-9 December (episode III), while the non-episode days including 22-25 November
323 (non-episode I), 26-27 and 30 November (non-episode II). The corresponding daytime
324 mean values (6:00-18:00 LT) during all episode days and non-episode days are shown
325 in Table 1. During the daytime of episode days (episodes I, II, and III), the mean
326 concentrations of O₃ were 70.1±28.6, 59.5±32.4, and 71.3±31.0, respectively. The
327 mean *T* and RH were 22.3±2.5 °C and 56.2±14.5 % for episode I, 20.4±3.2 °C and
328 52.2±16.7 % for episode II, and 20.6±3.4 °C and 58.2±17.2 % for episode III. During
329 non-episode days, the mean concentrations of O₃ were 45.3±16.2 and 63.7±21.3 ppbv
330 for non-episode I and II, respectively. The corresponding mean *T* and RH were
331 18.4±4.3 °C and 69.5±15.4 % for non-episode I, and 21.3±2.7 °C and 51.8 ±13.7 % for
332 non-episode II. These observations indicate that the *T* and RH during episode days were
333 not statistically different from those during non-episode days. This phenomenon
334 contrasts with previous studies in PRD area, where O₃ pollution episodes were
335 generally associated with high *T* and low RH (Mousavinezhad et al., 2021; Hong et al.,
336 2022).

337

338 **Figure 1. Time series of major trace gases, photolysis rate constants, and meteorological**
 339 **parameters at 5 m ground level during the observation period. The gray columns show the**

wind direction (°)	115.5±48.7	128.6±35.3	144.8±57.1	115.0±57.6	115.3±36.2

344 * All values here were calculated as the mean average values during daytime (6:00-18:00 LT).

345 The mean concentrations of O₃ precursors, including CO, NO, NO₂, and TVOC,
 346 were not statistically different between episodes and non-episodes. This suggests that

347 their concentrations during O₃ pollution episodes can vary, being either higher or lower
348 than those observed during non-episodes (as shown in Table 1). We further compared
349 daytime mean O₃ formation potential (OFP) and measured $P(O_3)_{net}$ during episodes and
350 non-episodes, and found that daytime average OFP and $P(O_3)_{net}$ on episode days were
351 also not statistically different with those during non-episode days, considering a range
352 within one standard deviation. These findings indicate that the O₃ pollution episodes
353 stem from either substantially elevated local photochemical O₃ formation (i.e., episode
354 II), or the accumulation of O₃ formed by moderate local photochemical O₃ formation
355 under stable weather conditions (i.e., episodes I and II). Notably, when local
356 photochemical reactions contribute intensely to the formation of O₃, favorable weather
357 conditions facilitating O₃ outflow diminish the likelihood of O₃ pollution occurrences
358 (i.e., non-episode II). In summary, O₃ pollution episodes are jointly affected by the
359 photochemical reactions and physical transport processes, which we will discuss further
360 in Sect. 3.2.1.

361 **3.1.2 Vertical profiles of ozone and its precursors at 5-335m level**

362 Figure 2 shows the contour plots illustrating the vertical profiles of O₃, NO_x,
363 Ox(=O₃+NO₂), and TVOC. From Fig. 2, minimal vertical gradients exist in the
364 concentration of all species—O₃, NO_x, Ox, and TVOC—due to the rapid vertical mixing
365 effects. However, distinct vertical gradients were observed during nighttime owing to
366 the stability of the nocturnal residual layer. Elevated concentrations of O₃ and Ox were
367 identified at higher altitudes, whereas higher NO_x concentrations predominantly
368 occurred at ground level. We further elucidated the vertical distribution patterns of
369 different pollutants as well as the OFP of different VOCs groups during local daytime
370 (6:00-18:00 LT) and nighttime (19:00-5:00 LT) for both episodes and non-episodes, as
371 shown in Fig. 3.

409

410 **Figure 3.** Average vertical profiles of O₃, NO, Ox, NO_x, and TVOC during both daytime and
 411 **nighttime, and OFP of different VOCs types during daytime at six heights (5, 40, 70, 120, 220,**
 412 **and 335 m), including episodes and non-episodes throughout the observation period. The**
 413 **error bars indicate the standard deviation calculated from the measured values during these**
 414 **periods.**

415 The vertical profiles of averaged concentrations of various pollutants exhibit similar
 416 trends during both episodes and non-episodes, with O₃ showing an increasing trend
 417 from 5 m above ground level to 355 m, aligning with findings from previous studies
 418 (Zhang et al., 2019; Wang et al., 2021). Given that NO_x has a significant titration effect
 419 on ozone, the lower O₃ concentration at ground level may be attributed to the increase
 420 in NO_x concentration (Zhang et al., 2022) and also the dry deposition near the ground
 421 (Li et al., 2022b). NO and NO_x showed an opposite trend compared to O₃. These two
 422 factors jointly effected the Ox changing trend with heights, and consequently, the
 423 gradients of Ox concentrations showed a weaker increasing trend from the 5 m ground

