14 **Abstract.** The timing of the last deglaciation of the Laurentide Ice Sheet in western New York is poorly constrained.  
15 The lack of direct chronology in the region has led to a hypothesis that the Laurentide Ice Sheet re-advanced to near  
16 its Last Glacial Maximum terminal position in western New York at ~13 ka, which challenges long-standing  
17 datasets. To address this hypothesis, we obtained new chronology from the Kent (terminal) and Lake Escarpment  
18 (first major recessional) moraines using radiocarbon ages in sediment cores from moraine kettles supplemented with  
19 two optically stimulated luminescence ages from topset beds in an ice-contact delta. The two optically stimulated  
20 luminescence ages date the Kent (terminal) position to  $19.8 \pm 2.6$  and  $20.6 \pm 2.9$  ka. Within the sediment cores, there  
21 is sedimentologic evidence of an unstable landscape during basin formation; radiocarbon ages from the lowest  
22 sediments in our cores are not in stratigraphic order and date from 19,350-19,600 to 14,050-14,850 cal BP. We  
23 interpret these ages as loosely minimum-limiting constraints on ice sheet retreat. Our oldest radiocarbon age of  
24 19,350-19,600 cal BP – from a rip-up clast – suggests ice-free conditions at that time. Above the lowest sediments  
25 there is organic-rich silt and radiocarbon ages in stratigraphic order. We interpret the lowest ages in these organic-  
26 rich sediments as minimum-limiting constraints on kettle basin formation. The lowest radiocarbon ages from  
27 organic-rich sediments from sites on both Kent and Lake Escarpment moraines range from 15,000-15,400 to 13,600-  
28 14,000 cal BP. We interpret the 5 kyr lag between the optically stimulated luminescence ages and kettle basin  
29 formation as the result of persistent buried ice in ice-cored moraines until ~15 to 14 ka. The cold conditions  
30 associated with Heinrich Stadial 1 may have enabled the survival of ice-cored moraines until after 15 ka, and in turn,  
31 climate amelioration during the Bølling Period (14.7 – 14.1 ka) may have initiated landscape stabilization. This  
32 model potentially reconciles the sedimentological and chronological evidence underpinning the re-advance  
33 hypothesis, which instead could be the result of moraine instability and sediment mobilization during the Bølling -  
34 Allerød periods (14.7 – 13 ka). Age control for future work should focus on features that are not dependent on local  
35 climate.

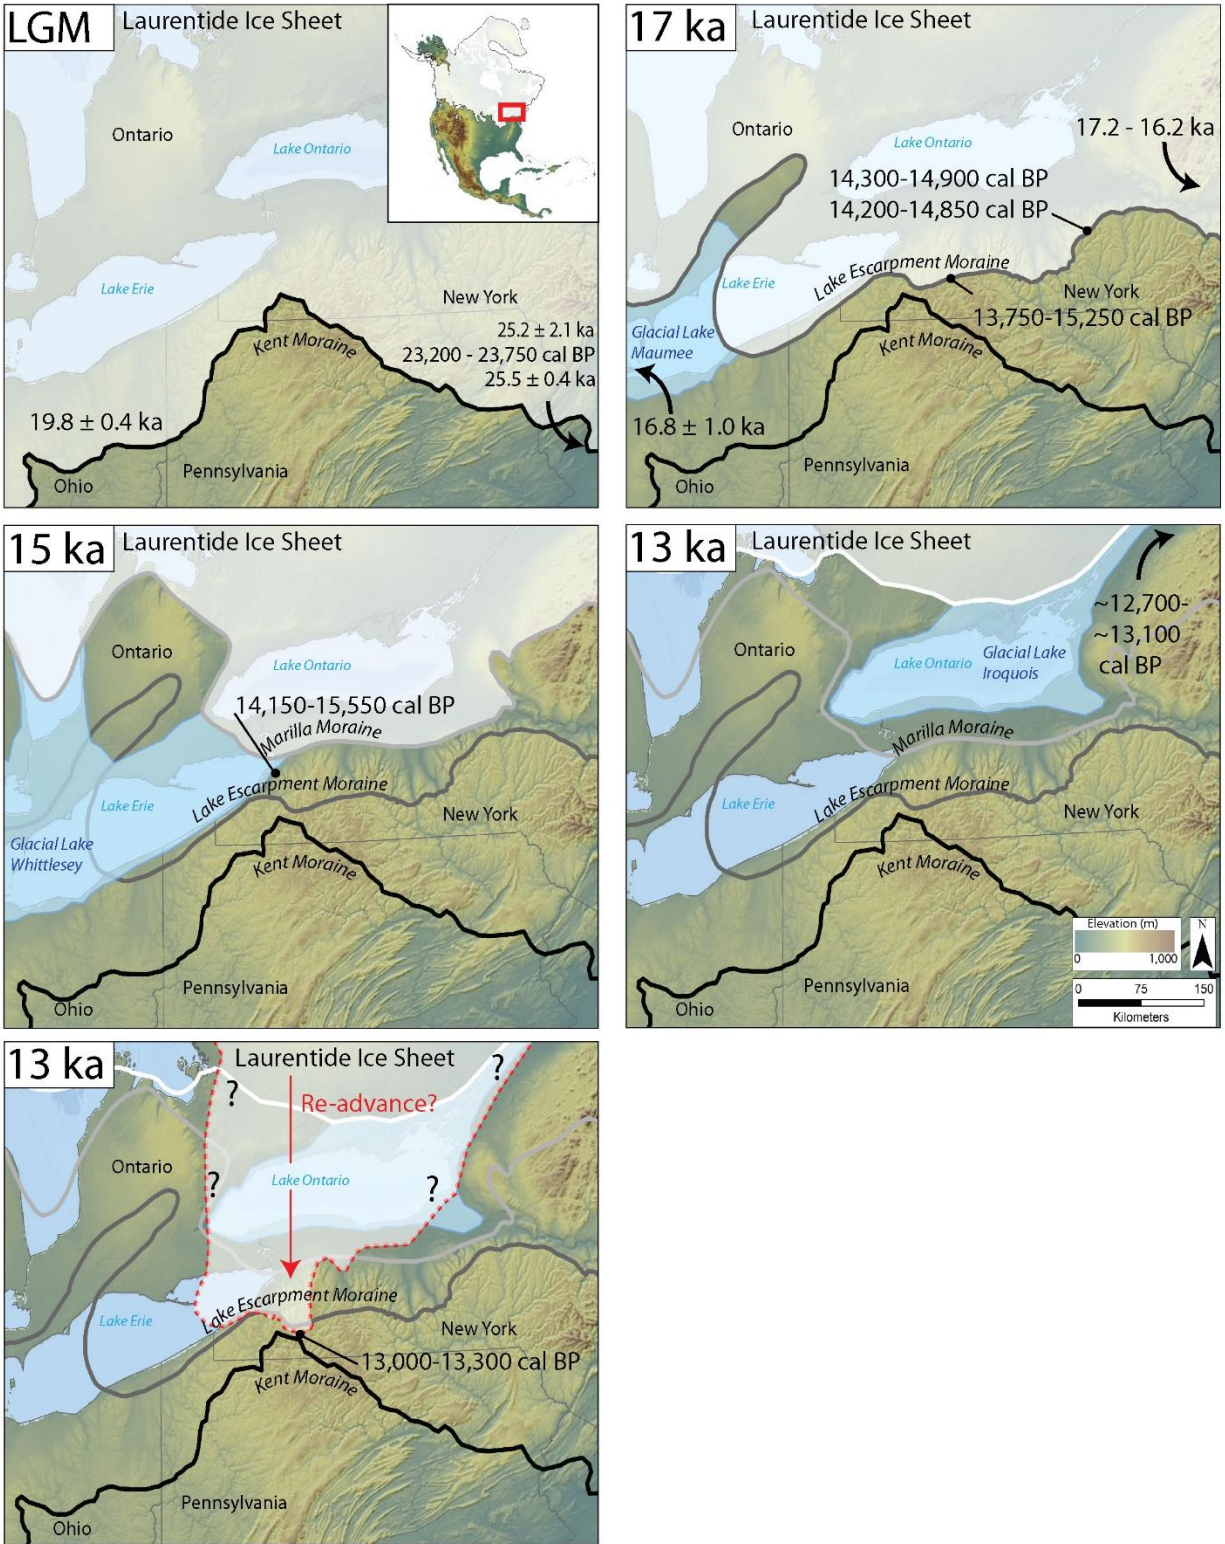

## 36 37 **1 Introduction**

38 Much glacial research over the last century has focused on the style and timing of Laurentide Ice Sheet  
39 (LIS) recession from the Great Lakes region of North America following the Last Glacial Maximum (LGM, 26-19  
40 ka; Dalton et al., 2020; Dyke, 2004; Fairchild, 1909). Well constrained ice sheet chronologies are necessary to  
41 determine the timing of meltwater re-routing events from ice-dammed lakes that occupied the Great Lakes basins  
42 during the last deglaciation (Barth et al., 2019; Calkin and Feenstra, 1985; Leydet et al., 2018; Porreca et al., 2018;  
43 Rayburn et al., 2007), as these events are hypothesized to have had significant climatic impacts (Broecker et al.,  
44 1989; Donnelly et al., 2005). Models that attempt to understand past climate change (Osman et al., 2021), ice sheet  
45 sensitivity (Briner et al., 2020), and atmospheric organization (Löffverström et al., 2014; Tulenko et al., 2020) all  
46 require paleo ice sheet configurations. Therefore, well-defined ice sheet retreat chronologies are critical for  
47 understanding dynamics and forcings within the late glacial climate system.

