27 **Abstract**

28 Non-methane volatile organic compounds (NMVOC), serving as crucial precursors
29 of O₃, have a significant impact on atmospheric oxidative capacity and O₃ formation.
30 However, both anthropogenic and biogenic NMVOC emissions remain subject to
31 considerable uncertainty. Here, we extended the Regional multi-Air Pollutant
32 Assimilation System (RAPAS) with the EnKF algorithm to optimize NMVOC
33 emissions in China in August 2022 by assimilating TROPOMI HCHO retrievals.
34 We also simultaneously optimize NO_x emissions by assimilating in-situ NO₂
35 observations to address the chemical feedback among VOC-NO_x-O₃. Furthermore,
36 a process-based analysis was employed to quantify the impact of NMVOC emission
37 changes on various chemical reactions related to O₃ formation and depletion.
38 NMVOC emissions exhibited a substantial reduction of 50.2%, especially in the
39 middle and lower reaches of the Yangtze River, revealing a prior overestimation of
40 biogenic NMVOC emissions due to extreme heatwave. Compared with the forecast
41 with prior NMVOC emissions, the forecast with posterior emissions significantly
42 improved HCHO simulations, reducing biases by 75.7%, indicating a notable
43 decrease in posterior emission uncertainties. The forecast with posterior emissions
44 also effectively corrected the overestimation of O₃ in forecast with prior emissions,
45 reducing biases by 49.3%. This can be primarily attributed to a significant decrease
46 in the RO₂ + NO reaction rate and an increase in the NO₂ + OH reaction rate in the
47 afternoon, thus limiting O₃ generation. Sensitivity analyses emphasized the
48 necessity of considering both NMVOC and NO_x emissions for a comprehensive
49 assessment of O₃ chemistry. This study enhances our understanding of the effects
50 of NMVOC emissions on O₃ production and can contribute to the development of
51 effective emission reduction policies.

59 **1 Introduction**

60 Since the Chinese government implemented the Air Pollution Prevention and Control
61 Action Plan in 2013, there has been a notable reduction in NO_x emissions (Zheng et al.,
62 2018). However, despite these advancements, the issue of O₃ pollution persists and, in
63 certain cases, has shown signs of worsening (Ren et al., 2022). The increase in O₃
64 concentration can be attributed not only to adverse meteorological conditions but also
65 predominantly to unbalanced joint control of non-methane volatile organic compounds
66 (NMVOCs) and nitrogen oxides (NO_x) (Li et al., 2020). NMVOCs are vital precursors
67 of O₃ and have a substantial impact on the atmospheric oxidation capacity, thereby
68 altering the lifetimes of other pollutants. Accurately quantifying NMVOC emissions
69 holds significant importance in investigating their impact on O₃ chemistry and in
70 formulating emission reduction policies.

71 Anthropogenic NMVOC emissions have traditionally been estimated using a “bottom-
72 up” method. However, the accuracy and timeliness of these estimations face challenges
73 owing to the scarcity of local measurements for emission factors, the incompleteness
74 and unreliability of activity data, and the diverse range of species and technologies
75 involved (Cao et al., 2018; Hong et al., 2017). Furthermore, uncertainties arise in
76 model-ready NMVOC emissions due to spatial and temporal allocations using various
77 “proxy” data for different source sectors (Li et al., 2017a). Li et al. (2021) reported
78 substantial discrepancies among emission estimates in various studies, ranging 23% to
79 56%. Biogenic NMVOC emissions are typically estimated using models like the Model
80 of Emissions of Gases and Aerosols from Nature (MEGAN) (Guenther et al., 2012) and
81 the Biogenic Emission Inventory System (BEIS) (Pierce et al., 1998). NMVOC
82 emissions result from the multiplication of plant-specific standard emission rates by
83 dimensionless activity factors. Nonetheless, apart from inaccuracies in the distribution
84 of plant functional types, empirical parameterization, especially concerning responses
85 to temperature and drought stress, can introduce substantial uncertainties (Angot et al.,
86 2020; Seco et al., 2022; Jiang et al., 2018). Warneke et al. (2010) determined isoprene
87 emission rates through field measurements and conducted a comparison with MEGAN
88 and BEIS estimates, revealing a notable tendency for MEGAN to overestimate
89 emissions, while BEIS consistently underestimated them. Similarly, Marais et al. (2014)
90 found that MEGAN's isoprene emission estimates were 5-10 times higher than the
91 canopy-scale flux measurements obtained from African field campaigns.

92 A top-down approach, utilizing observed data, has been developed for estimating VOCs
93 emissions. For instance, based on aircraft and ground-based field measurements, the
94 source-receptor relationships algorithm with Lagrangian particle dispersion model
95 (Fang et al., 2016), mixed layer gradient techniques (Mo et al., 2020), eddy covariance
96 flux measurements (Yuan et al., 2015), and box model (Wang et al., 2020) have been
97 employed to complement or verify bottom-up results. However, these approaches do
98 not comprehensively consider the complex nonlinear chemical reactions and transport
99 processes that VOCs undergo in the atmosphere. Formaldehyde (HCHO) and glyoxal
100 (CHOCHO) in the atmosphere serve as crucial oxidization intermediates for various
101 VOCs (Hong et al., 2021; Liu et al., 2012). Satellite-based observations can readily
102 detect their presence in the form of vertical column density (VCD) from space, making
103 them widely utilized for estimating NMVOC emissions. A commonly used approach
104 assumes that the observed HCHO/CHOCHO columns are locally linearly correlated
105 with VOC emission rates (Palmer et al., 2006; Liu et al., 2012). However, this approach
106 does not consider the spatial offset resulting from chemistry reactions and transport
107 processes. Chaliyakunnel et al. (2019) conducted a Bayesian analysis to derive an
108 optimal estimate of VOC emissions using HCHO measurements over the Indian
109 subcontinent. Their results indicated that biogenic VOC emissions modeled by
110 MEGANv2.1 were overestimated by approximately 30–60%, whereas anthropogenic
111 VOC emissions derived from the RETRO inventory were underestimated by 13–16%.
112 Cao et al. (2018) employed the GEOS-Chem model and its adjoint, incorporating
113 tropospheric HCHO and CHOCHO column data from the GOME-2A and OMI
114 satellites as constraints, to quantify Chinese NMVOC emissions. They demonstrated a
115 low bias in the MEGAN model, in contrast to the significant overestimation shown in
116 Bauwens et al. (2016), especially in southern China.

117 Several investigations have been conducted to explore the implications of inverted
118 VOC emissions on surface O₃. For instance, using the Eulerian box model, Zhou et al.
119 (2023) employed concurrent VOC measurements to constrain anthropogenic VOC
120 emissions. This led to improved simulations of VOCs and O₃, with a reduction in high
121 emissions by 15%–36% in the Pearl River Delta (PRD) region. Local model biases in
122 simulating the oxidation of NMVOCs and O₃ are closely related to uncertainties in NO_x
123 emissions (Wolfe et al., 2016; Chan Miller et al., 2017). To tackle these critical
124 questions, Kaiser et al. (2018) applied an adjoint algorithm to estimate isoprene

125 emission over the southeast US by downwardly adjusting anthropogenic NO_x emissions
126 by 50% to rectify NO_2 simulations. Their findings indicated that isoprene emissions
127 from MEGAN v2.1 were overestimated by an average of 40%, slightly lower than the
128 50% reduction in Bauwens et al. (2016). Souri et al. (2020) simultaneously optimized
129 NMVOC and NO_x emissions utilizing OMPS-NM HCHO and OMI NO_2 retrievals in
130 East Asia. They found that predominantly anthropogenic NMVOC emissions from
131 MIX-Asia 2010 increased over the North China Plain (NCP), whereas predominantly
132 biogenic NMVOC emissions from MEGAN v2.1 decreased over southern China after
133 the adjustment. Unfortunately, the posterior simulations exacerbated the overestimation
134 of O_3 levels in northern China.