424 level to 355 m height compared to O₃. This observation demonstrated a more
425 pronounced NO titration effect at the 5 m ground level compared to the effect at 355 m
426 height. However, the TVOC showed variable trends with the increased height for
427 daytime and nighttime during episodes and non-episodes. During daytime, TVOC
428 initially decreased from 5 m to 40 m, and then continuously increased from 40 m to 355
429 m during episodes, while continuously slightly decreased from 5 m to 335 m during
430 non-episodes. During nighttime, TVOC concentrations first increased from 5 m to 40
431 m and then continuously decreased from 40 m to 335 m during both episodes and non-
432 episodes. We further plotted the OFP of different VOCs groups at various altitudes, and
433 found that the total OFP was highest at 5 m ground level and exhibited higher levels
434 during episodes compared to non-episode periods. Subsequently, there was a significant
435 decrease at 40 m height during both episodes and non-episodes. However, there was a
436 sharp increase observed at 70 m, 120 m, and 220 m during episodes, contrasting with a
437 gradual rise during non-episode periods, which eventually reach a peak at 220 m during
438 non-episodes. Besides, a consistent decrease of OFP from 220 m to 335 m was observed
439 during both episodes and non-episodes. The OFP was primarily attributed to OVOCs
440 at different altitudes throughout both episodes and non-episodes, followed by aromatics
441 and alkane during episodes and non-episodes, respectively.

442 **3.2 O₃ pollution episodes formation mechanism at near-ground surface**

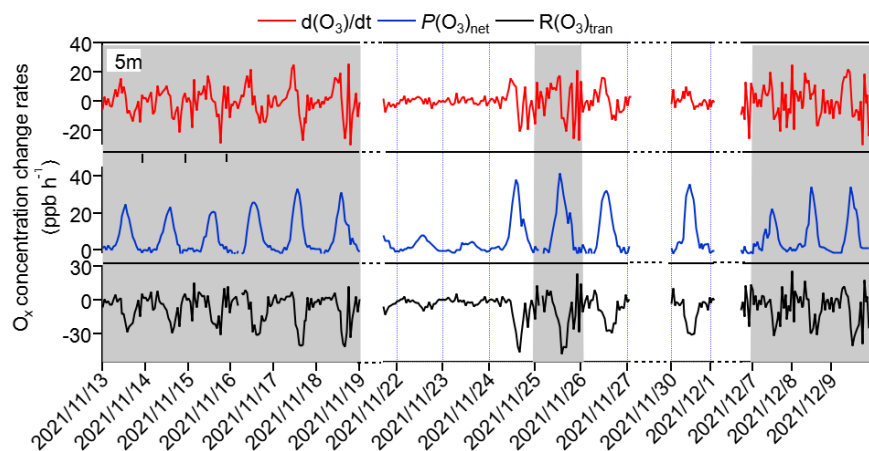

443 In this section, we first explored the possible reason for O₃ pollution episodes on the 5
444 m ground level, i.e., identify the contribution of chemical and physical processes to O₃
445 concentration changes (Sect. 3.2.1), then checked the modelling performance and the
446 possible reason for the modelling bias in photochemical O₃ formation by comparing the
447 measured $P(\text{O}_3)_{\text{net}}$ with the modelled $P(\text{O}_3)_{\text{net}}$ (Sect. 3.2.2). To gain insights into the
448 photochemical O₃ formation mechanism at different heights and understand their role
449 in overall O₃ pollution, we further discussed the chemical budget of O₃ at different
450 heights (Sect. 3.2.3), the vertical and temporal variability of $P(\text{O}_3)_{\text{net}}$ and O₃ formation
451 regime (Sect. 3.2.4), and their possible bias within the modelling approach (Sect. 3.2.5).

452 **3.2.1 Contribution of chemical and physical processes to O₃ changes on the** 453 **ground level**

454 As concluded in Sect. 3.3.1, O₃ pollution episodes may be jointly affected by the
455 photochemical reactions and physical transport. In order to identify the main reasons

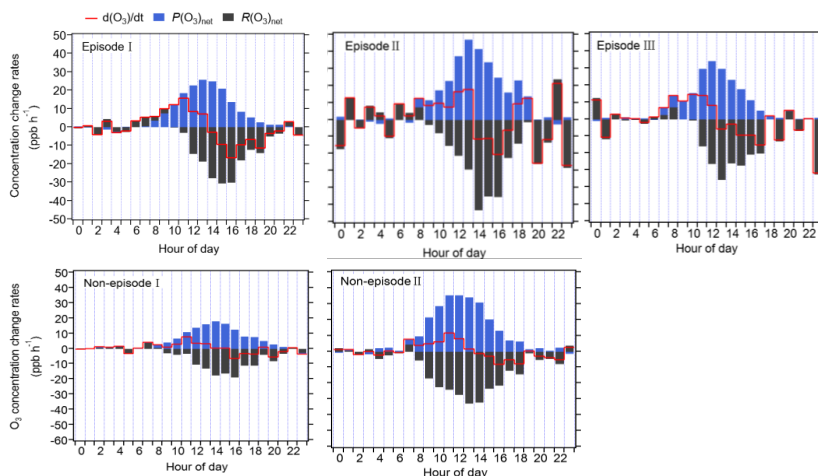

456 for O_3 pollution on the ground level, we calculated the contribution of chemical and
 457 physical processes to O_3 changes at 5 m ground level separately for all 3 episodes and
 458 2 non-episodes. As the dry deposition are usually contribute a quite small portion and
 459 can be negligible, the main contributor to physical processes is the vertical and
 460 horizontal transport (Tan et al., 2019). Their hourly averages and diurnal variations are
 461 shown in Figs. 4 and 5, respectively.