48 Despite the critical need for precise chronologies of ice margin retreat of the LIS in the Great Lakes region,  
49 ice margin reconstructions in western New York lack detailed age control. Here, there are no local ages on the

50 terminal moraine and few from the recessional moraines (Muller and Calkin, 1993), leaving the deglacial  
51 chronology to be largely based on correlations with dated moraines and proglacial shorelines to the west in Ohio and  
52 to the east in New York (Fullerton, 1980; Ridge, 2003). These correlations suggest that the western New York Kent  
53 (terminal) and Lake Escarpment (recessional) moraines date to ~20 and 17 ka, respectively (Fig. 1). However,  
54 Young et al. (2020) recently interpreted new and existing radiocarbon ages from western New York to support a re-  
55 advance of the LIS ~13 ka that overtopped the Lake Escarpment Moraine and nearly reached the Kent Moraine (Fig.  
56 1). The evidence includes the re-interpretation of several unrelated sites throughout western New York, but largely  
57 hinges on new trenched sediment sections near the Kent Moraine revealing logs in clayey diamicton, which Young  
58 et al. (2020) suggest requires glacial overriding of a forest ~13.3 to 13.0 ka. In contrast to Young et al.'s (2020)  
59 reconstruction, most literature places the LIS margin north of Lake Ontario at this time (Dalton et al., 2020; Muller  
60 and Calkin, 1993; Terasmae, 1980; and references therein), with the drainage of Glacial Lake Iroquois occurring at  
61 ~13 ka (Fig. 1; Cronin et al., 2012; Lewis and Anderson, 2019; Rayburn et al., 2005). To reconcile the disagreement  
62 in timing between the hypothesized re-advance and existing chronologies, Young et al. (2020) invoke a largely  
63 floating ice mass that left minimal traces of its existence in most areas. If a re-advance of the scale hypothesized by  
64 Young et al. (2020) occurred (henceforth referred to as the 'Allerød re-advance hypothesis'), there would be a need  
65 to revisit many regional deglaciation chronologies.

66 To further constrain moraine ages in western New York and to test the Allerød re-advance hypothesis, we  
67 obtained 23 new macrofossil-based radiocarbon ages from five sediment cores collected on the Kent Moraine, and  
68 18 new macrofossil-based radiocarbon ages from two sediment cores on the Lake Escarpment Moraine. The Lake  
69 Escarpment Moraine is within the extent of the proposed re-advance, so if basal ages from sites on this moraine pre-  
70 date ~13 ka, and the subsequent stratigraphy shows no evidence of a re-advance, then the evidence would refute the  
71 Allerød re-advance hypothesis. Conversely, basal radiocarbon ages that post-date ~13 ka, and/or evidence that the  
72 sediment stratigraphy is interrupted at ~13 ka, would support an Allerød re-advance. Additionally, we obtained two  
73 optically stimulated luminescence (OSL) ages from kame delta sediments associated with deposition of the Kent  
74 Moraine to provide a more complete understanding of deglaciation. Our results provide new chronological  
75 constraints in the western New York data gap, and do not support the ~13 ka re-advance proposed by Young et al.  
76 (2020). Rather, our data support a model of initial moraine deposition followed by thousands of years before kettle  
77 basin formation and final moraine stabilization.

Figure 1. Map depictions of the deglaciation of the eastern Great Lakes after the Last Glacial Maximum. Black line is the Kent Moraine, modified from Dalton et al. (2020), the 'Pennsylvania Department of Conservation and Natural Resources Late Wisconsin Glacial Border' (<https://www.pasda.psu.edu>), and the 'Quaternary Geology 500K - Glacial Boundary of Ohio' (<https://gis.ohiodnr.gov>). Dark gray line is the 17 ka ice margin from Dalton et al. (2020) which depicts the Lake Escarpment Moraine. Light gray line is the 15 ka ice margin from Dalton et al. (2020) which depicts the Marilla Moraine.

84 Glacial Lake Maumee and Whittlesey are included for general reference, and drawn with shoreline elevations (Fisher et  
85 al., 2015). White line is the 13 ka ice margin from Dalton et al. (2020) and we estimated Glacial Lake Iroquois using Bird  
86 and Kozlowski (2016). Red dashed line depicts a hypothesized ice sheet configuration to explain the hypothesis presented  
87 in Young et al. (2020). Note that the LIS would dam a pro-glacial lake in the Lake Erie basin and overrun several moraine  
88 belts, including the Lake Escarpment Moraine. Radiocarbon, cosmogenic nuclide, and OSL ages discussed in the text are  
89 shown with approximate locations. Arrows indicate study sites are off the map extent. Panel LGM: Glover et al. (2011),  
90 Corbett et al. (2017), Stanford et al. (2020), Balco et al. (2009), and Balco et al. (2002). Panel 17 ka: Fisher et al. (2015), Fritz  
91 et al. (1987), Kozlowski et al. (2018), and Ridge (2003). Panel 15 ka: Calkin and McAndrews (1980). Panels 13 ka: Lewis  
92 and Anderson (2019), Rayburn et al. (2007), Richard and Occhietti (2005), and Young et al. (2020). DEM from U.S.  
93 Geological Survey's Center for Earth Resources Observations and Science (EROS).

94

## 95 2 Geologic Setting

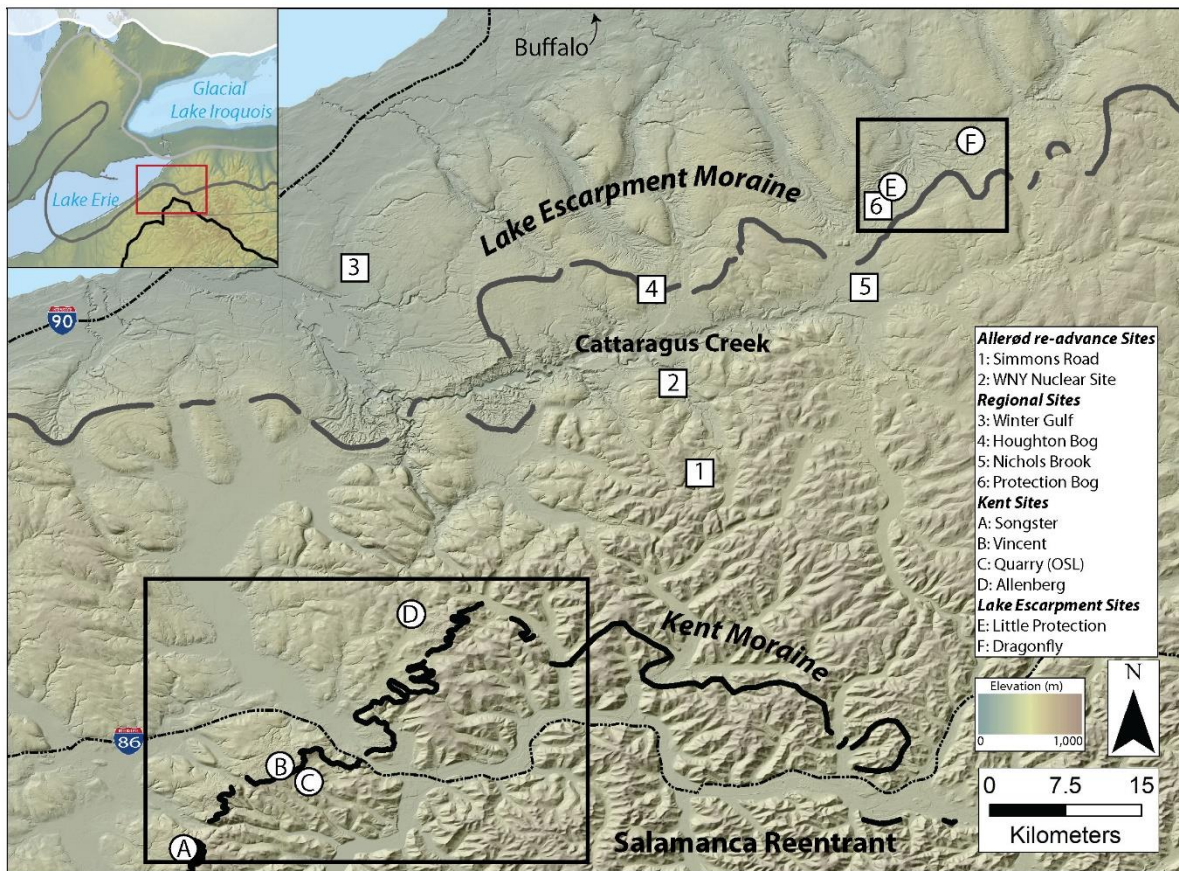

96 The Kent Moraine in western New York is correlated to the Kent Moraine in northwest Ohio, the Olean  
97 Moraine in Pennsylvania, the Harbor Hill Moraine in New Jersey, and the Martha's Vineyard Moraine in  
98 Massachusetts (Fig. 1; Balco et al., 2002; Fullerton, 1980; Muller and Calkin, 1993; Stanford et al., 2020). Retreat  
99 from the LGM moraine in these adjacent regions is dated to  $19.8 \pm 0.4$  ka in Ohio (Glover et al., 2011),  $25.2 \pm 2.1$  ka  
100 (Corbett et al., 2017) and 23,200-23,750 cal BP in New Jersey (Stanford et al., 2020), and  $25.5 \pm 0.4$  ka in  
101 Massachusetts (Balco et al., 2009; Balco et al., 2002). Therefore, we infer that the Kent Moraine in western New  
102 York was likely deposited sometime between 25 and 20 ka.