135 Most studies regarding the inversion of NMVOC emissions or its impact on O_3
136 neglected the uncertainties associated with NO_x -dependent production or loss of
137 NMVOC oxidation and O_3 . An iteratively nonlinear joint inversion of NO_x and
138 NMVOCs using multi-species observations is expected to minimize the uncertainties
139 in their emissions and is well-suited to address the intricate relationship among VOC-
140 NO_x - O_3 . In this study, we extended the Regional multi-Air Pollutant Assimilation
141 System (RAPAS) upon the ensemble Kalman filter (EnKF) assimilation algorithm to
142 enhance the optimization of NMVOC emissions over China, utilizing the
143 TROPospheric Monitoring Instrument (TROPOMI) HCHO retrievals with high spatial
144 coverage and resolution. To more accurately quantify the impact of NMVOC emissions
145 on O_3 , NO_x emissions were simultaneously adjusted using nationwide in-situ NO_2
146 observations. Process analysis was subsequently employed to quantify various
147 chemical pathways associated with O_3 formation and loss. Through a top-down
148 constraint on both emissions, this study aims to offer a more scientific insight into the
149 consequences of optimizing NMVOC emissions on O_3 and contribute to the
150 development of appropriate emission reduction policies.

151 **2 Data and Methods**

152 **2.1 Data Assimilation System**

153 The RAPAS system (Feng et al., 2023) has been developed based on a regional
154 chemical transport model (CTM) and ensemble square root filter (EnSRF) assimilation
155 modules (Whitaker and Hamill, 2002), which are employed for simulating atmospheric
156 compositions and inferring anthropogenic emissions by assimilating surface

157 observations, respectively (Feng et al., 2022; Feng et al., 2020). The inversion process
158 follows a two-step procedure within each inversion window, in which the emissions are
159 inferred first and then input into the CMAQ model to simulate initial conditions of the
160 next window. Meanwhile, the optimized emissions are transferred to the next window
161 as prior emissions. The two-step inversion strategy facilitates error propagation and
162 iterative emission optimization, which have proven the superiority and robustness of
163 our system in estimating emissions (Feng et al., 2023). In this study, we extended the
164 data frame to include the assimilation of TROPOMI HCHO retrievals for optimizing
165 NMVOC emissions. Concise descriptions of the forecast model, data assimilation
166 approach, and experimental settings follow.

167 **2.1.1 Atmospheric Transport Model**

168 The Weather Research and Forecast (WRF v4.0) model (Skamarock and Klemp, 2008)
169 and the Community Multiscale Air Quality Modeling System (CMAQ v5.0.2) (Byun
170 and Schere, 2006) were applied to simulate meteorological conditions and atmospheric
171 chemistry, respectively. WRF simulations were conducted with a 27-km horizontal
172 resolution, covering the entire mainland China on a grid of 225×165 cells (Figure 1).
173 The CMAQ model was run over the same domain, but with a removal of three grid cells
174 on each side of the WRF domain. The vertical settings in WRF and CMAQ was the
175 same as Feng et al. (2020). To account for the rapid expansion of urbanization, we
176 updated underlying surface information for urban and built-up land using the MODIS
177 Land Cover Type Product (MCD12C1) Version 6.1 of 2022. Chemical lateral boundary
178 conditions for NO, NO₂, HCHO, and O₃ were extracted from the output of the global
179 CTM (i.e., the Whole Atmosphere Community Climate Model, WACCM) with a
180 resolution of $0.9^\circ \times 1.25^\circ$ at 6-hour intervals (Marsh et al., 2013). Meanwhile, boundary
181 conditions for the other NMVOCs were obtained directly from background profiles. In
182 the first data assimilation (DA) window, chemical initial conditions (excluding
183 NMVOCs) were also derived from the WACCM outputs, whereas in subsequent
184 windows, they were derived through forward simulation using optimized emissions
185 from the previous window. Table S1 lists the detailed physical and chemical
186 configurations. To assess the impact of updated NMVOC emissions on O₃ production
187 efficiency, we further decoupled the contribution of the primary chemical processes to
188 the O₃ levels using the CMAQ Integrated Reaction Rate (IRR) analysis.

189

190 2.1.2 EnKF Assimilation Algorithm

191 The emissions are constrained using the Ensemble Square Root Filter (EnSRF)
192 algorithm introduced by Whitaker and Hamill (2002). This approach fully accounts for
193 temporal and geographical variations in both the transportation and chemical reactions
194 within the emission estimates. During the forecast step, the background ensembles are
195 derived by applying perturbation to the prior emissions. The perturbed samples are
196 typically drawn from Gaussian distributions with a mean of zero and a standard
197 deviation equal to the prior emission uncertainty in each grid cell. Ensemble runs of the
198 CMAQ model were subsequently performed to propagate the background errors with
199 each ensemble sample of state vectors.

200 In the analysis step, the ensemble mean $\overline{\mathbf{X}^a}$ of the analyzed state is regarded as the best
201 estimate of emissions, which is obtained by updating the background ensemble mean
202 through the following equations:

$$203 \quad \overline{\mathbf{X}^a} = \overline{\mathbf{X}^b} + \mathbf{K}(\mathbf{y} - \mathbf{H}\overline{\mathbf{X}^b}) \quad (1)$$

$$204 \quad \mathbf{K} = \mathbf{P}^b \mathbf{H}^T (\mathbf{H} \mathbf{P}^b \mathbf{H}^T + \mathbf{R})^{-1} \quad (2)$$

205 where \mathbf{y} is the observational vector; \mathbf{H} represents the observation operator mapping
206 model space to observation space; The expression $\mathbf{y} - \mathbf{H}\overline{\mathbf{X}^b}$ quantifies the disparities
207 between simulated and observed concentrations; $\mathbf{P}^b \mathbf{H}^T$ illustrates how uncertainties in
208 emissions relate to uncertainties in simulated concentrations; The Kalman gain matrix
209 \mathbf{K} , dependent on background error covariance \mathbf{P}^b and observation error covariance \mathbf{R} ,
210 determines the relative contributions to the updated analysis.

211 State variables for emissions include NO_x and NMVOCs. To reduce the degree of
212 freedom in the analysis and avoid the difficulty associated with estimating spatio-
213 temporal variations in background errors for individual species, we focus on optimizing
214 the lumped total NMVOC emissions. During the forecast step, we differentiate
215 individual NMVOC species emissions from the total NMVOC emissions using bottom-
216 up statistical information. For a consistent comparison between simulations and
217 observations, model-simulated NO_2 were diagnosed at the time and location of surface
218 NO_2 measurements, whereas model-simulated HCHO was horizontally sampled to
219 align with TROPOMI HCHO VCD retrievals, and subsequently integrated vertically.

220 In this study, the DA window was set to one day and daily TROPOMI HCHO columns
221 were utilized as observational constraints in our inversion framework. The ensemble
222 size was set to 50 to strike a balance between computational cost and inversion accuracy.
223 To reduce the impact of unrealistic long-distance error correlations, the Gaspari and
224 Cohn function (Gaspari and Cohn, 1999) was utilized as covariance localization to
225 ensure the meaningful influence of observations on state variables within a specified
226 cutoff radius, while mitigating their negative impacts on distant state variables. The
227 optimal localization scale is interconnected with factors such as the assimilation
228 window, the dynamic system, and the lifetime of chemical species. Given the average
229 wind speed of 2.8 m/s (Table S2) and a DA window of 1 day, the localization scales for
230 NO₂ and HCHO, both characterized as highly reactive species with lifespans of just a
231 few hours, were set to 150 km and 100 km, respectively.