462

463 **Figure 4. Time series of O_3 contributions from local photochemical production and physical**
 464 **transport.**

465

466

467

468

469

470

471

472

473

474 **Figure 5. Diurnal variation of the contribution of chemical and physical transport to O_3**
 475 **changes on the ground level.**

476 The results shown here indicate that fluctuation of the O_3 concentration change

477 rate (represented as $d(O_3)/dt$) on the ground level was usually small and dominated by
478 the physical processes during nighttime. At around 6:00-7:00, O_3 concentrations were
479 increasing for all episodes and non-episodes, mainly attributed to the physical transport,
480 this may be due to the short-term strong vertical turbulence in the early morning due to
481 the expansion of the boundary layer height, which make the residual layer became
482 “leaky” and vertical transport occurred. During this time, the O_3 precursors were also
483 transported down from the residue layer and the sun radiation start to increase, O_3
484 precursors were then underwent the rapid photochemical reaction and led to the sharp
485 increase of $P(O_3)_{net}$ between 8:00 to 12:00. The $P(O_3)_{net}$ reached a peak at around 11:00-
486 14:00, and started to decrease at around 15:00, which approached zero at around 19:00-
487 20:00. Between 7:00-8:00, $R(O_3)_{tran}>0$ for all episodes and non-episodes, indicating the
488 inflow of O_3 from physical transport, the physical transport increase the surface O_3
489 concentration by 4.7, 3.9, 2.3, 3.5, and 4.5 $ppbv\ h^{-1}$ on average for episodes I, II, III,
490 and non-episodes I and II, respectively. From 9:00 to 10:00, $R(O_3)_{tran}>0$ for episodes I,
491 which increase the O_3 concentration by 1.5 $ppbv\ h^{-1}$, indicating the inflow of O_3 from
492 physical transport; on the contrary, $R(O_3)_{tran}<0$ for episodes II and III, and non-episodes
493 I and II, indicating the outflow of O_3 from physical transport, which decrease the O_3
494 concentration by 3.1, 0.1, 3.0, and 16.9 $ppbv\ h^{-1}$, respectively. After 10:00, $R(O_3)_{tran}<0$
495 for all episodes and non-episodes, indicating the outflow of O_3 from the observation
496 sites, this may be due to the accumulation of the photochemically formed O_3 increases
497 the O_3 concentration at the observation site, thus diffuses to upward directions or the
498 surrounding areas.

499 In conclusion, the observed daytime O_3 concentration change during all episodes
500 and non-episodes was influenced by both photochemical production and physical
501 transport. In the early morning, O_3 concentrations increase can be attributed to
502 photochemical reaction, physical process, and may also be the reduced NO titration
503 effects as the boundary layer height increases. At around noon time, the O_3
504 concentration became stable, suggests that the photochemical reaction competed
505 against physical transport and jointly affect O_3 concentration change. In the afternoon,
506 the O_3 concentration decreases due to the diffuse of photochemically formed O_3 from
507 the observation site to upward directions or the surrounding areas. Our findings suggest
508 that local photochemical reaction dominates O_3 pollution. For example, O_3 pollution
509 episodes recorded during the observation period manifest under specific conditions: ①

510 high photochemical O₃ production (i.e., episode II); ② moderate photochemical O₃
511 productions coupled with O₃ accumulation under stable weather conditions (i.e.,
512 episodes I and III). In contrast, non-episodes observed during the observation period
513 occur under different conditions: ① low levels of photochemical O₃ production (i.e.,
514 non-episodes I); ② elevated photochemical O₃ production, with O₃ diffuse to
515 surrounding areas under favorable diffusion conditions (i.e., non-episodes II).