103 The first major moraine belts deposited after the maximum LGM position were the Ashtabula Moraine in  
104 Ohio and northwest Pennsylvania, the Lake Escarpment Moraine in western New York, and Valley Heads moraines  
105 in central New York (Fig. 1; Fullerton, 1980; Muller and Calkin, 1993). During this ice position, Glacial Lake  
106 Maumee occupied the Lake Erie basin around 17,000 - 16,000 cal BP based on radiocarbon dating at the paleo-  
107 outlet and OSL dating of strandlines (Calkin and Feenstra, 1985; Eschman and Karrow, 1985; Fisher et al., 2015).  
108 Ridge (2003) tied the outer and inner Valley Heads moraines to the New England Varve Chronology, placing these  
109 moraines at 17,200 and 16,200 cal BP, respectively. Kozlowski et al. (2018) report basal ages of 14,300-14,900 and  
110 14,200-14,850 cal BP from basins within the outer Valley Heads limit. These ages are younger than previous  
111 estimates, leading Kozlowski et al. (2018) to suggest the moraine may have been re-occupied. Fritz et al. (1987)  
112 report minimum-limiting radiocarbon ages of 13,750-15,250 cal BP from wood within lake deposits stratigraphically  
113 above outwash sands from Nichols Brook in western New York (Fig. 2). Muller and Calkin (1993) extrapolated  
114 their ages to estimate ~17,600 cal BP for the emplacement of the outwash.

115 Following the deposition of the Lake Escarpment Moraine, Glacial Lakes Whittlesey and Warren occupied  
116 the Lake Erie basin between 16 and 14 ka (Fig. 1; Fullerton, 1980; Muller and Calkin, 1993). The lowering of  
117 Glacial Lake Whittlesey to Glacial Lake Warren is dated to 14,150-15,550 cal BP at Winter Gulf in western New  
118 York (Fig. 2; Calkin and McAndrews, 1980), and Warren strandlines in northwest Ohio have been dated to  $14.2 \pm$   
119  $1.3$  ka (Higley et al., 2014) and  $14.1 \pm 1.0$  ka in (Campbell et al., 2011). These proglacial lake chronologies provide  
120 unambiguous minimum age constraints of  $>15$  ka for the deposition of the Lake Escarpment Moraine.

121 The LIS continued its northward retreat and formed Glacial Lake Iroquois from 14.7 to 13.0 ka in the Lake  
122 Ontario basin (Fig. 1; Muller and Calkin, 1993; Muller and Prest, 1985; Teller, 2003). The switch of the Glacial

123 Lake Iroquois spillway from the Mohawk River valley to the lower outlet at Covey Hill is constrained between  
 124 13,200 and 13,000 cal BP by numerous radiocarbon constraints from the pre- and post-flood histories of Lake  
 125 Vermont and Lake Iroquois (Lewis and Anderson, 2019; Rayburn et al., 2007; Richard and Occhietti, 2005).  
 126 Similarly, the formation of the Champlain Sea occurred between 13,100 and 12,700 cal BP, which post-dates the  
 127 final draining of Glacial Lake Iroquois and requires an ice margin north of the Lake Ontario outlet (Cronin et al.,  
 128 2012; Rayburn et al., 2011). Collectively, this ice recession chronology is at odds with the Allerød re-advance  
 129 hypothesis, with its LIS advance across the Lake Ontario basin and to near the terminal moraine in western New  
 130 York ~13 ka (Fig. 1; Young et al., 2020).

 137 **(EROS).**

138

## 139 3 Methods

### 140 3.1 Sediment cores

141 Our primary approach for constraining the timing of deglaciation and testing the Allerød re-advance  
142 hypothesis was obtaining basal sediment ages from kettles within the Kent and Lake Escarpment Moraines. Newly  
143 available light detection and ranging (LiDAR)-based bare-Earth 1-m digital elevation models (DEMs) enabled us to  
144 identify natural kettle basins (Fig. 3). Typically, moraines in western New York have both single ridges where the  
145 ice sheet abutted higher topography, and hummocky moraine belts that contain numerous kettle basins. Kame deltas  
146 exist in places where the ice sheet dammed adjacent river valleys. The hummocky nature of most moraines indicates  
147 that the moraines were ice-rich when deposited (Fig. 3).

148 We collected sediment cores from kettles that presently range from bogs to wetlands. We cored five sites  
149 on the Kent Moraine referred to as the Vincent-1 (core name: 20VIN1), Vincent-3 (20VIN3), Vincent-4 (20VIN4),  
150 Songster (21SONG1), and Allenberg (15ABB7) sites (Table 1, Fig. 3), and two sites on the Lake Escarpment  
151 Moraine referred to as the Little Protection (21LPB1) and Dragonfly (13DFK1) sites (Table 1, Fig. 3). All sites are  
152 within hummocky moraine.

153 We determined basin depocenters using thin steel rods to measure the depth of the organic sediment infill.  
154 In the depocenter, we used Livingstone- and Russian Peat-style corers to collect organic-rich sediment infill, and a  
155 manual percussion GeoProbe system to collect the underlying stiff, minerogenic sediments. From some sites, our  
156 sediment cores extended from the present surface to mineral-rich sediments below the organic-sediment infill; from  
157 others, our sediment cores began and ended at depth, spanning the organic-to-mineral sediment contact and  
158 downward until we penetrated coarse deposits (Table 1). We returned and cored the Vincent-1 and -4 sites multiple  
159 times to collect the entire sequence.

160 We split, imaged, and generated downcore data on all sediment cores at the University at Buffalo. We  
161 measured magnetic susceptibility in contiguous 1 cm intervals using a Bartington MS2E High Resolution Surface  
162 Scanning Sensor scanner connected to a Bartington MS2 Magnetic Susceptibility Meter to assess the minerogenic  
163 content. We calculated loss-on-ignition (LOI) percent by burning  $\sim 1 \text{ cm}^3$  of sediment in a Thermolyne Muffle  
164 Furnace at successively higher temperatures for water ( $105^\circ\text{C}$ ), organic carbon ( $550^\circ\text{C}$ ), and carbonate ( $950^\circ\text{C}$ )  
165 content to help characterize the sediment units and depositional setting (Heiri et al., 2001; Last and Smol, 2001). To  
166 calculate composite core length, we spliced together overlapping sediment sections using visual lithologic changes  
167 and magnetic susceptibility measurements. We volumetrically sampled portions of the Little Protection sediment  
168 cores to determine sediment bulk density; these data are used to check for overcompaction during an Allerød re-  
169 advance. The data are only from Little Protection because Dragonfly data creation took place previous to Young et  
170 al. (2020) and we did not measure bulk density.

171 We use radiocarbon dating of macrofossils for age control (Table 2). The sediments are organic-rich in the  
172 upper portions of the cores and are organic-poor in the lower sections. Where available, we picked full plant  
173 macrofossils. We picked macrofossils that were from the center of the sediment core and demonstrably in-situ. In  
174 macrofossil-devoid sections, we wet sieved sediment with deionized water to isolate and combine the largest

175 macrofossil fragments for dating. We attempted to identify macrofossils, but some macrofossil fragments were small  
 176 and unidentifiable (Table 2). We rinsed samples with deionized water, freeze-dried them, and sent samples to the  
 177 National Ocean Sciences Accelerator Mass Spectrometry (NOSAMS) or the Keck Lab at the University of  
 178 California Irvine (KCCAMS) for radiocarbon analysis. The facilities conducted acid-base-acid (ABA)  
 179 pretreatments, converted samples to graphite, and ran them on the AMS (Elder et al., 2019; Olsson, 1986; Pearson et  
 180 al., 1997; Shah Walter et al., 2015; Vogel et al., 1984).

181 In Table 2, we report the  $2\sigma$  age range and round ages according to Stuiver and Polach (1977). We  
 182 calibrated all the radiocarbon results using Calib8.1 with the IntCal20 dataset (Reimer et al., 2020; Stuiver and  
 183 Reimer, 1993). All radiocarbon ages in the text were recalibrated with IntCal20.  $\delta^{13}\text{C}$  measurements were measured  
 184 on a split of the  $\text{CO}_2$  gas generated from each sample on an isotope-ratio mass spectrometer. Uncertainties in the  
 185  $\delta^{13}\text{C}$  from both labs are  $<0.1\%$ . We report  $\delta^{13}\text{C}$  values as ‰ VPDB.

186

Table 1: Site location, core lengths, and ownership.

Site Name	Core Name	Latitude (DD)	Longitude (DD)	Elevation (m asl)	Site Length (m)	Core Top (m bg)	Core Bottom (m bg)	Property Ownership

Figure 3. Site maps of the sediment core locations. 1-m bare-Earth DEM hillshade from <https://data.gis.ny.gov/> with the Kent (black) and Lake Escarpment (gray) moraines. Open yellow circles depict study site location and yellow lines associate each site location with a site map. Figure 4 contains the site map for the open yellow circle with no associated site map. The

192 filled circles indicate the type of coring device used in each site and the coring location. The filled yellow circles depict where  
193 we used a Livingstone. The filled red circles depict where we used a Russian Peat Corer. The filled semi-circles indicate  
194 where we used a Livingstone or Russian Peat Corer in the soft sediment infill and then used the GeoProbe in the stiff  
195 minerogenic sediment.