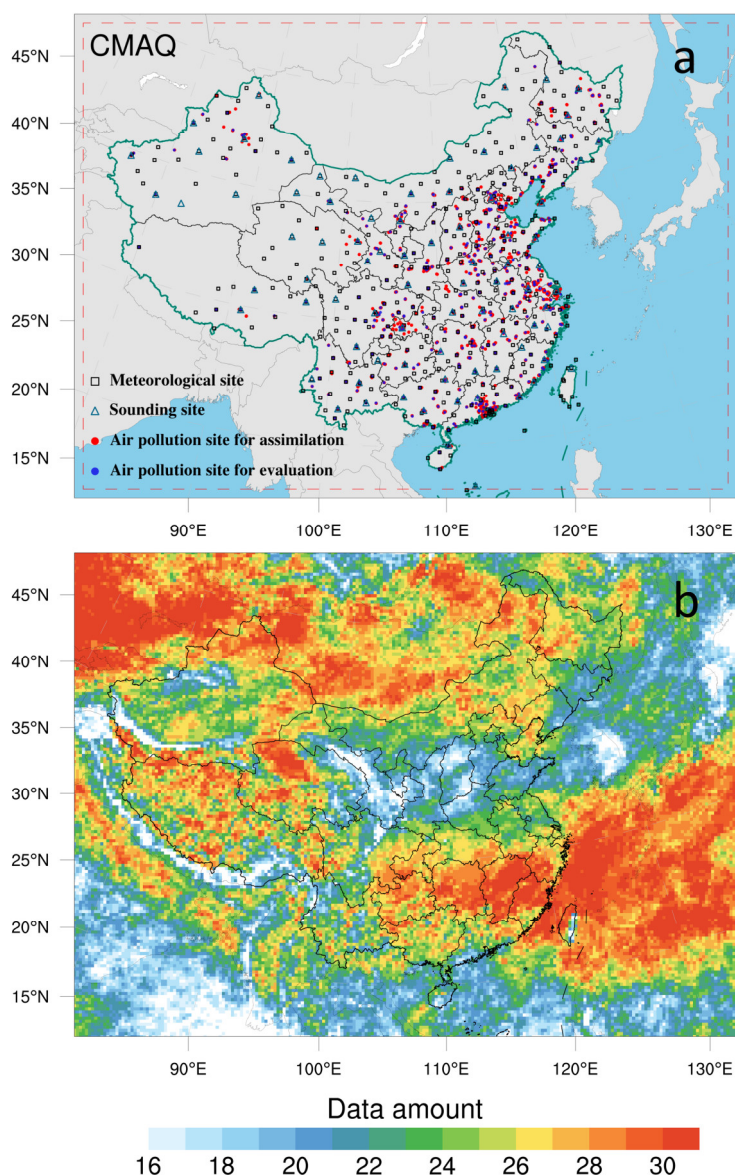

232 **2.2 Observation Data and Errors**

233 Considering the availability of HCHO data, we utilized daily offline retrievals of
234 tropospheric HCHO columns from Sentinel-5P (S5P) L3 TROPOMI data obtained
235 through Google Earth Engine (De Smedt et al., 2018). The S5P satellite follows a near-
236 polar sun-synchronous orbit at an altitude of 824 km with a 17-day repeating cycle. It
237 crosses the Equator at 13:30 local solar time (LST) on the ascending node. The spatial
238 resolution at nadir was refined to $3.5 \times 5.5 \text{ km}^2$ on 6 August 2019. Following the
239 recommendations in the S5P HCHO product user manual, we filtered the source data
240 to exclude pixels with qa_value less than 0.5 for HCHO column number density and
241 0.8 for aerosol index (AER_AI). The remaining high-quality pixels with minimal
242 snow/ice or cloud interference are averaged to 27-km grids. Figure 1b illustrates the
243 coverage and data amount of TROPOMI HCHO retrievals in August 2022 after
244 processing. Although the distribution of filtered data exhibits spatial non-uniformity,
245 most grid cells have observational coverage for over half of the time, particularly in the
246 southern region of China where NMVOC emissions are higher. Based on validation
247 against a global network of 25 ground-based Fourier transform infrared (FTIR) column
248 measurements (Vigouroux et al., 2020), TROPOMI HCHO overestimates by 25%
249 ($<2.5 \times 10^{15} \text{ molec cm}^{-2}$) in clean regions and underestimates by 30% ($\geq 8 \times 10^{15} \text{ molec}$
250 cm^{-2}) in polluted regions. Therefore, we set the measurement error to 30%. To evaluate
251 the effect of observational data retrieval errors on emission estimates, we conducted a
252 sensitivity experiment in which HCHO columns were empirically bias-corrected

253 according to the error characteristics described above (Figure S1). The posterior
254 emissions increased by 12.8% compared to those in the base experiment (EMDA),
255 indicating that the existing retrieval error in HCHO measurements likely exerts an
256 influence on the estimation of NMVOC emissions. The representation error can be
257 disregarded because the model's resolution significantly surpasses that of the
258 TROPOMI pixels.

259 To address the chemical feedback among VOC-NO_x-O₃, we also simultaneously
260 optimized NO_x emissions by assimilating in-situ NO₂ observations. The extensively
261 covered and high-precision monitoring network can provide sufficient constraints for
262 emission inversion (Figure 1a). Hourly averaged surface NO₂ observations from
263 national control air quality stations obtained from the Ministry of Ecology and
264 Environment of the People's Republic of China (<http://106.37.208.228:8082/>, last
265 access: 5 May 2023). In case where multiple stations are located within the same grid,
266 a random site is chosen for validation, while the remaining sites are averaged to mitigate
267 the impact of error correlation (Houtekamer and Zhang, 2016) for assimilation. In total,
268 1276 stations were chosen for assimilation and an additional 425 independent stations
269 were selected for verification (Figure 1a). The observation error covariance matrix **R**
270 incorporates contributions from both measurement and representation errors. The
271 measurement error is defined as $\varepsilon_0 = 1.0 + 0.005 \times \Pi_0$, where Π_0 represents the
272 observed NO₂ concentration. Following the approach of Elbern et al. (2007) and Feng
273 et al. (2018), the representative error is defined as $\varepsilon_r = \gamma \varepsilon_0 \sqrt{\Delta l / L}$, where γ is a tunable
274 parameter (here, $\gamma=0.5$), Δl is the grid spacing (27 km), and L is the radius (here, $L=0.5$)
275 of the observation's influence area. The total observation error (r) was defined as $r =$
276 $\sqrt{\varepsilon_0^2 + \varepsilon_r^2}$. The observation errors are assumed to be uncorrelated so that **R** is a
277 diagonal matrix.

278

279

280 **Figure 1.** Model domain and observation network (a) and data amount of TROPOMI
 281 HCHO retrievals during August 2022 in each grid (b). The red dashed frame delineates
 282 the CMAQ computational domain; black squares denote surface meteorological
 283 measurement sites; navy triangles indicate sounding sites (Text S1), and red and blue
 284 dots represent air pollution measurement sites, where red dots are used for assimilation
 285 and blue dots for independent evaluation.

286 **2.3 Prior Emissions and Uncertainties**

287 The prior anthropogenic NO_x and NMVOC emissions for China were obtained from
 288 the most recent Multi-resolution Emission Inventory for China of 2020 (MEIC,
 289 <http://www.meicmodel.org/>, last access: 8 May 2023) (Zhang et al., 2009). For
 290 anthropogenic emissions outside China, we utilized the mosaic Asian anthropogenic

291 emission inventory (MIX) for the base year of 2010 (Li et al., 2017b). The daily
292 emission inventory, which was arithmetically averaged from the combined monthly
293 emission inventory, was employed as the first guess. Ship emissions were derived from
294 the shipping emission inventory model (SEIM) for 2017, which was calculated based
295 on the observed vessel automatic identification system (Liu et al., 2017). Biomass
296 burning emissions were retrieved from the Global Fire Emissions Database version 4.1
297 (GFEDv4, <https://www.globalfiredata.org/>, last access: 8 May 2023) (van der Werf et
298 al., 2017; Mu et al., 2011). Biogenic NO_x and NMVOC emissions were calculated using
299 the Model of Emissions of Gases and Aerosols from Nature (MEGAN) developed by
300 Guenther et al. (2012).

301 As previously mentioned, the optimized emissions are transferred to the next DA
302 window as prior emissions for iterative inversion. For biogenic emissions, it is
303 decomposed into hourly scales based on the daily varying temporal profiles in MEGAN
304 as model inputs. Daily emission variations will largely dominate the uncertainty in
305 emissions. Taking into account compensating for model errors and avoiding filter
306 divergence, we consistently applied an uncertainty of 25% to each model grid of NO_x
307 emissions at each DA window, as in Feng et al. (2020). NMVOC emissions typically
308 exhibit greater uncertainties compared to NO_x emissions (Li et al., 2017b). Based on
309 model evaluation, the uncertainty of NMVOC emissions was set to 40% (Kaiser et al.,
310 2018; Sourì et al., 2020; Cao et al., 2018). A sensitivity experiment involving a doubling
311 of the prior uncertainty (80%) revealed that the differences in posterior NMVOC
312 emissions amounted to a mere 0.2% (Figure S2). The implementation of a ‘two-step’
313 inversion strategy allows for the timely correction of residual errors from the previous
314 assimilation window in the current window, thus ensuring that the RAPAS system has
315 a relatively low dependence on prior uncertainty settings. This study also addresses
316 uncertainties in emissions for CO, SO₂, primary PM_{2.5}, and coarse PM₁₀ to consider the
317 chemical feedback between different species following Feng et al. (2023).