516 3.2.2 The model performance

517 In order to test the simulation ability of MCM model for $P(O_3)_{net}$, we compared
518 the measured and modelled $P(O_3)_{net}$ at 5 m ground level, as depicted in Fig. S2. The
519 measured $P(O_3)_{net}$ exhibited close alignment with the values during episodes I and III,
520 yet displayed discernible variations during episode II, non-episode I, and non-episode
521 II. Assessment metrics including IOA, NMB and NME were computed based on the
522 observed and modelled $P(O_3)_{net}$ at 5 m level over the whole measurement period as
523 described in Sect. 2.3.3. Results revealed an IOA range between 0.87 (25th percentile)
524 and 0.90 (75th percentile) for the measured and modelled $P(O_3)_{net}$ across the
525 measurement period, indicating the acceptable performance of the MCM model
526 simulation (a higher IOA value signifies a stronger agreement between simulated and
527 observed values). We also compared the measured and modelled O₃ concentrations at
528 different heights (as shown in Fig. S3). Notably, during daytime, the modelled O₃
529 concentrations generally exhibited higher values than the measured O₃ concentrations.
530 However, during nighttime, the modelled O₃ concentrations closely matched the
531 measured values at lower heights (i.e., 5 m, 40 m, and 70 m), but were mostly higher
532 than the measured values at higher heights (i.e., 120 m, 220 m, and 335 m), these
533 phenomena may be primarily attributed to uncertainties in the assumed physical
534 processes (such as vertical and horizontal transport) in the modelling, the effect of
535 which was set as a constant dilution factor of $1/43200\text{ s}^{-1}$ during the whole modelling
536 period. Further investigations revealed an IOA range between 0.80 (25th percentile) and
537 0.82 (75th percentile) for the measured and modelled O₃ concentrations at 5 m ground
538 level, which lies in between the IOA result for the modelled and observed O₃
539 concentrations in previous studies, which range between 0.68 and 0.89 (Wang et al.,
540 2018), signifying the modelling results for O₃ concentrations here are acceptable. The
541 calculated NMB and NME using the modelled and observed $P(O_3)_{net}$ at 5 m ground

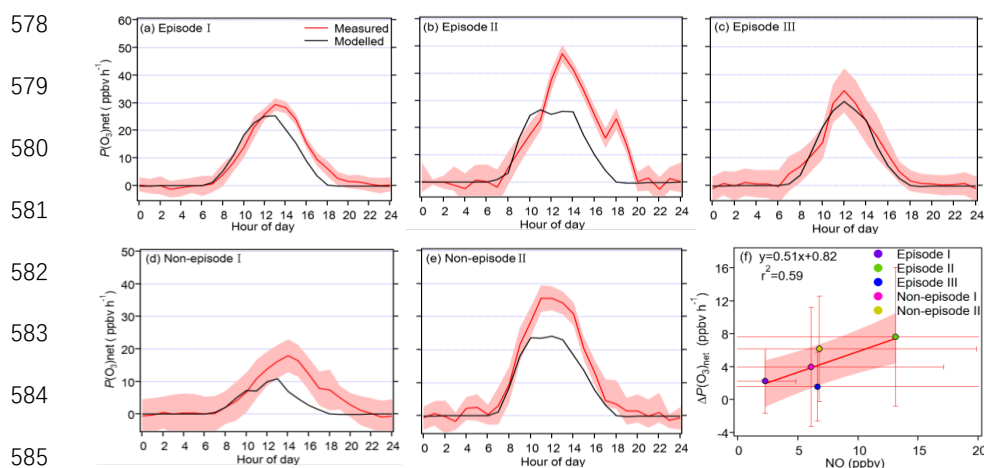

542 level during the whole measurement period ranged from -0.42 (25th percentile) to -0.31
543 (75th percentile) and -0.42 (25th percentile) to 0.54 (75th percentile), respectively.

544 The mean diel variation of measured and modelled $P(\text{O}_3)_{\text{net}}$ during different
545 episodes and non-episodes are shown in Fig. 6a-e. The maximum daily $P(\text{O}_3)_{\text{net}}$ values
546 were 29.3, 47.2, and 34.2 ppbv h⁻¹ for episodes I, II, and III, and 17.9 and 35.5 non-
547 episodes I and II, respectively. These maximum daily $P(\text{O}_3)_{\text{net}}$ values were similar or
548 lower than that measured in the urban area of Houston in the United States (40-50 and
549 100 ppbv h⁻¹ in autumn and spring, respectively) (Baier et al., 2015; Ren et al., 2013),
550 and in Indiana in the United States (~ 30 ppbv h⁻¹ in spring) (Sklaveniti et al., 2018),
551 but higher than that measured at the Wakayama Forest Research Station in a remote
552 area of Japan (10.5 ppbv h⁻¹ in summer, Sadanaga et al., 2017) and in an urban area of
553 Pennsylvania in the United States (~ 8 ppbv h⁻¹ in summer) (Cazorla and Brune, 2020).
554 The averaged diel profiles of the measured and simulated $P(\text{O}_3)_{\text{net}}$ have large standard
555 deviations (as depicted in Table 1), representing their day-to-day variation throughout
556 the campaign. The results shown in Fig. 6a-e indicate that the measured $P(\text{O}_3)_{\text{net}}$ were
557 mostly higher than the modelled $P(\text{O}_3)_{\text{net}}$. Previous studies have highlighted the
558 presence of missing RO₂ under high NO conditions, contributing significantly to
559 substantial disparities between calculated $P(\text{O}_3)_{\text{net}}$ derived from measured and modelled
560 RO₂ concentrations (Whalley et al., 2018, 2021; Tan et al., 2017, 2018). To delve
561 deeper, we further investigated the relationship between the average daily disparities of
562 measured and modelled $P(\text{O}_3)_{\text{net}}$ ($\Delta P(\text{O}_3)_{\text{net}}$) and the average daytime NO
563 concentrations during different episodes and non-episodes, as depicted in Fig. 6f. The
564 observed elevated $\Delta P(\text{O}_3)_{\text{net}}$ at higher NO concentrations aligns with findings from
565 previous studies, which suggest that multiple factors could contribute to these outcomes.
566 For example, the reaction of OH with unknown VOCs (Tan et al., 2017), the lack of the
567 correction for the decomposition of CH₃O₂NO₂ or the missing RO₂ production from the
568 photolysis ClNO₂ (Whalley et al., 2018; Tan et al., 2017), and the underestimation of
569 OVOCs photolysis (Wang et al., 2022) in modelling approach, may result in the
570 underestimation of RO₂, thus underestimate the modelled $P(\text{O}_3)_{\text{net}}$ and the NO_x-limited
571 regime. Nonetheless, the derived IOA, NMB, and NME values from the modelled and
572 observed $P(\text{O}_3)_{\text{net}}$ at 5 m ground, as previously outlined, indicate that the model
573 proficiently reproduces the genuine $P(\text{O}_3)_{\text{net}}$ at the observation site. Consequently, these
574 results give us confidence to explore the vertical and temporal variations of $P(\text{O}_3)_{\text{net}}$