196

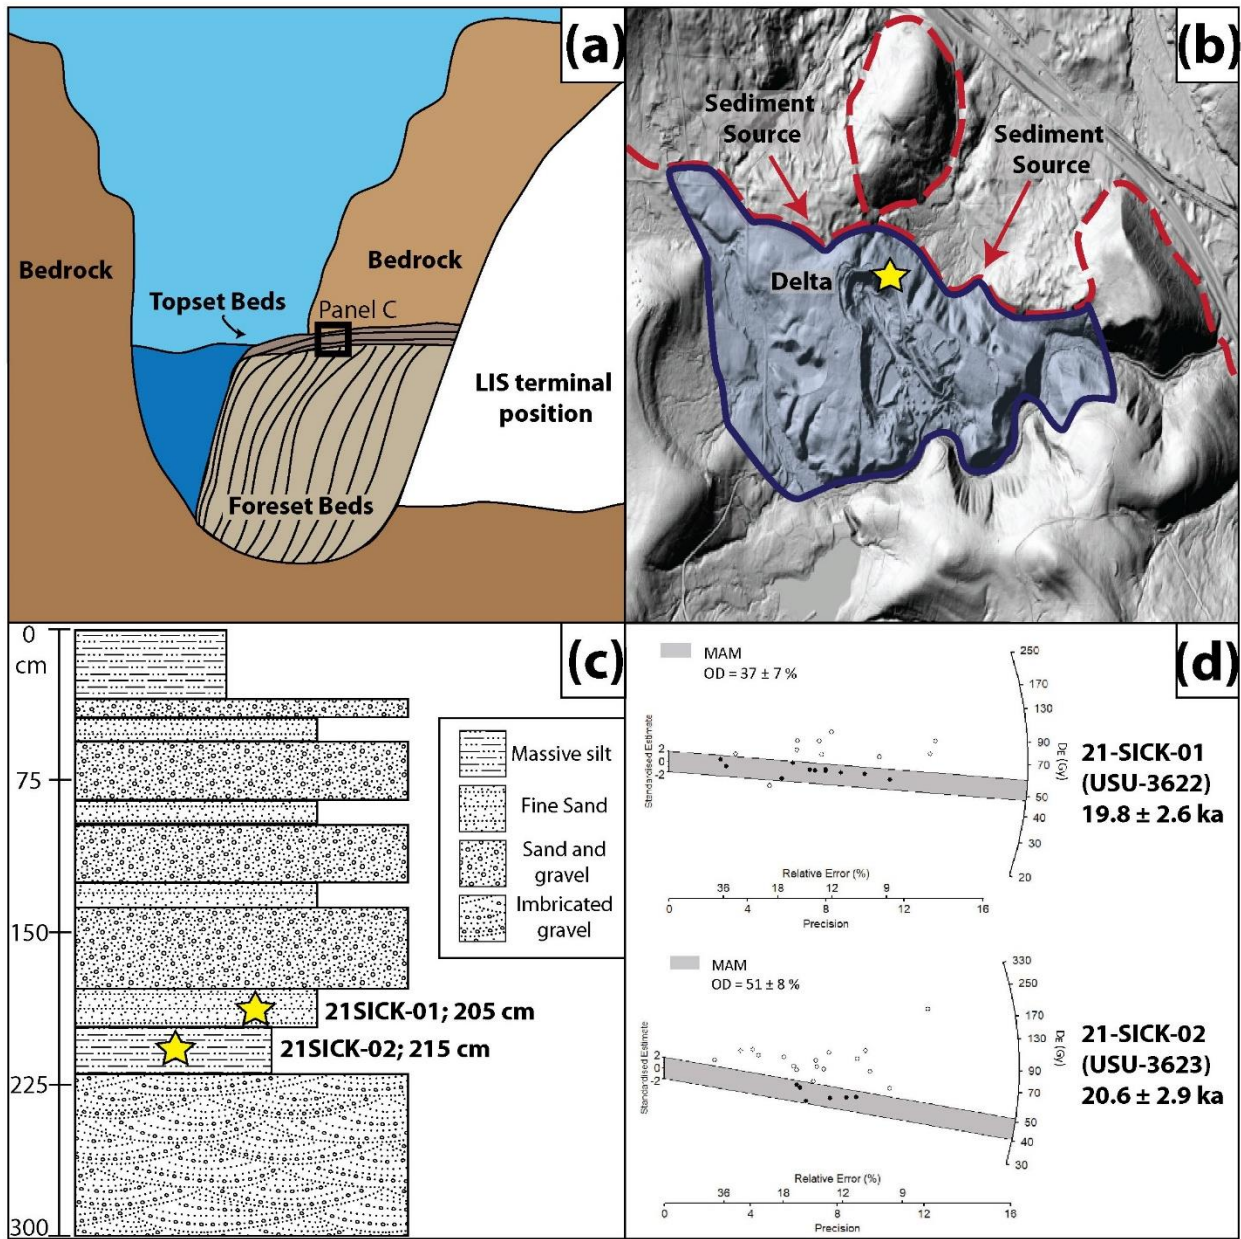

### 197 3.2 Optically stimulated luminescence dating

198 We collected sediment samples for OSL dating from topset beds within an ice-contact delta deposit  
199 associated with the Kent Moraine to determine when the LIS was present at this location (Fig. 3 & 4). Our sample  
200 location was Corbett Hill Gravel Quarry, an active aggregate quarry that exposes large sedimentary sequences  
201 indicative of a proglacial delta. The sediments consisted of cobble-rich foreset beds overlain by ~3 m of near-  
202 horizontal topset beds. We collected sand samples for OSL dating from the topset sequence ~2.1 m below the delta  
203 surface. We created a fresh exposure of the topset beds with an excavator, exposing alternating layers of gravels and  
204 coarse sands, with lenses of medium/fine-sand and silt. We collected two samples for OSL dating in fine-sand lenses  
205 in 5.1 x 25.4 cm (2 x 10 inch) aluminum tubes after clearing back outer sediments (Fig. 4). Samples for water  
206 content and dose rate determination were collected from surrounding sediments.

207 We processed the samples at the Utah State University Luminescence Laboratory for small aliquot OSL  
208 dating of fine-grained quartz sand (Table 3, Table S1). First, we purified samples to 150-250  $\mu\text{m}$  quartz sand using  
209 wet sieving, and chemical treatment with 10% hydrochloric acid to remove carbonates, 5% peroxide to remove  
210 organics, 2.72 g/cm<sup>3</sup> sodium polytungstate to remove heavy minerals and 48% hydrofluoric acid to remove feldspars  
211 and etch the quartz grains. We analyzed small aliquots of quartz (0.4 to 1 mm diameter of sand mounted on disk,  
212 ~10-20 grains) on Risø DA-20 readers, using the single-aliquot regenerative-dose (SAR) protocol (Murray and  
213 Wintle, 2000). We analyzed 42 aliquots for sample 21SICK-01 and 37 for sample 21SICK-02, of which we used 21  
214 and 23 aliquots for age calculations, respectively (Fig. 4 & S7). Aliquots were rejected from age calculation if they  
215 showed signal depletion with infrared stimulation indicating feldspar contamination (0-12 aliquots), poor recycling  
216 of a repeat point (greater than 80% difference between repeat points, 7-8 aliquots), high recuperation of a zero-dose  
217 point (>10% of the Natural signal, 0-6 aliquots), extrapolation of the equivalent dose beyond the dose-response  
218 curve (0-2 aliquots) and poor dose-response curve fit (0-3 of aliquots). We applied a minimum age model (MAM) to  
219 the samples to calculate our equivalent doses ( $D_E$ ; Grays; Gy, Fig. 4 & S7), as used by similar studies on LIS  
220 glaciofluvial terraces elsewhere in the northern United States (Rittenour et al., 2015). MAMs are useful in these  
221 glaciofluvial environments because of the increased potential for incomplete bleaching from subglacial or turbid  
222 water sediment transport.

223 We determined the dose rate for OSL age calculation based on U, Th, K, and Rb concentrations from the  
224 surrounding sediments using inductively coupled plasma-mass spectrometry and atomic emission spectrometry.  
225 Using the conversion factors of Guérin et al. (2011), we converted elemental concentrations to dose rate. The  
226 contribution of cosmic radiation was based on sample depth, elevation and latitude following Prescott and Hutton  
227 (1994). We also determined water content by measuring the mass of the samples before and after desiccation. With  
228 these three factors, we were able to calculate environmental dose rates (Gy/kyr). Our reported OSL ages are simply

229 the  $D_E$  (determined with the MAM) divided by the dose rate with  $1\sigma$  standard error (Table 3). We report ages with  
 230  $1\sigma$  uncertainty (Table 3).

231  
 232 **Figure 4.** Panel A) is a schematic of the kame delta creation. The LIS dammed a lake and deposited the delta outboard of  
 233 the Kent Moraine. B) is a 1-m DEM hillshade showing the kame delta outboard of the Kent Moraine (within the open yellow  
 234 circle in Fig. 3). Red dashed line depicts the extent of the Kent Moraine. Red arrows depict the sediment source for the  
 235 delta. Blue line and shading depicts the delta deposit. Yellow star on the side of the active quarry shows our sampling site.  
 236 C) shows a stratigraphic column of the topset beds. We use the FGDC Digital Cartographic Standard for Geologic Map  
 237 Symbolization (U.S. Geological Survey). Yellow stars show our sampling location. D) Equivalent dose ( $D_E$ ) distributions for  
 238 the luminescence samples collected from the kame delta associated with an ice-margin position near the Kent moraine.  
 239 MAM = minimum age model of Galbraith and Roberts (2012) fit to the  $D_E$  data (gray shaded region). OD = overdispersion,  
 240 a metric of  $D_E$  scatter beyond instrumental error, where  $OD > 30\%$  is interpreted to be due to partial bleaching due to  
 241 incomplete solar resetting of the luminescence signals in the quartz grains.

242

## 243 4 Results

### 244 4.1 Stratigraphy and Radiocarbon Results

#### 245 Vincent-1 (Kent Moraine)

246 The bottom 2.5 m is a gray massive pebbly diamicton with a silty matrix that we call Unit 1. We only  
247 recovered Unit 1 at this study site and collected it with the Geoprobe system (Fig. 5). There is a sharp contact with  
248 layered gray sand and silt that grades to alternating massive brown and gray silt with sparse macrofossils. We call  
249 this Unit 2. There is a sharp contact with massive dark brown organic-rich silt that we call Lower Unit 3. In the  
250 initial sediments of Lower Unit 3, there are three layers of gray silt and an inclusion of gray clay that are identical to  
251 the sediment of Unit 2. There is a sharp contact with peat which continues to the top of the core that we call Upper  
252 Unit 3. Broadly, this sediment progression is found in the other six sediment cores from both moraines, so we use  
253 Unit 2 and 3 terminologies for them as well. Figures 5a and 5b depict the downcore data. For all seven sediment  
254 cores, magnetic susceptibility values are higher in Unit 2 than Unit 3, water and organic carbon content values are  
255 lowest in Unit 2, rise in Lower Unit 3, and are highest in Upper Unit 3, and calcium carbonate remains below 8% in  
256 all sediment cores so it is not plotted in Fig. 5.