318 **3 Experimental Design**

319 During the summer of 2022, southern China experienced severe heatwave conditions.
320 The combination of high temperatures and drought had a pronounced effect on
321 vegetation growth and NMVOC emissions, thereby influencing O₃ production (Wang
322 et al., 2023). Consequently, we opted to focus on August 2022, as it presented an ideal
323 period for testing the capabilities of our DA system. Before implementing the emission

324 inversion, a relatively perfect initial field is generated at 0000 UTC on August 1 2022
 325 through conducting a 5-day simulation with 6-hour interval 3D-Var data assimilation.
 326 Subsequently, daily emissions are continuously updated over the entire month of
 327 August (EMDA). Additionally, we designed a sensitivity experiment (EMS) to illustrate
 328 the significance of optimizing NO_x emissions in quantifying VOC-O₃ chemical
 329 reactions. In this experiment, NO_x emissions were not optimized. To validate the
 330 posterior emissions of NO_x and NMVOCs in EMDA, we compared two parallel
 331 forward simulation experiments, denoted as CEP and VEP, corresponding to prior and
 332 posterior emission scenarios, respectively, against NO₂ and HCHO measurements. To
 333 investigate the impact of optimizing NMVOC emissions on the secondary production
 334 and loss of surface O₃, a forward simulation experiment (CEP1) was conducted with
 335 the prior NMVOC emissions and the posterior NO_x emissions. Another forward
 336 modelling experiment (CEP2) used the posterior emissions of EMS to evaluate its
 337 performance. All experiments employ identical meteorological fields, as well as the
 338 same gas-phase and aerosol modules. Table 1 summarizes the different emission
 339 inversion and validation experiments conducted in this study.

340 **Table 1.** The assimilation, sensitivity, and validation experiments conducted in this
 341 study.

Exp.Type	Exp. Name	NMVOC emissions	NO _x emissions
Assimilation	EMDA	MEIC 2020 and MEGAN for August (the first DA window), optimized emissions of the previous window (other DA windows)	MEIC 2020 and MEGAN for August (the first DA window), optimized emissions of the previous window (other DA windows)
Sensitivity	EMS	Same as EMDA	MEIC 2020 and MEGAN for August
Validation	CEP	MEIC 2020 and MEGAN for August	MEIC 2020 and MEGAN for August
	VEP	Posterior emissions of EMDA	Posterior emissions of EMDA
	CEP1	Same as CEP	Posterior emissions of EMDA
	CEP2	Posterior emissions of EMS	Same as CEP

342

343

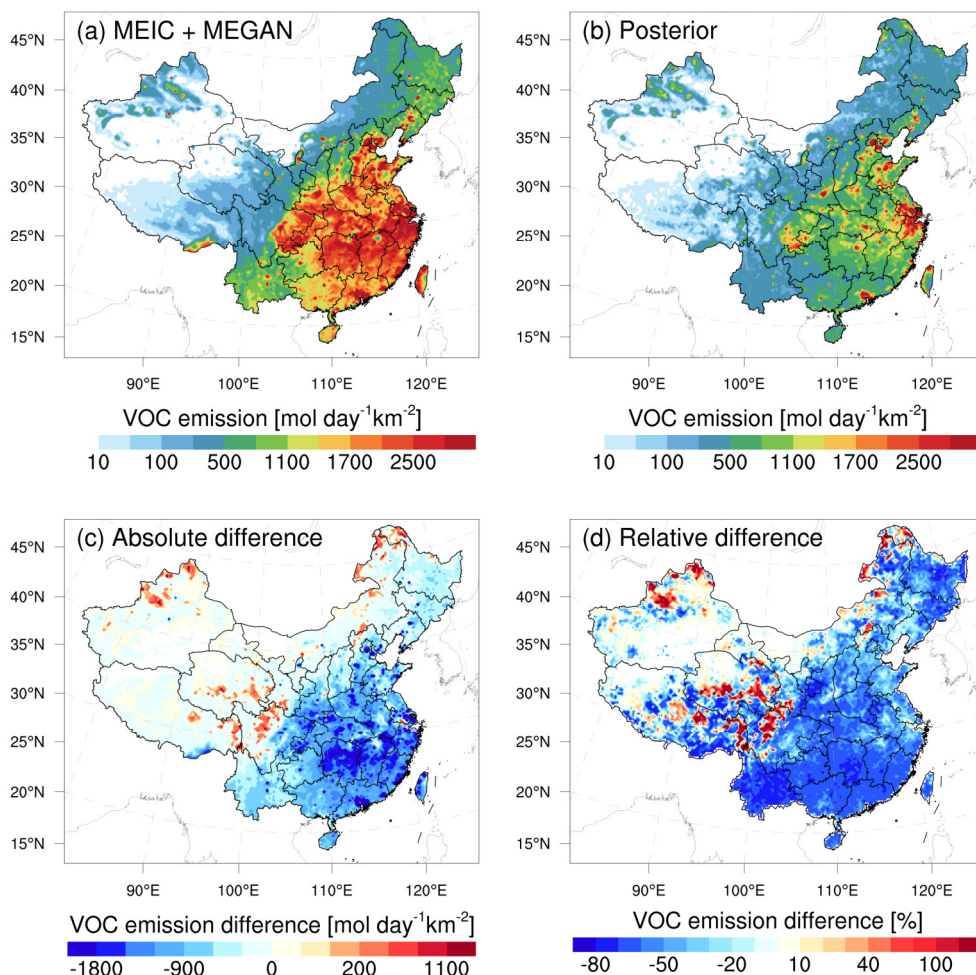

344 **4 Results**

345 **4.1 Inverted Emissions**

346 Figure 2 shows the spatial distribution of temporally averaged prior and posterior
347 NMVOC emissions, along with their differences, in NMVOC emissions. Hotspots of
348 prior NMVOC emissions were prevalent across much of central and southern China.
349 However, posterior NMVOC emissions were predominantly concentrated in the NCP,
350 Yangtze River Delta (YRD), PRD, and Sichuan Basin (SCB), characterized by high
351 levels of anthropogenic activity. High emissions are also located in parts of central and
352 southern China with warm climate favorable for emitting biogenic NMVOCs.
353 Employing TROPOMI HCHO observations as constraints led to widespread decreases
354 of approximately 60–70% over these areas, indicating a large substantial of biogenic
355 NMVOC emissions. In northwestern China, there was a moderate increase in NMVOC
356 emissions.

357 A potential significant TROPOMI retrieval errors in polluted regions could exacerbate
358 the emission decreases (Text S2). Additionally, uncertainties in MEGAN
359 parameterization have significant implications for NMVOC emission estimations,
360 particularly concerning the responses of vegetation in MEGAN to temperature and
361 drought stress (Angot et al., 2020; Jiang et al., 2018). Zhang et al. (2021) highlighted
362 that the temperature-dependent activity factor noticeably increases with rising
363 temperatures in MEGAN. Wang et al. (2021b) pointed out that the missing of a drought
364 scheme is one of the factors causing the overestimation of isoprene emissions in
365 MEGAN. Opacka et al. (2022) optimized the empirical parameter in the MEGANv2.1
366 soil moisture stress algorithm, resulting in significant reductions in isoprene emissions
367 and providing better agreement between modelled and observed HCHO temporal
368 variability in the central U.S. During the study period, China experienced severe
369 heatwave conditions, which may further hinder the MEGAN's ability to effectively
370 capture the impacts of high temperatures and drought on vegetation, thus resulting in
371 significant overestimation in NMVOC emissions (Wang et al., 2022). Ultimately, the
372 biogenic NMVOC emissions decreased by 53.7%, which was higher than the 43.4%
373 decrease in anthropogenic NMVOC emissions (Figure S3). Overall, the large
374 magnitude of emission decrease of 50.2% in our inversion is comparable to studies in
375 southern China (Bauwens et al., 2016; Zhou et al., 2023), southeastern US (Kaiser et
376 al., 2018), Africa (Marais et al., 2014), India (Chaliyakunnel et al., 2019), Amazonia

377 (Bauwens et al., 2016), and parts of Europe (Curci et al., 2010), but opposite to the
 378 large-scale emission increase over China in Cao et al. (2018). For NO_x (Figure S4), the
 379 nationwide total emissions decreased by 10.2%, with the main reductions concentrated
 380 in the NCP, YRD, parts of Central China, and most key urban areas.