575 and O_3 formation sensitivities utilizing the outcomes from the modelling approach.
 576 However, it is important to acknowledge and discuss the potential biases caused by the
 577 modelling methodology in this study.

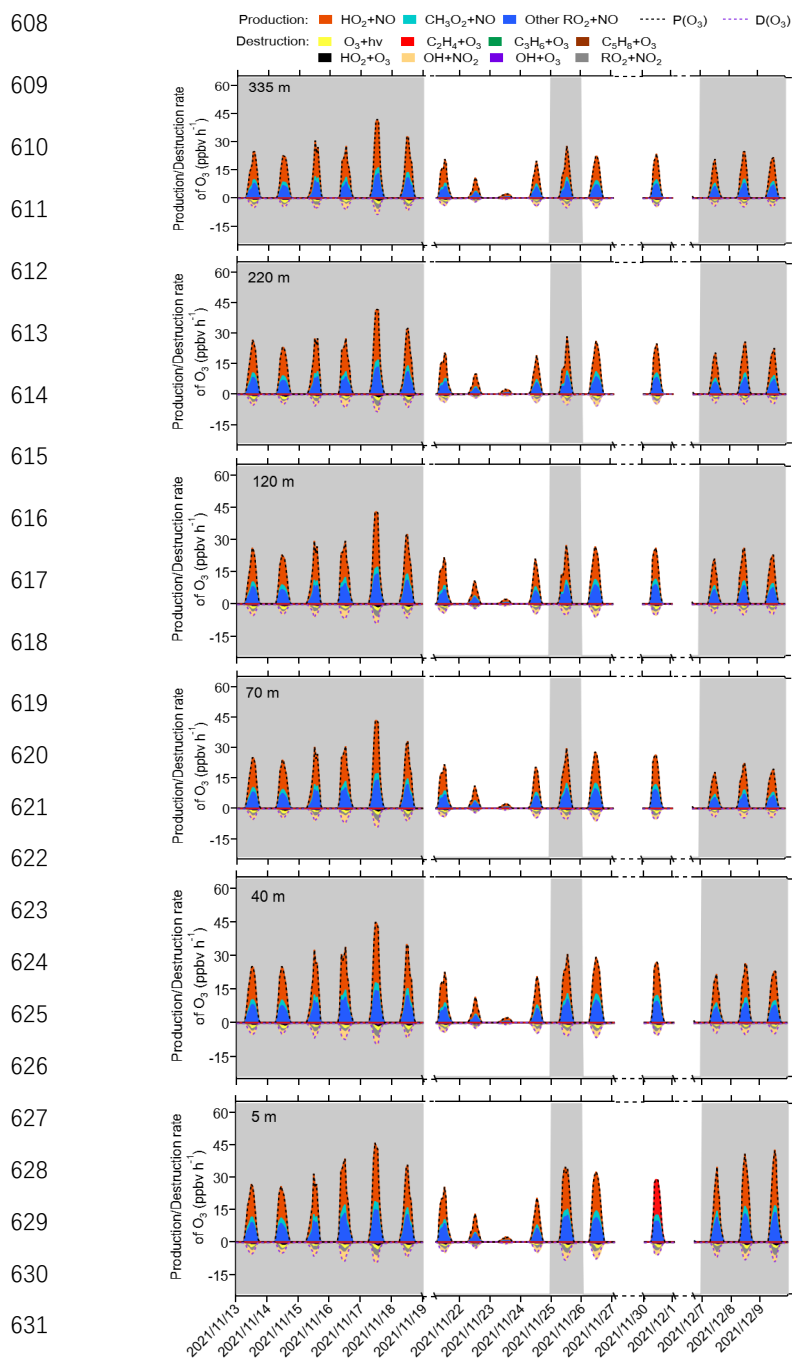

586 **Figure 6.** (a-e) diurnal variations of the measured and modelled $P(O_3)_{net}$ during the
 587 observation period, and (f) the relationship between the average daily differences of measured
 588 and modelled $P(O_3)_{net}$ ($\Delta P(O_3)_{net}$) and the average daytime NO concentrations during different
 589 episodes and non-episodes.