257 Figure 5 and Supplementary Figure 1 show the ten radiocarbon ages from 20VIN1. The seven ages in Unit  
258 2 are from combined macrofossils and have little stratigraphic order. The three ages in Unit 3, from single  
259 macrofossils, are in stratigraphic order. 20VIN1 has an age of 15,050-15,550 cal BP from the bottom of Unit 2, yet  
260 is stratigraphically below older ages from Unit 2 of 15,650-15,900, 15,800-16,150, and 16,050-16,300 cal BP. There  
261 is an inclusion of macrofossils at the Unit 2/3 contact that was dated twice and yields two radiocarbon ages from  
262 combined macrofossils of 19,350-19,600 and 14,050-14,850 cal BP; combined macrofossils from the surrounding  
263 sediment produce an age of 14,300-15,050 cal BP. *Picea* seeds from the top of Lower Unit 3 are 13,650-14,050 cal  
264 BP. There are two ages in the Upper Unit 3; a twig that dates to 13,150-13,300 and wood that dates to 8,390-8,520  
265 cal BP.

#### 266 Vincent-3 (Kent Moraine)

267 In 20VIN3, Unit 2 begins as gray silt, transitions to a light brown silt, and is topped by gray clay. The  
268 contact with Unit 3 is sharp. Unit 3 is massive organic-rich silt. There is a layer of gray silt in the base of Unit 3.  
269 There are two radiocarbon ages from 20VIN3 (Fig. 5; Fig. S2). The one age in Unit 2 is from combined macrofossils  
270 that date to 14,350 – 15,150 cal BP. The one age at the base of Unit 3 is from combined macrofossils and dates to  
271 15,350 – 15,650 cal BP.

#### 272 Vincent-4 (Kent Moraine)

273 In 20VIN4, Unit 2 contains alternating layers of pebbly diamicton (with some clasts up to 5 cm long) and  
274 silty clay. The contacts between the layers are sharp and one is undulating. Unit 3 is a massive organic-rich silt.

275 There are four radiocarbon ages from Unit 2 (Fig. 5; Fig. S3). The lowest age is from a piece of wood that dates to  
276 14,250 – 15,000 cal BP. Then the next three ages are from combined macrofossils and date to 14,150 – 14,850,  
277 14,300 – 14,900, and 14,300 – 14,900 cal BP.

278 **Songster (Kent Moraine)**

279 In 21SONG1, Unit 2 is silty clay with pebbles. The contact with Unit 3 is sharp. Unit 3 begins with  
280 organic-rich silt with some sand and pebbles. Large macrofossils are common. This grades into organic-rich silt.  
281 One radiocarbon age from a piece of wood in the bottom of Unit 3 dates to 14,350 – 15,050 cal BP (Fig. 5).

282 **Allenberg (Kent Moraine)**

283 In 15ABB7, we did not collect Unit 2. Lower Unit 3 is an organic-rich silt and Upper Unit 3 is peat. There  
284 are four ages from Unit 3 (Fig. 5; Fig. S4). These samples were not identified at the time of dating. The lowest age is  
285 13,800 – 14,050 cal BP. The next 3 ages are in stratigraphic order and range from 12,700 – 12,850 to 795 – 920 cal  
286 BP.