381
 382 **Figure 2.** Spatial distribution of the time-averaged (a) prior emissions (MEIC 2020 +
 383 MEGAN), (b) posterior emissions, (c) absolute difference (posterior minus prior), and
 384 (d) relative difference of NMVOCs over China.

385 Table 2 shows the changes in emissions of biogenic NMVOCs across different land
 386 cover types (Figure S5) after inversion. The most significant reduction in biogenic
 387 emissions occurred within woody savannas, accounting for 26.9% of the overall
 388 reduction, followed by savannas and croplands, accounting for 21.2% and 17.2%
 389 respectively. Among all vegetation types, the broadleaf evergreen forests, recognized
 390 as the primary source of isoprene emission (Wang et al., 2021a), presented the greatest
 391 uncertainty, with NMVOC emissions experiencing a significant reduction of 66.2%.
 392 Standard emission rates in MEGAN are derived from leaf- or canopy-scale flux

393 measurements and extrapolated globally across regions sharing similar landcover
 394 characteristics, based on very limited observations (Guenther et al., 1995). This
 395 methodology introduces biases due to the large variability in emission rates among
 396 plant species.

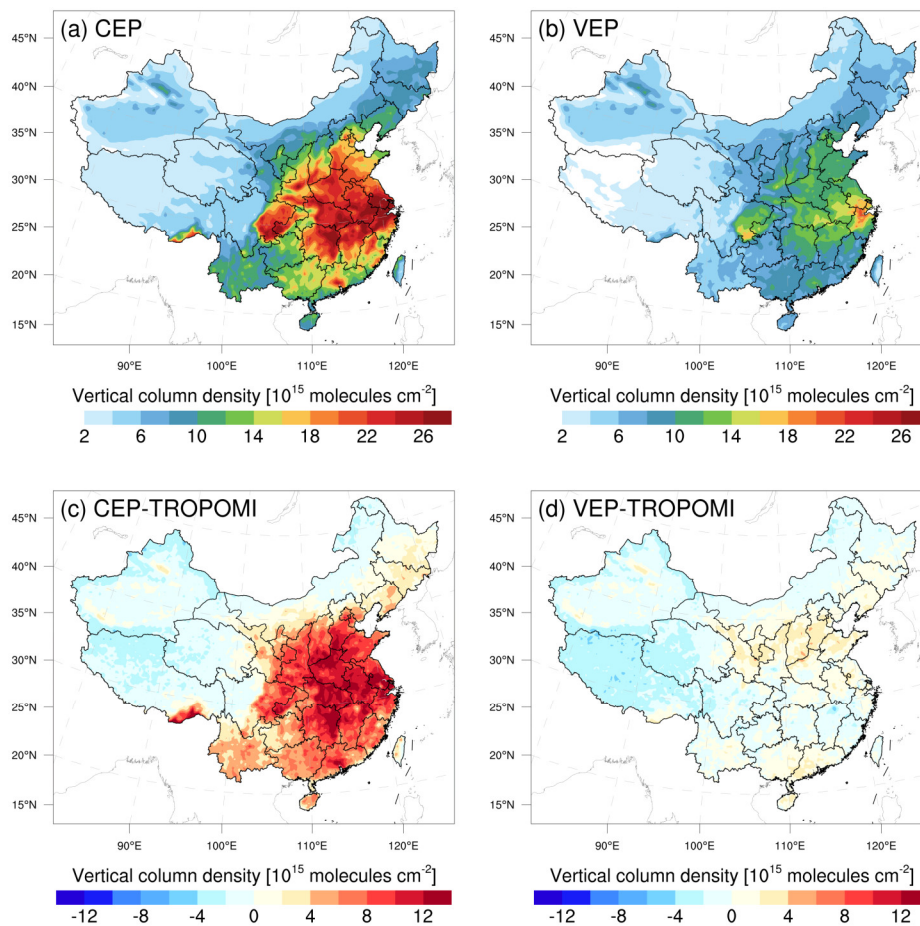

397 **Table 2.** Prior and posterior biogenic NMVOC emissions, as well as their differences
 398 for different land cover types.

Land cover type	Prior Mmol/month	Posterior Mmol/month	Difference Mmol/month (%)
Evergreen needleleaf forests	955.7	549.3	-406.4 (-42.5)
Evergreen broadleaf forests	13985.1	4728.2	-9256.8 (-66.2)
Deciduous needleleaf forests	46.6	48.8	2.2 (4.7)
Deciduous broadleaf forests	8335.5	3487.4	-4848.1 (-58.2)
Mixed forests	8731.0	3961.7	-4769.4 (-54.6)
Closed shrublands	9.7	3.7	-6.0 (-61.5)
Open shrublands	21.3	8.6	-12.8 (-59.8)
Woody savannas	39327.2	16925.2	-22402.0 (-57.0)
Savannas	28319.7	10629.4	-17690.3 (-62.5)
Grasslands	16912.7	14269.6	-2643.1 (-15.6)
Permanent wetlands	286.1	115.4	-170.8 (-59.7)
Croplands	25537.8	11215.5	-14322.2 (-56.1)
Cropland-natural vegetation mosaics	10894.7	4289.8	-6605.0 (-60.6)
Sparsely vegetated	1814.7	1644.0	-170.6 (-9.4)

399 4.2 Evaluations for Posterior Emissions

400 The NO_x emissions were first evaluated by indirectly comparing the forward simulated
 401 NO₂ concentrations with measurements. As shown in Figure S6, the CEP with prior
 402 emissions exhibited positive biases in eastern China and negative biases in western
 403 China. However, when posterior emissions were used in the VEP, a substantial
 404 improvement in simulation performance was observed. Biases were limited to within
 405 $\pm 3 \mu\text{g m}^{-3}$, and correlation coefficients exceeded 0.7 across the entire region. Figure 3
 406 presents the simulated HCHO VCDs using prior and posterior NMVOCs emissions,

407 along with their associated biases. Both experiments showed high VCDs over central
408 and eastern China, especially in the YRD and SCB. However, the CEP displayed
409 substantial overestimation across most of mainland China, with the largest bias
410 reaching 12×10^{15} molec cm^{-2} in Central China. Conversely, the VEP demonstrated
411 notable improvements in both the magnitude and spatial distribution of simulated
412 HCHO columns after the inversion compared to TROPOMI retrievals. More than 84%
413 of the areas exhibited biases of less than 1×10^{15} molec cm^{-2} , and no significant spatial
414 variation was observed. Overall, the biases in simulated HCHO VCDs decreased by
415 75.7% after the inversion. These results emphasize the efficiency of our system in
416 reducing uncertainty in both NO_x and NMVOC emissions.