590 3.2.3 Vertical and temporal variability of $P(O_3)_{net}$ budget

591 The detailed $P(O_3)_{net}$ budget at different heights during the observation period from the
 592 modelling results are shown in Fig. 7. We saw that at different heights, or at different
 593 episodes and non-episodes, the contributions of different reaction pathways to $P(O_3)$
 594 were almost the same, with HO_2+NO as the major O_3 production pathway, followed by
 595 CH_3O_2+NO and other RO_2+NO , where other RO_2+NO is defined as all RO_2 except
 596 CH_3O_2 , these results are similar with previous studies (Liu et al., 2021; Liu et al., 2022).
 597 The major O_3 destruction pathway was $OH+NO_2$ (loss of OH radicals), followed by net
 598 RO_2+NO_2 (form peroxyacetyl nitrate, commonly called PAN species) and O_3
 599 photolysis, while the other O_3 destruction pathways, including O_3+OH , O_3+HO_2 ,
 600 $C_3H_8+O_3$, $C_3H_6+O_3$, and $C_2H_4+O_3$ together contributed a negligible O_3 destruction. All
 601 these $P(O_3)$ and $D(O_3)$ reaction pathways happened between 6:00-18:00 LT, and
 602 showed a strong diurnal variation, which increased sharply between at 6:00-11:00 LT
 603 in the morning, reached a peak between 11:00 and 14:00 LT, and decreased quickly
 604 after 14:00 LT. These phenomena were in accordance with the concentration changes
 605 of the major oxidants (i.e., OH, O_3 , and NO_3), as shown in Fig. S4. OH radicals and O_3

606 concentrations increased significantly in the morning and reached a peak at around
607 noon time, and decreased sharply in the afternoon.

632 **Figure 7: Time series of model-simulated O₃ production and destruction rates during 13**
633 **November and 9 December 2021, at different heights at SZMGT, the gray columns show the**
634 **typical ozone episodes that occurred.**

635 The diurnal changes in the concentrations of different reaction pathways to $P(O_3)$
636 and $D(O_3)$ at 5 m ground level during different episodes and non-episodes are depicted
637 in Fig. S5. We note that the maximum total $P(O_3)$ resulting from diel variations at 5 m
638 ground level for episode I, II, and III were 32.0, 34.9, and 38.3 ppbv h⁻¹, respectively.
639 These values were consistently higher than the maximum total $P(O_3)$ observed for non-
640 episodes I and II, which were 15.6 and 30.7 ppbv h⁻¹, respectively. However, as $P(O_3)_{net}$
641 was determined by both $P(O_3)$ and $D(O_3)$, the maximum total $D(O_3)$ values resulting
642 from diel variations during episodes I, II, III, and non-episode I, II, were 5.0, 5.7, 5.1,
643 2.4, and 5.3 ppbv h⁻¹, respectively. Consequently, the modelled $P(O_3)_{net}$ during episodes
644 not exhibiting a statistically difference with that during non-episodes, as shown in Fig.
645 S5, which is in accordance with the measured $P(O_3)_{net}$ as depicted in Sect. 3.1.1.

646 The diurnal variation of $P(O_3)_{net}$ during different episodes and non-episodes
647 obtained by MCM modelling at different heights are shown in Fig. 8. We saw that the
648 $P(O_3)_{net}$ all showed a decrease trend with the increase of the measurement height during
649 different episodes and non-episodes, but the $P(O_3)_{net}$ variation along with the
650 measurement height differs for different episodes and non-episodes. For example, the
651 decrement of the averaged $P(O_3)_{net}$ during 6:00-18:00 from 5 m to 335 m are 1.5 and
652 0.6 ppbv h⁻¹ for episode I and non-episode I, respectively, which are relatively smaller
653 than that during episode II, episode III, and non-episode II, which are 5.3, 5.4, and 4.0
654 ppbv h⁻¹, respectively. To explore the reason, we plotted the differences of calculated
655 OH reactivities at 5 m and 335 m of different VOCs groups (marked as ΔOH reactivity)
656 as a function of the $P(O_3)_{net}$ change at 5 m and 335 m (marked as $\Delta P(O_3)_{net}$), including
657 nonmethane hydrocarbons (NMHC), anthropogenic volatile organic compounds
658 (AVOC), biogenic volatile organic compounds (BVOC), and oxygenated volatile
659 organic compounds (OVOC) (as shown in Fig.8f). We found that OH reactivities of
660 AVOC and OVOC have the highest correlation coefficients (R^2) with the $\Delta P(O_3)_{net}$,
661 which are 0.85 and 0.67, respectively, indicates their predominant influence to the
662 decrement of $P(O_3)_{net}$ from 5 m to 335 m. However, the OH reactivity change from 5
663 m to 335 m of different groups are pretty different, therefore, we further explored O₃
664 formation sensitivity to its different precursors and precursor groups.