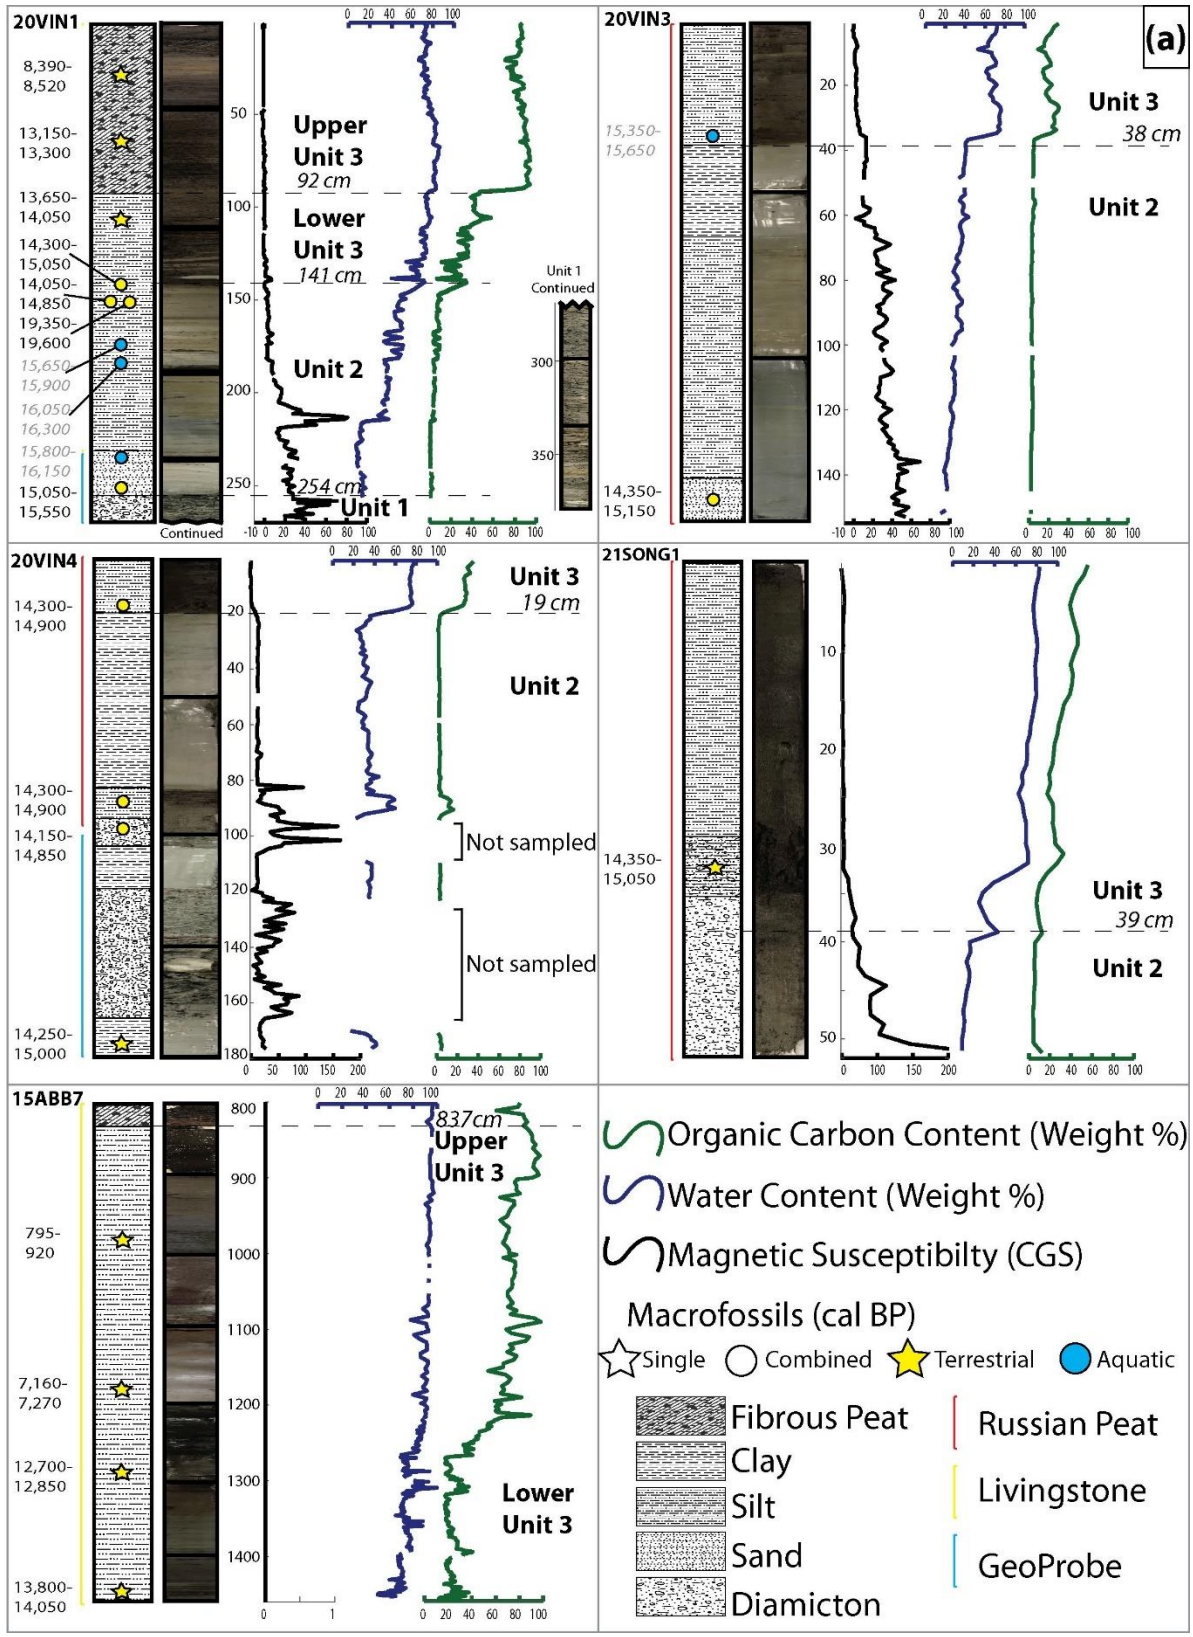

287 **Little Protection (Lake Escarpment Moraine)**

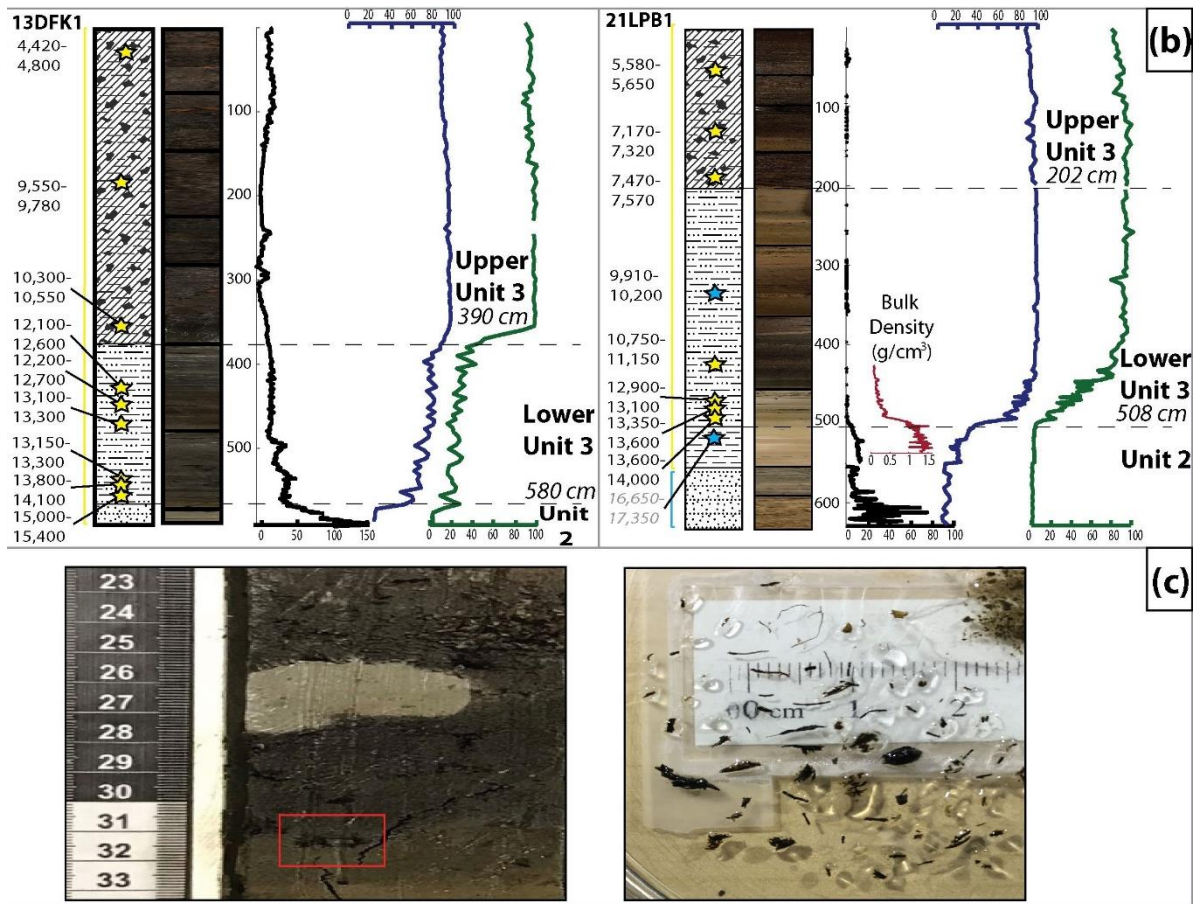

288 In 21LPB1, Unit 2 begins with 2 cm of gray silty gravel before a sharp contact with massive, oxidized sand  
289 and gravel. Above this is a sharp transition to alternating layers of gray silt, silty gravel, and sand; these layers have  
290 sharp and sometimes undulating contacts. That is overlain by massive gray clay. The contact with Unit 3 is gradual  
291 over 3 cm. Lower Unit 3 is an organic-rich silt and Upper Unit 3 is peat. There is one radiocarbon age from Unit 2  
292 on a fish bone that dates to 16,650 – 17,350 cal BP. There are eight radiocarbon ages from Unit 3 (Fig. 5; Fig. S6).  
293 The lowest age is from a piece of wood that dates to 13,600 – 14,000 cal BP. The next seven are in stratigraphic  
294 order and range from 13,350 – 13,600 to 5,580 – 5,650 cal BP. To address the Allerød re-advance hypothesis and  
295 seek evidence of whether the coring sites were overridden, we measured dry bulk density at 1-cm-resolution through  
296 the time interval of hypothesized re-advance. The bulk density decreases from 1.55 g/cm<sup>3</sup> to 0.42 g/cm<sup>3</sup> in the  
297 transition from Unit 2 to 3. (Fig. 5) The density decreases due to the transition from minerogenic silt to organic-rich  
298 silt and remains below 0.42 g/cm<sup>3</sup> into Unit 3.

299 **Dragonfly (Lake Escarpment Moraine)**

300 In 13DFK1, Unit 2 is gray silt. The contact with Unit 3 is sharp. Lower Unit 3 is an organic-rich silt and  
301 Upper Unit 3 is peat. There are nine radiocarbon ages from Unit 3 (Fig. 5; Fig. S5). The lowest age is from grass and  
302 dates to 15,000 – 15,400 cal BP. The next eight radiocarbon ages are in stratigraphic order and range from 13,800 –  
303 14,000 to 4,420 – 4,800 cal BP.

304

307

308 **Figure 5.** Panel A) has the sediment core stratigraphy from the Kent Moraine sites, and B) has the sediment  
 309 core stratigraphy from the Lake Escarpment Moraine sites. We show sediment texture next to the core images  
 310 using the FGDC Digital Cartographic Standard for Geologic Map Symbolization (U.S. Geological Survey). We  
 311 plot magnetic susceptibility (CGS; black line), water content (weight %; blue line), and organic content (weight  
 312 %, green line) by composite depth (cm). The colored line next to the stratigraphic column depicts if we used  
 313 the Russian Peat Corer (red), Livingstone Corer (yellow), or GeoProbe (blue). Stars indicate single macrofossils  
 314 and circles indicate when we combined macrofossils. The yellow filling indicates the sample is terrestrial and  
 315 blue indicates the sample has aquatic macrofossils within it. Radiocarbon ages presented as the full  $2\sigma$  range  
 316 in cal BP. We used gray text and italics for radiocarbon ages we suspect have hardwater contamination. C) is  
 317 a close-up image of the inferred gray clay and macrofossil-rich rip-up clasts in the transition from Unit 2 to 3  
 318 in 20VIN1 (shown in red box). The black box has post-sieve macrofossils from the rip-up clast in the red box.

## 329 4.2 Optically stimulated luminescence dating

330 Our small-aliquot  $D_e$  results from both 21SICK-01 and -02 show evidence of partial bleaching, as expected  
331 in a glaciofluvial environment (Table 3; Fig. 4 & S7; Rittenour et al., 2015).  $D_e$  results from the two samples are  
332 considerably scattered, positively skewed, and have overdispersion values between ~30 and ~60%, all indicative of  
333 incomplete bleaching and justify the use of the MAM (e.g., Olley et al. (1999)). Our two OSL MAM ages are  $19.8 \pm$   
334  $2.6$  and  $20.6 \pm 2.9$  ka. The two samples are from within 10 cm of each other and yield statistically indistinguishable  
335 ages.

Table 3. Optically Stimulated Luminescence Age Information

Sample num.	USU num.	Depth (m)	Num. of Analyses <sup>1</sup>	Dose Rate (Gy/kyr)	Equivalent Dose <sup>2</sup> $\pm 2\sigma$ (Gy)	OSL Age $\pm 1\sigma$ (ka)

<sup>2</sup> Equivalent dose ( $D_e$ ) calculated using the Minimum Age Model (MAM) of Galbraith and Roberts (2012).

336

337

## 338 5 Discussion

### 339 5.1 Stratigraphy

340 We interpret Unit 1 as the primary till that comprises the Kent Moraine. At the Vincent-1 (20VIN1) site we  
341 cored from 4.1 to 6.6 m below the wetland surface (2.5 m), but only recovered 1.2 m due to compaction with the  
342 GeoProbe system. We assume we reached below the post-glacial infill and into the primary glacial deposit since this  
343 unit spans 2.5 m and we found no changes in stratigraphy (Fig. 5).

344 Given the hummocky nature of the moraines (Fig. 3), the complex stratigraphy within Unit 2 (Fig. 5), and  
345 the similarity between Unit 2 from all sediment cores, we interpret this unit to record the transition from an ice-  
346 cored moraine to the modern kettled topography for both moraines. The most striking feature of Unit 2 are the  
347 numerous transitions between fine- and coarse-grained deposition. We interpret Unit 2 silt and clay as being settled  
348 out of suspension in lacustrine conditions, indicating that all seven basins likely held small kettle lakes of shifting  
349 dimension during this period. We propose that the alternating clay and diamicton sediments captured in 20VIN4, on  
350 the Kent Moraine, are slumps of primary till into the kettle lake with otherwise clay-rich sedimentation; these  
351 slumps potentially occurred as buried glacial ice melted and destabilized the basin's slopes. The stratigraphy of Unit  
352 2 in 21LPB1, on the Lake Escarpment Moraine, is likely the result of similar processes.