417

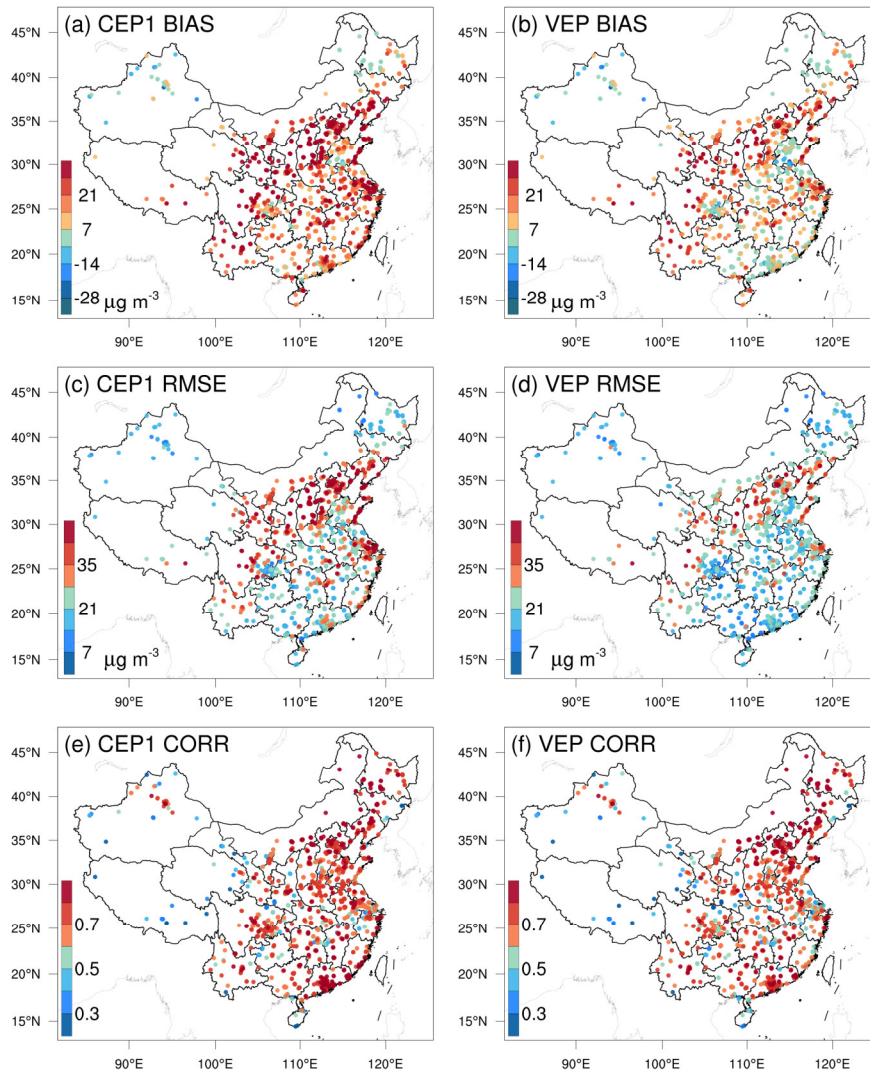

418 **Figure 3.** Simulated HCHO vertical column densities using prior (a) and posterior (b)
419 NMVOC emissions, along with their biases (c and d) against TROPOMI measurement.
420 All model results were sampled at TROPOMI overpass time.

421

422

423 4.3 Implications for Surface O₃

424 Figure 4 shows the spatial distribution of the mean bias (BIAS), root mean square error
425 (RMSE), and correlation coefficient (CORR) for simulated O₃ concentrations in the
426 CEP1 and VEP experiments compared to assimilated observations. Beyond the
427 northwestern region of China, the CEP1 exhibited significant overestimation
428 throughout the entire area, with a BIAS of 20.5 μg m⁻³. In the VEP, the modeled O₃
429 chemical production were alleviated, especially in the southern regions of China where
430 NMVOC emissions had significantly decreased. Overall, observation-constrained
431 NMVOC emissions resulted in a 49.3% decrease in the BIAS, bringing it down to 10.4
432 μg m⁻³. Additionally, the RMSE showed noticeable improvement due to the
433 assimilation of HCHO observation, reducing the value from 30.9 to 23.3 μg m⁻³.
434 Despite a significant reduction in NMVOC emissions after inversion, notable
435 overestimations persisted in northern provinces such as Liaoning, Hebei, Shanxi, and
436 Shaanxi. This may be attributed to limited NMVOC constraints resulting from
437 insufficient observations during the study period (Figures 1b and 3d). The remaining
438 discrepancies between simulations and observations can be attributed to the combined
439 results of intricate urban-rural sensitivity regimes and O₃ photochemistry reactions,
440 which may not be comprehensively represented by CMAQ model, masking any
441 potential improvement expected from the constrained emissions (See Sect. 4.4). The
442 CORR was comparable between the CEP1 and VEP experiments, reflecting that the
443 CMAQ model effectively simulated the temporal variation of O₃ concentrations. The
444 biases at the independent sites were similar to those at the assimilated sites (Figure S7).
445 In comparison to CEP1, the decreasing ratios in BIAS and RMSE in VEP were 46.7%
446 and 23.4%, respectively.

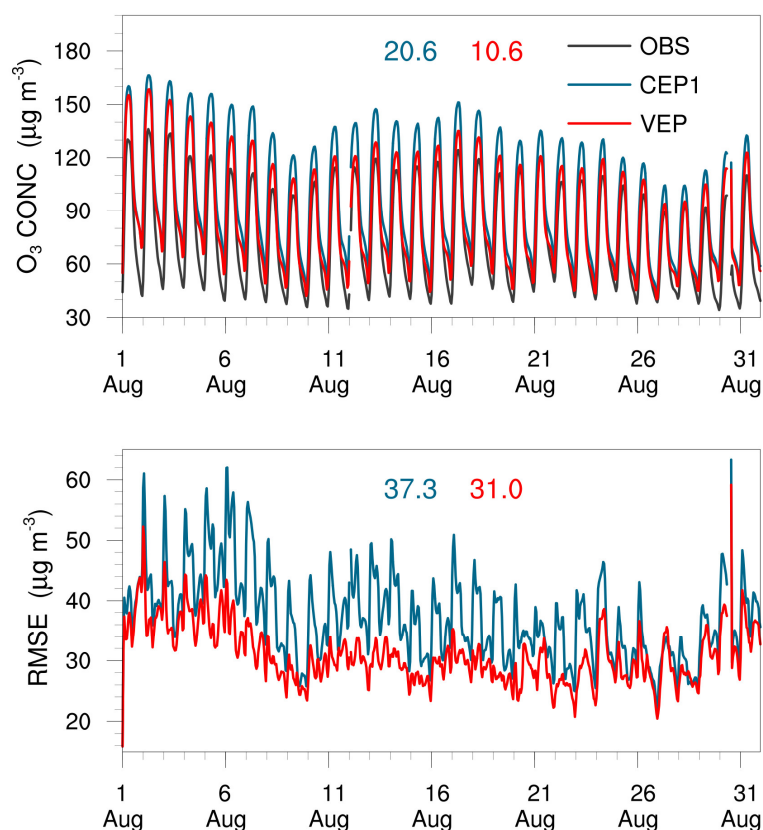

447

448 **Figure 4.** Spatial distribution of mean bias (BIAS, a and b), root mean square error
 449 (RMSE, c and d), and correlation coefficient (CORR, e and f) for simulated O₃ using
 450 prior (left, CEP1) and posterior (right, VEP) emissions, respectively, against
 451 assimilated observations.

452 Figure 5 shows the time series of simulated and observed hourly O₃ concentrations and
 453 their RMSEs, verified against surface monitoring sites. The VEP achieved better
 454 representations of diurnal O₃ variations compared with those in the CEP1, especially
 455 excelling in reproducing elevated O₃ concentrations at noon. Constraining the NMVOC
 456 emissions also led to better model simulations in terms of RMSE throughout the entire
 457 study period. Time-averaged BIAS and RMSE decreased from 20.6 and 37.3 $\mu\text{g m}^{-3}$ to
 458 10.6 and 31.0 $\mu\text{g m}^{-3}$, respectively. We also evaluated the simulation results for seven
 459 key cities (i.e., Beijing, Shanghai, Guangzhou, Wuhan, Chongqing, Yinchuan, and
 460 Changchun, which represent key cities in North, East, South, Central, Southwest,

461 Northwest, and Northeast China, respectively), and the biases in the VEP with posterior
462 emissions all showed a significant reduction (Figure S8). Overall, the assimilation of
463 HCHO column observations effectively reduced NMVOC emission uncertainties and
464 consequently improved simulations of HCHO and O₃. These improvements hold
465 promise for further research into the implications of emission optimizations on regional
466 O₃ photochemistry.