682

3.2.4 Vertical distributions of O₃ formation regime

683

684 To investigate the reason for the variable $P(\text{O}_3)_{\text{net}}$ distribution at varying heights, the
 685 sensitivity of O₃ formation to different O₃ precursors or precursor groups, including
 686 NMHC, AVOC, BVOC, OVOC, CO, and NO_x, were clarified by calculating their RIRs
 during different episodes and non-episodes, as shown in Fig. 9.

692

693

694

695

696 **Figure 9: RIR values for O₃-precursor or precursor groups at different heights during**
697 **different classified episodes.**

698 As illustrated in Fig. 9, for a specific episode or non-episode, the RIR values for
699 different O₃-precursors or precursor groups don't have significant variation at different
700 heights, indicates the similar photochemical O₃ formation regime. However, for
701 different episodes or non-episodes, the O₃ formation regimes are different. The O₃
702 formation located in transition regime and more sensitive to VOCs emissions during O₃
703 polluted episode I. Conversely, it is located in VOCs sensitive regime during O₃
704 polluted episodes II and III, and non-episodes I and II. This outcome is in accordance
705 with previous studies that photochemical O₃ formation in the PRD region is likely
706 VOC-limited or mixed-limited (Hong et al., 2022; Lu et al., 2018). The results shown
707 here indicate the complexity of O₃ mitigation at the observation site. For example,
708 during polluted episode I, both reduce VOCs and NO_x can mitigate photochemical O₃
709 formation, but during the other O₃ polluted episodes and non-episodes, reduce VOCs
710 can effectively alleviate photochemical O₃ formation, while the reduction of NO_x might
711 aggravate photochemical O₃ formation. Still, during all episodes and non-episodes, O₃
712 formation are most sensitive to AVOC (RIR: 0.83-1.12), followed by OVOC (RIR:
713 0.59-0.79) at different heights, indicates the urgent needs to reduce AVOC and OVOC
714 emissions to mitigate O₃ pollution in this area.

715 The RIR tests for different episodes and non-episodes at different hours of the local
716 day time are shown in Supplement (Fig. S6). Results show that the diurnal changes of
717 RIR values for different episodes and non-episodes are quite similar. In the morning
718 time, the RIR values for different VOC groups, including AVOC, BVOC, OVOC, and
719 CO are usually higher than that for NO_x, but gradually decrease in the following hours
720 of the day until 16:00 LT, which were then increase and reach a peak at 18:00 LT, but
721 the RIR values at this peak are lower than those at 8:00 LT in the morning. For the RIR
722 values for NO_x, they are usually around zero or below zero, and then gradually increase
723 at around 16:00 LT and then reaches a peak at 18:00 LT, this indicates that the
724 photochemical O₃ formation regime changes during the daytime, which located in the
725 VOC-limited regime in the morning and changes to transition regime but more sensitive
726 to NO_x in the afternoon at around 16:00 LT. The diurnal variations of the RIRs of
727 different O₃ precursor or precursor groups could provide us more detailed information

728 to diagnose the dominating factor that influence the photochemical formation of O₃ at
729 different time of a day.

730 Through the sensitivity study, we note that NO_x would not be the limiting factor
731 that effect $P(O_3)_{net}$, thus the RO_x radicals cycle reactions involved NO_x should
732 occurred efficiently, such as RO₂+NO→HO₂ and HO₂+NO→OH. Meanwhile, the
733 reactions that not involved NO_x should be the limiting steps of RO_x radicals cycling,
734 such as OH+VOCs→RO₂. As the photochemical O₃ formation were most sensitive to
735 AVOC, OVOC and NMHC groups, hence, we should take the priority to reduce AVOC
736 and OVOC to mitigate O₃ pollution in PRD area in China.

737 4. Conclusions

738 We carried out a field observation campaign to investigate the vertical temporal
739 variability of near-surface ozone production mechanism in an urban area in Pearl River
740 Delta (PRD) in China, by using a newly built vertical observation system and the
741 observation-based model coupled to the Master Chemical Mechanism (OBM-MCM)
742 v3.3.1. In total 3 O₃ pollution episodes and 2 non-episodes happened during the
743 observation period. In order to check the modelling performance for O₃ production rates
744 and sensitivity, and the possible reason for O₃ pollution episodes at 5 m ground level,
745 a net photochemical ozone production rate (NPOPR, $P(O_3)_{net}$) detection system based
746 on the current dual-channel reaction chamber technique was employed to directly
747 measure $P(O_3)_{net}$ at 5 m ground-level.