353 The transition in sediment type between Units 2 and 3 likely reflects a shift to more vegetation growing in  
354 the lake and landscape, in concert with increased stabilization of the surrounding moraine. We infer the minerogenic

355 sediments in the transition zone (inclusions of gray clay and brown silty macrofossils in 20VIN1) are rip-up clasts  
356 by their clast-like appearance and stark contrast to the surrounding sediment (Fig 5; Panel C). They were potentially  
357 frozen during the time of deposition. This suggests the presence of reworked material near the Unit 2/3 transition.  
358 The subsequent transition from lacustrine organic-rich silt to peat (Lower and Upper Unit 3, respectively) records  
359 the shift from lake to bog/wetland due to the filling of the basin, shallowing of the lake, and encroachment of the  
360 shoreline.

361

## 362 5.2 Chronology

363 The OSL samples are from 2 m below the surface of the ~70 m thick kame delta. The sample location  
364 within the topset beds of a short-lived ice-contact delta suggests that our OSL samples constrain the time just before  
365 the ice sheet retreated and ceased building the delta  $19.8 \pm 2.6 - 20.6 \pm 2.9$  ka. The OSL ages support the estimated  
366 age of 25 – 20 ka for the Kent Moraine from prior literature and affirms our confidence in the age assignments using  
367 correlations of dated features elsewhere (Balco et al., 2009; Balco et al., 2002; Corbett et al., 2017; Glover et al.,  
368 2011; Stanford et al., 2020).

369 We have identified spores and seeds of aquatic plants *Chara* and *Potamogeton* (O. Bennike, personal  
370 communication) among the macrofossils from samples dating to 15,800 - 16,150, 16,050-16,300 and 15,650-15,900  
371 cal BP from 20VIN1 and the sample dating to 15,350-16,650 cal BP from 20VIN3. These macrofossil samples also  
372 have enriched  $\delta^{13}\text{C}$  values, suggesting they contained aquatic material (except 15,800 - 16,150, which was too small  
373 for a  $\delta^{13}\text{C}$  measurement; Deuser and Degens, 1967; Oana and Deevey, 1960; Wang and Wooller, 2006). Our sites lie  
374 within calcareous tills that overlie sedimentary bedrock (LaFleur, 1979; MacClintock and Apfel, 1944), which can  
375 add aged carbon to the lake water. Aquatic plants derive their carbon from lake water, so radiocarbon ages from  
376 aquatic plants could produce radiocarbon ages that overestimate the age of the material (the 'hardwater effect';  
377 Deevey et al., 1954; Keeley and Sandquist, 1992). The lowest sample in 21LPB1 is from a fish bone (16,650 -  
378 17,350 cal BP); a fish could be susceptible to the same hardwater effect as aquatic vegetation, and thus we do not  
379 use it in our evaluation. We move forward using samples assumed to be terrestrial from a lack of identifiable aquatic  
380 macrofossils and supported by  $\delta^{13}\text{C}$  values.

381 The Unit 2 ages are trustworthy as minimum-limiting constraints on moraine abandonment, but we find the  
382 evidence for slumps and rip-up clasts in Unit 2, plus the stratigraphic discordance in radiocarbon ages, reason to  
383 doubt the reliability of the radiocarbon ages to reflect the age of the sediment they are within. Our oldest minimum-  
384 limiting constraint from Unit 2 is from the macrofossil-rich rip-up clast in 20VIN1 on the Kent Moraine, which  
385 holds evidence for two important interpretations: 1) the landscape was ice-free and at least sparsely vegetated as  
386 early as 19,350-19,600 cal BP, consistent with our OSL ages suggesting ice sheet retreat by  $19.8 \pm 2.6 - 20.6 \pm 2.9$   
387 ka, and 2) the landscape stored this long-dead vegetation for thousands of years before it was re-deposited. This age  
388 also bolsters our confidence that the MAM is working well in our study area.

389 We use the lowest ages in Unit 3 as minimum limits on the timing of kettle formation and moraine  
390 stabilization. The lowest ages from Unit 3 from the Kent Moraine range from 13,650 - 14,050 (20VIN1) to 14,350 -

391 15,050 (21SONG1) cal BP. The lowest ages from Unit 3 from the Lake Escarpment Moraine are 13,600 - 14,000  
392 (21LPB1) to 15,000 - 15,400 (13DFK1) cal BP. The range of ages shows the kettles formed through the interval of  
393 13,600 to 15,400 cal BP, reflecting the time the moraines stabilized. This shows both moraines stabilized at the same  
394 time, even though they are likely several thousand years different in age. Using our OSL ages and minimum-limiting  
395 radiocarbon age from Unit 2 to estimate the deposition of the Kent Moraine before 19,350 - 19,600 cal BP, there  
396 appears to be a 5 kyr lag time between moraine deposition and stabilization.  
397

### 398 **5.3 A model for kettle basin formation**

399 We propose the following post-glacial history in western New York (Fig. 6). The deposition of the Kent  
400 Moraine occurred at least  $19.8 \pm 2.6 - 20.6 \pm 2.9$  ka and the landform remained ice-cored for the ensuing 5 – 6 kyr.  
401 The deposition of the Lake Escarpment Moraine took place around 17 ka and likewise remained ice-cored for the  
402 next 2 – 3 kyr. The hummocky nature of the moraines indicate that they were ice-cored, and we suggest that  
403 persistent buried glacial ice prohibited stabilization until well after deposition. Our interpretation is that after ~15 ka  
404 buried ice began to melt, and morainal topography – including kettle basins – began to evolve more rapidly (Fig. 6  
405 & 7). During the earliest stages of kettle basin formation, there was increased mobilization of sediments from within  
406 the uneven ice-rich topography. These initial sediments contained both re-worked and contemporary organic matter  
407 from the catchment and were deposited in our study sites as Unit 2. According to this interpretation, our radiocarbon  
408 ages from Unit 2 could reflect plant death anytime between moraine deposition and kettle basin stabilization. The  
409 13,750 - 15,250 cal BP wood age from basal lake sediments in Nichols Brook is likely another example of delayed  
410 kettle formation in this area (Fritz et al., 1987).

411 Moraines can remain ice-cored for thousands of years after deposition due to sediment cover that insulates  
412 and preserves the buried ice (Florin and Wright, 1969). If the region is cold enough to support permafrost it may  
413 extend the duration that the moraine remains ice-cored (Clayton et al., 2001; Henriksen et al., 2003; Schomacker,  
414 2008). Given that the kettles appear to have formed within ~1 kyr of each other, and their formation coincided with  
415 the warm Bølling/Allerød period, this suggests the climate during Heinrich Stadial 1 may have been cold enough to  
416 help preserve the ice.  
417

418

419 **Figure 6.** Conceptual model of kettle basin formation of the Kent Moraine in western New York building on Florin and  
 420 Wright (1969). The same model applies to the Lake Escarpment moraine, except the timeline begins ~17 ka. First, the LIS  
 421 deposited the ice-cored Kent Moraine. It remained ice-cored, perhaps influenced by permafrost, while tundra vegetation  
 422 grew atop the moraine and stored carbon in the soil. Next, during climate amelioration in the Bølling-Allerød periods, the  
 423 ice in the moraine melted. This led to the formation of basins that filled with both contemporaneous and reworked  
 424 sediments. This is also likely the time when trees and other organic material could be slumped and formed deposits that  
 425 placed primary tills adjacent to younger material. Finally, organic-rich sediment deposition dominates after ~13.8 ka.

426

#### 427 **5.4 Implications for the climate in western New York**

428 The climate of western New York between 20 and 15 ka is poorly known, but records from Ontario, Ohio,  
 429 and New England suggest the climate events of the North Atlantic influenced the northeastern U.S. These terrestrial  
 430 climate reconstructions depict a cold Heinrich Stadial 1 (~18 to ~14.7 ka), a shift to warmer temperatures during the  
 431 Bølling-Allerød, and a cool Younger Dryas (Gill et al., 2012; Gonzales and Grimm, 2009; Grigg et al., 2021;  
 432 Shuman et al., 2002; Watson et al., 2018; Yu, 2007; Yu and Eicher, 1998). A stable Heinrich Stadial 1 and shift to  
 433 warmer temperatures during the Bølling-Allerød is shown by Watson et al. (2018), who used biomarkers (branched-

434 GDGTs) to report that mean annual temperature in central Ohio varied between  $-2.0$  and  $-0.5$  °C from 17.0 to 14.5  
435 ka before warming  $5$ °C between 14.5 and 13.0 ka.