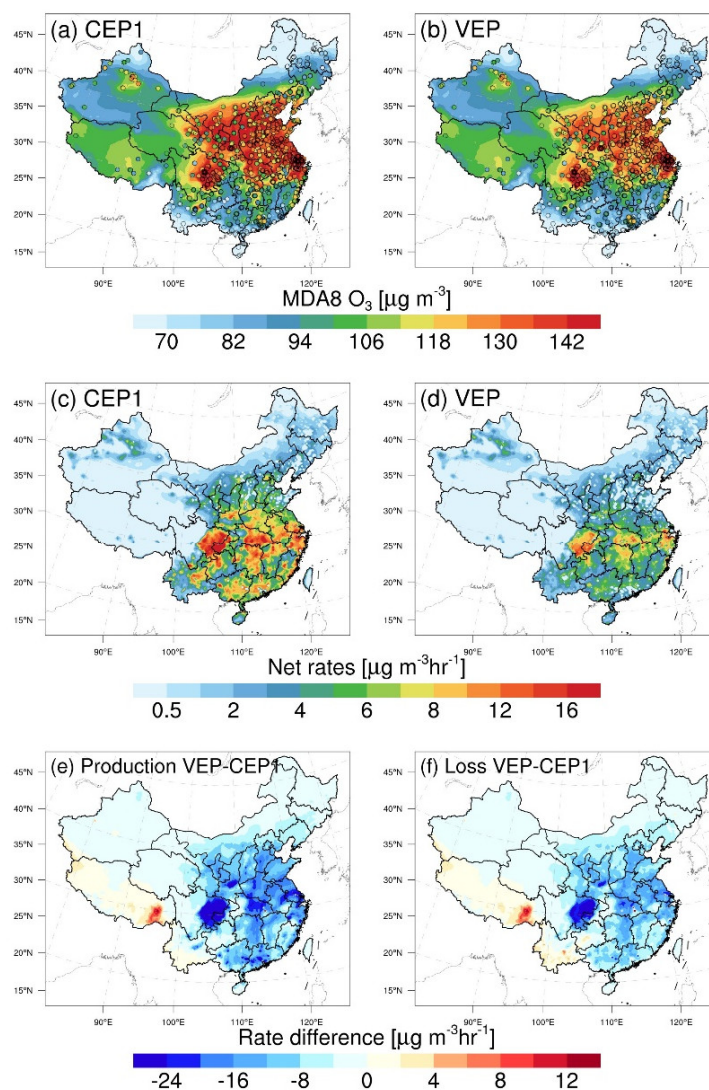

467

468 **Figure 5.** Time series comparison of hourly surface O₃ concentrations (µg m⁻³) and
469 RMSE (µg m⁻³) from CEP1 and VEP experiments against all observations at 1701
470 monitoring sites. The blue and red values on the graph represent the time-averaged
471 statistics in the CEP1 and VEP experiments, respectively.

472 As crucial O₃ precursors, the abundance of NMVOCs plays a significant role in
473 modulating O₃ production. Here we employed the IRRs to elucidate changes related to
474 O₃ production and loss at the surface, stemming from constrained NO_x and NMVOC
475 emissions. Figure 6 illustrates comparisons of the simulated maximum daily 8-hour
476 average (MDA8) surface O₃ levels and net reaction rates before and after the inversion.
477 The CEP1 exhibited an overestimation of O₃ levels, with a BIAS of 22.6% compared
478 to observed O₃ concentrations. This overestimation corresponded to the high net

479 chemical rates of O₃ in these areas (Figure S9). After inversion, O₃ net rates mitigated
 480 in most regions. Consequently, the VEP experiment yielded results that closely aligned
 481 with observations, with a BIAS of 9.2%. Referring to Figure 6e and 6f, differences in
 482 production rates of O₃ closely track the changes in the NMVOC emissions (Figure 2).
 483 The discrepancies in specific regions may be attributed to the complex nonlinear
 484 relationships associated with O₃ and its precursors, which depend on prevailing
 485 chemical regimes and regional transport. Additionally, changes in O₃ production
 486 predominantly drive the overall decrease in O₃ concentrations, outweighing changes in
 487 O₃ loss.

488

489 **Figure 6.** Comparisons of (a, b) simulated maximum daily 8-hour average (MDA8) O₃
 490 concentrations, (c, d) net reaction rates, (e, f) and differences in production and loss
 491 rates between CEP1 and VEP experiments at the surface. Surface MDA8 O₃ values
 492 (circles) from the national control air quality stations were overlaid

493 Figure 7 shows the differences in the six principal pathways responsible for O₃ loss and
494 formation, when comparing simulations employing prior and posterior emissions. The
495 reactions of HO₂ + NO and RO₂ + NO are treated as the pathways leading to O₃
496 formation, whereas O₃ loss involves reactions including NO₂ + OH, O₃ + HO₂, O₃ +
497 NMVOCs, and O¹D + H₂O (Wang et al., 2019). Our analysis was focused on the time
498 frame from 12:00 to 18:00 according to China standard time (CST). The differences
499 were computed by subtracting the simulation with posterior emissions from those with
500 prior emissions. Following the emission of NMVOCs, they undergo rapid oxidation by
501 atmospheric hydroxyl (OH) radicals. Due to the substantial decrease in NMVOC
502 emissions, there was a reduction in the production of hydroperoxy radicals (HO₂) and
503 organic peroxy radicals (RO₂) (Figure S10). Consequently, this reduction in HO₂/RO₂
504 levels, coupled with their reaction with NO, resulted in diminished O₃ production
505 (Figures 7a and 7b). A strong correlation was observed between changes in O₃
506 production via the RO₂ + NO reaction and NMVOC emissions (Figure 2), consistent
507 with the findings of Sourì et al. (2020). Typically, in NMVOC-rich environments, a
508 decrease in NMVOC emissions boosts OH concentrations. Consequently, we noted an
509 enhancement in the NO₂ + OH reaction in the eastern and central regions of China. In
510 response to heightened HO_x concentrations over these areas, an increased O₃ loss
511 through the O₃ + HO_x pathway was observed. Furthermore, we detected a substantial
512 decrease in O₃ loss through reactions with NMVOCs, especially in the southern China,
513 where substantial isoprene emissions are prevalent. This reduction was primarily
514 attributable to the decrease in NMVOC and O₃ levels. While the NMVOC + O₃ reaction
515 proceeds at a substantially slower rate NMVOC + OH, this specific chemical pathway
516 remains significant in oxidizing NMVOC and forming HO_x in forests areas (Paulson
517 and Orlando, 1996). The difference in O¹D + H₂O is primarily driven by the decrease
518 of O₃ photolysis. Although the rate of O₃ loss decreases in some chemical pathways,
519 overall, the rate of O₃ production dominates the changes in O₃ concentration.

520

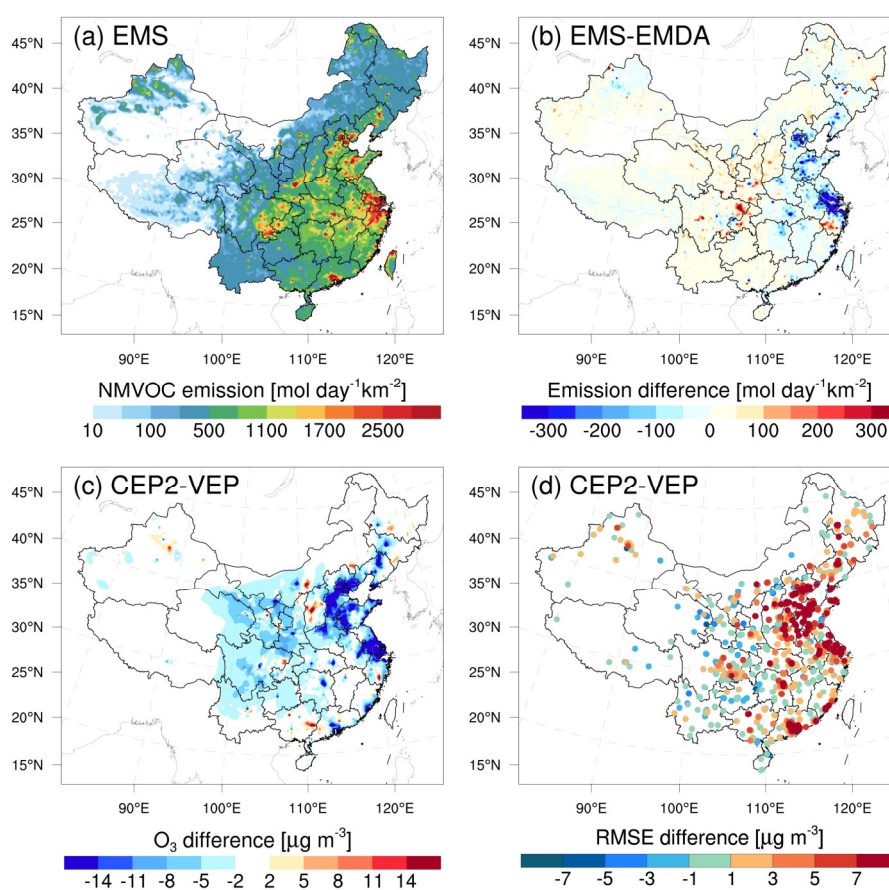

521 **Figure 7.** Differences in six major pathways of O_3 production and loss between CEP1
 522 and VEP experiments at the surface. Time period: August 2022, 12:00–18:00 CST. PO_3
 523 and LO_3 represent the pathways of O_3 formation and loss, respectively.