748 The vertical profiles of averaged concentrations of various pollutants exhibit similar
749 trends during both episodes and non-episodes. The O₃, NO_x, and Ox concentrations
750 show minimal vertical gradient during daytime due to the rapid vertical mixing effects,
751 but there are distinct vertical gradients during nighttime owing to the stability of the
752 nocturnal residual layer. Higher concentrations of O₃ and Ox were found at higher
753 heights, while higher NO and NO_x concentrations mainly occurred at ground level.
754 Given that NO_x has a significant titration effect on ozone, the lower O₃ concentration
755 at ground level may be attributed to the increase in NO_x concentration due to a more
756 pronounced NO titration effect, besides the dry deposition near the ground. However,
757 the TVOC and their OFP showed variable trends with the increased height for daytime
758 and nighttime during episodes and non-episodes. Total OFP was highest at 5 m ground
759 level and exhibited higher levels during episodes compared to non-episode periods. The

760 OFP was primarily attributed to OVOCs at different altitudes throughout both episodes
761 and non-episodes.

762 The mean concentrations of O₃ precursors, including CO, NO, NO₂, and TVOC,
763 were not statistically different between episodes and non-episodes. By combining the
764 observed O₃ concentrations change and the measured $P(O_3)_{net}$ at 5 m ground level, we
765 found that the O₃ pollution episodes were jointly influenced by both photochemical
766 production and physical transport, with local photochemical reactions play a dominate
767 role. O₃ pollution episodes recorded during the observation period manifest under
768 specific conditions: ① high photochemical O₃ productions; ② moderate photochemical
769 O₃ productions coupled with O₃ accumulation under stable weather conditions. The
770 index of agreement (IOA) ranged from 0.87 (25th percentile) to 0.90 (75th percentile)
771 for the measured and modelled $P(O_3)_{net}$ across the measurement period, indicated the
772 rationality to investigate the vertical and temporal variability of O₃ formation
773 mechanism using modelling results. However, the measured $P(O_3)_{net}$ were generally
774 higher than the modelled $P(O_3)_{net}$, the differences of measured and modelled $P(O_3)_{net}$
775 ($\Delta P(O_3)_{net}$) are correlated with the NO concentrations. Base on previous studies, this
776 phenomenon could potentially be attributed to the underestimation of RO₂ at high NO
777 conditions, arising from inadequate knowledge concerning photochemical reaction
778 mechanisms. Therefore, the potential biases caused by the modelling methodology
779 were acknowledged and discussed.

780 From the modelling results, the contribution of different reaction pathways to $P(O_3)$
781 were almost the same at varying heights during episodes and non-episodes, with
782 HO₂+NO as the major O₃ production pathway, followed by other RO₂+NO (all RO₂
783 except CH₃O₂) and CH₃O₂+NO. The major O₃ destruction pathway was OH+NO₂ (loss
784 of OH radicals), followed by net RO₂+NO₂ (form peroxyacetyl nitrate) and O₃
785 photolysis, while the other O₃ destruction pathways, including O₃+OH, O₃+HO₂,
786 C₃H₈+O₃, C₃H₆+O₃, and C₂H₄+O₃ together contributed a negligible O₃ destruction.
787 However, $P(O_3)_{net}$ showed a decrease trend with the increase of height during different
788 episodes and non-episodes, which was found mainly due to the decrease of O₃ precursor
789 anthropogenic organic compounds (AVOC) and oxygenated volatile organic
790 compounds (OVOC) groups. We find that the modelling biases were correlated with
791 NO concentrations and VOCs categories, which impact $P(O_3)_{net}$ through the regulation

792 of the RO_2 radicals' budget. The maximum estimated error of modelled $P(\text{O}_3)_{\text{net}}$ ranged
793 from 22-45 % during different episodes and non-episodes. Therefore, the $P(\text{O}_3)_{\text{net}}$
794 variation along with the measurement height might be even larger than our initial
795 assessment.

796 Similar photochemical O_3 formation regimes were observed at different heights for
797 a specific episode or non-episode, yet they varied between different episodes or non-
798 episodes. The O_3 formations were located in transition regime and more sensitive to
799 VOCs emissions during O_3 polluted episode I; whereas located in VOCs sensitive
800 regime during O_3 polluted episodes II and III, and non-episodes I and II. Further
801 analysis revealed a daytime shift in photochemical O_3 formation regime, which located
802 in the VOC-limited regime in the morning and changes to transition regime but more
803 sensitive to NO_x at around 16:00 LT in the afternoon. However, the underestimation of
804 RO_2 radicals in the modelling, especially at lower heights with higher NO
805 concentrations, could result in an overestimate of the VOCs-limited regime. This
806 study highlights the need for more precise analysis using the direct measurement
807 techniques in future studies. Still, throughout all episodes and non-episodes, O_3
808 formation are most sensitive to AVOC, followed by OVOC at various heights,
809 emphasizing the urgent needs to reduce emissions of these compounds to mitigate O_3
810 pollution in this area.

811 This is the first measurement report of the vertical temporal of O_3 formation
812 mechanisms near the ground surface. Together with the deliberation of the possible bias
813 on the vertical temporal profile of O_3 formation rate and sensitivity using modelling
814 study, this study provides the critical foundational insights. The research findings
815 provide us in-depth understanding of near-ground vertical variability of O_3 formation
816 mechanism, which benefit us to formulate proper ozone control strategies in PRD area
817 in China.