524 4.4 Discussions

525 O_3 simulations over China have a tendency to be overestimated in studies involving
 526 chemical transport modeling. For example, by intercomparing 14 state-of-the-art CTMs
 527 with O_3 observations within the framework of the MICS-Asia III, Li et al. (2019)
 528 identified a substantial overestimation of annual surface O_3 in East Asia, ranging from
 529 20 to $60 \mu\text{g m}^{-3}$. Notably, the NCP exhibited substantial overestimations, with most
 530 models overestimating O_3 by 100–200% during May–October. Despite our

531 optimization of O₃ precursor emissions, the posterior simulations still exhibit some
532 degree of overestimation (Figure 4), suggesting that there may indeed be an effect of
533 systematic bias, such as meteorological fields, spatial resolution, model treatments of
534 nonlinear photochemistry and other physical processes. The WRF can generally
535 reproduce meteorological conditions sufficiently in terms of their temporal variation
536 and magnitude over China (Figure S11), with small biases of -0.5 °C, -5.3%, 0.3 m/s,
537 and -42.4 m for temperature at 2 m, relative humidity at 2 m, and wind speed at 10 m,
538 and planetary boundary layer height, respectively. However, due to the relatively coarse
539 spatial resolution, NO titration effects in urban areas may not be well represented in the
540 model, which can lead to an overestimation of O₃ in these areas. Additionally, model
541 inherent errors arising from the model structure, parameterization, and the
542 simplification or lack of chemical mechanisms inevitably affect the O₃ simulations. For
543 example, Li et al. (2018) reported that heterogeneous reactions of nitrogen compounds
544 could weaken the atmospheric oxidation capacity and thus reduce surface O₃
545 concentration by 20–40 μg m⁻³ for the polluted regions over China. These reactions
546 have not been fully incorporated in CMAQ chemical mechanisms. However, there is
547 still a lack of reasonable and effective algorithms for addressing model errors through
548 assimilation (Houtekamer and Zhang, 2016). O₃ concentration and NO_x (VOC)
549 emissions are positively correlated in the NO_x (VOC)-limited region and negatively
550 correlated in the VOC (NO_x)-limited region (Tang et al., 2011). Therefore, the
551 uncertainty in NO_x emissions can affect the model's diagnosis of O₃-NO_x-VOC
552 sensitivity, thereby introducing substantial model errors in the HCHO yield from VOC
553 oxidation. In the base inversion experiment (EMDA), we simultaneously assimilated
554 NO₂ and HCHO observations to optimize NO_x and NMVOC emissions. To evaluate the
555 impact of optimized NO_x emissions on O₃-VOC chemistry, EMS disregarded the
556 uncertainty of NO_x and focused on optimizing NMVOC emissions. Compared to the
557 EMDA, in areas where NO_x is significantly overestimated, NMVOC emissions in the
558 EMS have correspondingly decreased (Figure 8b). This might be due to under high-
559 NO_x conditions, HCHO production occurs promptly, thereby compensating for the
560 substantial amount of HCHO already present in the atmosphere by reducing emissions
561 (Chan Miller et al., 2017). Figure S12 shows comparisons of concentrations and RMSE
562 between the simulations using posterior emissions from EMS and EMDA experiments.
563 Compared to VEP, CEP2 showed a larger RMSE, highlighting the necessity for
564 simultaneous optimization of NO_x emissions when evaluating the impact of NMVOC

565 emission optimization on O₃. Additionally, CEP2 using prior NO_x emissions exhibited
 566 lower O₃ levels over parts of NCP and YRD, as well as some urban areas (Figure 8c),
 567 but with larger biases and RMSEs (Figure 8d). The reduction in NMVOC emissions
 568 contributed to a partial decrease in O₃ concentration. More significantly, these areas
 569 typically align with VOC-limited mechanisms (Wang et al., 2019; Wang et al., 2021c).
 570 Therefore, the overestimation of NO_x emissions (Figure S4) excessively inhibits O₃
 571 accumulation due to the titration effect, thereby disrupting the evaluation of NMVOC
 572 contributions to O₃. This substantial disparity also seriously affects O₃ source
 573 apportionment, precursor-sensitive area delineation, and emissions reduction policy
 574 formulation.

575

576 **Figure 8.** Spatial distribution of (a) posterior emissions in the EMS experiment, (b)
 577 differences in posterior emissions between EMS and EMDA, and differences in
 578 simulated (c) O₃ concentrations and (d) RMSE between CEP2 and VEP experiments.
 579 EMS did not optimize NO_x emissions compared to EMDA.

580

581 **5 Summary and Conclusions**

582 In this study, we extended the RAPAS assimilation system with the EnKF assimilation
583 algorithm to optimize NMVOC emissions using the TROPOMI HCHO retrievals.
584 Taking the MEIC 2020 for anthropogenic emissions and MEGANv2.1 output for
585 biogenic sources as a priori, NMVOC emissions over China in August 2022 were
586 inferred. Importantly, we implicitly took the chemical feedback among VOC-NO_x-O₃
587 into account by simultaneously adjusting NO_x emissions using nationwide in-situ NO₂
588 observations. Furthermore, we quantified the impact of NMVOC emission inversion on
589 surface O₃ pollution using the CMAQ-IRR model.

590 The application of TROPOMI HCHO observations as constraints led to a substantial
591 reduction of 50.2% compared to the prior emissions for NMVOCs in August 2022. A
592 domain-wide significant decrease was found over central and southern China with
593 abundant forests, especially for the broadleaf evergreen forests, implying a considerable
594 overestimation of biogenic NMVOC emissions. Observation-constrained emissions
595 significantly improved the performance of surface NO₂ and HCHO column simulations,
596 reducing biases by 97.4% and 75.7%, respectively. This highlights the effectiveness of
597 the RAPAS in reducing uncertainty in NO_x and NMVOC emissions. Isolating the
598 impact of NO_x emission changes, the posterior NMVOC emissions significantly
599 mitigated the overestimation in prior O₃ simulations, resulting in a 49.3% decrease in
600 surface O₃ biases. This is mainly attributed to a substantial decrease in the RO₂ + NO
601 reaction rate (a major pathway for O₃ production) and an increase NO₂ + OH reaction
602 rate (a major pathway for O₃ loss) during the afternoon, resulting in a decrease in the
603 simulated MDA8 surface O₃ concentrations by approximately 15 μg m⁻³.

604 Sensitivity inversions demonstrate the robustness of top-down emissions to variations
605 in prior uncertainty settings, yet they are sensitive to HCHO column biases,
606 highlighting the importance of comprehensive validation studies utilizing available
607 remote-sensing data and, if possible, airborne validation campaigns. Moreover, we
608 found that, in comparison to optimizing NMVOC emissions alone, the joint
609 optimization of NMVOC and NO_x emissions can significantly improve the overall
610 performance of O₃ simulations. Ignoring errors in NO_x emissions introduces uncertainty
611 in quantifying the impact of NMVOC emissions on surface O₃, especially in areas
612 where overestimated NO_x emissions can unrealistically amplify titration effects,

613 highlighting the necessity of simultaneous optimization of NO_x emissions.

614

615 **Data availability**

616 The observations used for assimilation and the optimized emissions in this study can be
617 accessed at <https://doi.org/10.5281/zenodo.10079006> (Feng and Jiang, 2023).

618

619 **Author contribution**

620 SF and FJ conceived and designed the research. SF developed the data assimilation
621 code, analyzed data, and prepared the paper with contributions from all co-authors. FJ
622 supervised and assisted in conceptualization and writing. TQ, NW, MJ, SZ, JC, FY, and
623 WJ reviewed and commented on the paper.

624

625 **Competing interests**

626 The authors declare that they have no conflict of interest.