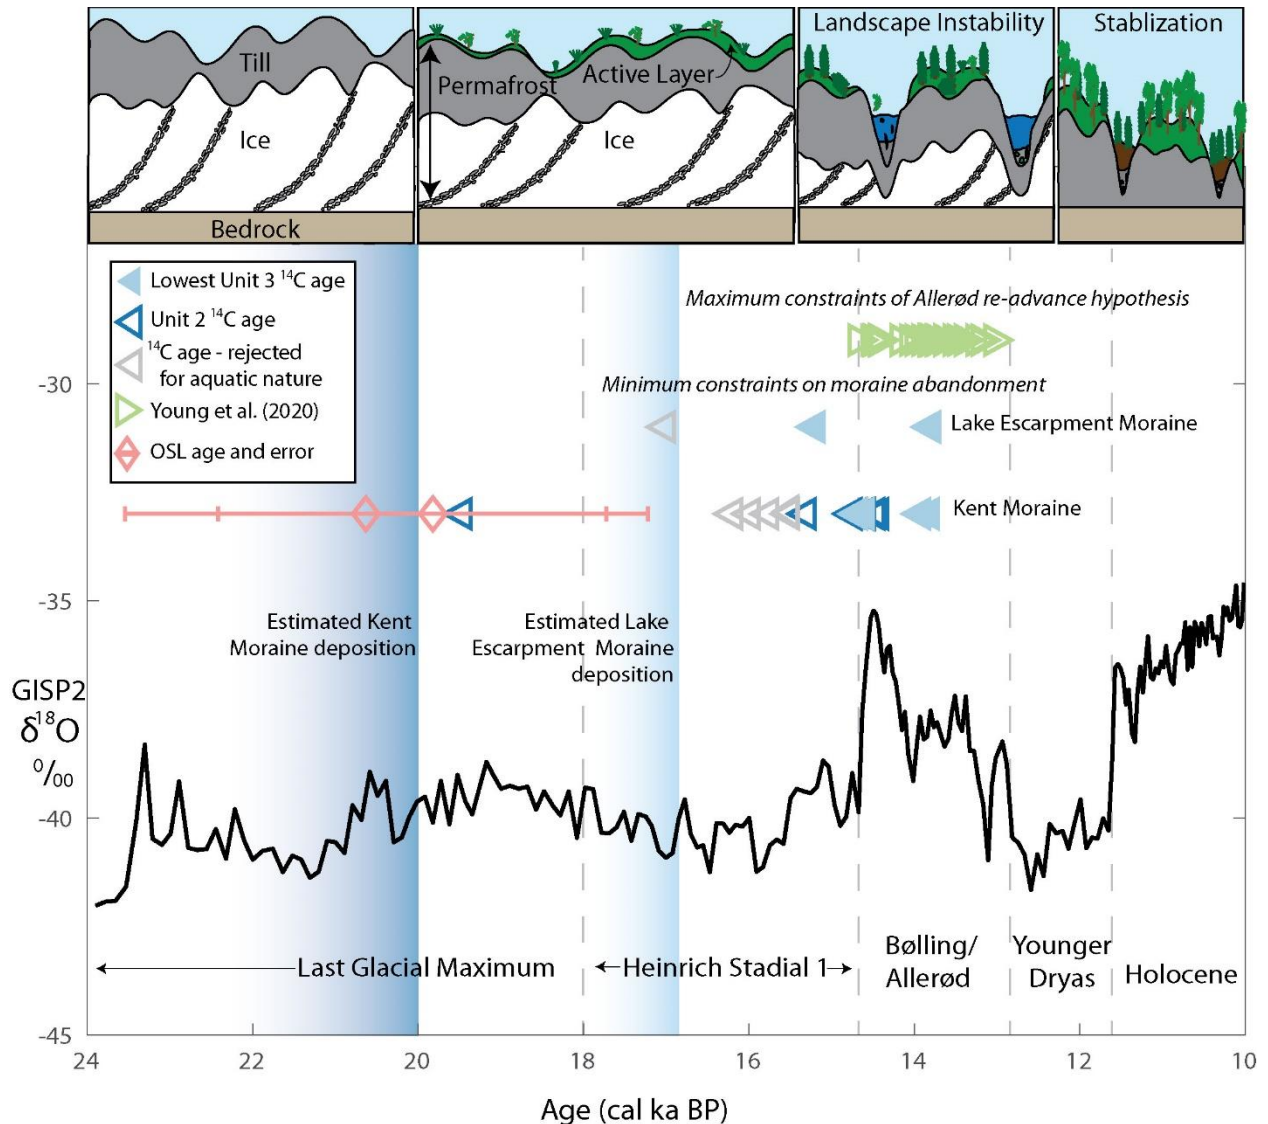

436 The rate of LIS retreat offers additional insight into the climate in the northeast US. Barth et al. (2019) used  
437 cosmogenic nuclide dating of glacially-transported boulders to estimate LIS thinning in the Adirondack Mountains  
438 and showed increased thinning between  $15.4 \pm 1.0$  and  $13.9 \pm 0.9$  ka, generally coincident with the Bølling. The  
439 New England Varve Chronology shows a relatively steady net retreat rate of the LIS through the Hudson Valley  
440 between 18 and 14.7 ka; during the Bølling the net retreat rate tripled, implying that New England experienced  
441 elevated warmth at that time (Ridge et al., 2012).

442 Ice-wedge casts can be used to identify areas that experienced past permafrost and constrain past  
443 temperature because their formation requires mean annual temperatures between  $-6$  to  $-8$ °C (French, 2007; French  
444 and Miller, 2014). Ice-wedge casts are preserved in southern Ontario that were deposited 18-15 ka based on regional  
445 correlations (Dalton et al., 2020; Gao, 2005; Morgan et al., 1982). This suggests that the mean annual air  
446 temperature was low enough near our study site during Heinrich Stadial 1 to support permafrost. While this  
447 temperature depression is larger than reported by Watson et al. (2018), it's likely there was a strong temperature  
448 gradient between Ohio and western New York during deglaciation, with the latter remaining within 100 km of the  
449 ice margin until 14 ka (Dalton et al., 2020). This proximity to the ice sheet from the LGM to 14 ka may have been a  
450 driver of the cold climate that persisted in western New York. There are no reports of relict permafrost features  
451 within the LGM limit in western New York, but their presence south of the LGM extent suggest the likelihood of  
452 permafrost within the limit as well (French and Millar, 2014).

453 Finally, there are seven local pollen records from Miller (1973), Calkin and McAndrews (1980), and  
454 Doody (2018) that describe the initial deglacial vegetation in western New York. Only the Allenberg Bog (Miller,  
455 1973) and Dragonfly Kettle (Doody, 2018) pollen records captured a 'tundra' zone at the base, although the  
456 presence of both arctic and temperate vegetation complicates their interpretation. The tundra zone is overlain by an  
457 interval with high spruce and pine pollen; this is the lowest unit found in the other five records (Miller, 1973; Calkin  
458 and McAndrews, 1980). This is likely reflecting the new forest biome associated with warmer temperatures. Given  
459 our results, we believe the 'tundra' pollen zone captured both the tundra vegetation that was growing on the moraine  
460 prior to basin formation and the more temperate vegetation as spruce and pine moved in during the Bølling.  
461 Unfortunately, the pollen records may be unreliable before 14 ka due to the same reworking problems as our  
462 radiocarbon dating, but this remains site specific.

463 Altogether, there is evidence that the lag time between ice sheet retreat and kettle basin stabilization may be  
464 attributable to sustained permafrost in western New York due to cold North Atlantic conditions during Heinrich  
465 Stadial 1 (Fig. 7). The warming at the Bølling onset at  $\sim 14.7$  ka may have increased regional temperatures, causing  
466 the melting of buried ice, initiating a phase of rapid landscape evolution and the formation of kettle basins, and  
467 eventually stabilizing the morainal topography. Numerous studies discuss the role of permafrost in the lag time  
468 between moraine ages and basal macrofossils along the south-central LIS margin, including Indiana and Illinois  
469 (Curry et al., 2018; Fisher et al., 2020), Michigan (Yansa et al., 2020), and Wisconsin (Clayton et al., 2008).

470 Our findings support the observations and conclusions from numerous studies that radiocarbon dates can be  
 471 extreme minimum age constraints on deglaciation (Curry et al., 2018; Fisher et al., 2020; Florin and Wright, 1969;  
 472 Halsted et al., 2023; Yansa et al., 2020). In New England, minimum-limiting radiocarbon ages may be the reason for  
 473 the discrepancy between the timing of moraine deposition as recorded by  $^{10}\text{Be}$  exposure dating (e.g., Balco et al.,  
 474 2002; Corbett et al., 2017) and radiocarbon ages of basal macrofossils in lakes and bogs (e.g., Peteet et al., 2012).  
 475 The younger than expected radiocarbon ages from the Valley Heads Moraine from Kozłowski et al. (2018) may be  
 476 afflicted by similar processes. Permafrost during Heinrich Stadial 1 may have minimized landscape evolution in  
 477 New England and central New York as well and could help explain the offset.

478  
 479 **Figure 7. Comparison of radiocarbon ages from the Kent and Lake Escarpment moraine and Young et al. (2020) in the**  
 480 **context of North Atlantic deglacial climate changes. Black line is the GISP2  $\delta^{18}\text{O}$  record (Grootes and Stuiver, 1999). Dark**  
 481 **blue and light blue fading is the estimated deposition of the Kent Moraine and Lake Escarpment Moraine, respectively.**  
 482 **Dark blue and light blue triangles are Unit 2 and the lowest Unit 3 radiocarbon ages from the Kent and Lake Escarpment**  
 483 **Moraine sediment cores, respectively. Gray triangles are radiocarbon ages that we suspect have hardwater contamination.**  
 484 **Pink diamonds are OSL ages and  $2\sigma$  errors from the same delta outboard the Kent Moraine. Green triangles are ages from**

485 Young et al. (2020) interpreted by them to be maximum-limiting constraints on the 13 ka re-advance. Errors for all  
486 radiocarbon dates are not plotted because their width is smaller than the symbols.

487

## 488 5.5 Allerød re-advance hypothesis

489 The stratigraphically lowest radiocarbon ages from Unit 3 in the Lake Escarpment Moraine kettle basins,  
490 which are 15,000-15,400 and 13,600-14,000 cal BP, pre-date the ~13.1 ka re-advance suggested by Young et al.  
491 (2020) (Fig. 5 & 7). Chronologically constrained organic-rich sedimentation, with no stratigraphic evidence of  
492 interruption, ensued from at least 13,600-14,000 cal BP and well into the Holocene. Furthermore, there is no  
493 evidence of over-compaction in our bulk density measurements in 21LPB1 during this interval of time (Fig. 5).  
494 Thus, we do not find evidence that a ~13.1 ka LIS advance created or overran the Lake Escarpment Moraine as  
495 hypothesized by Young et al. (2020). Rather, we suggest that the landscape was unstable during its transition from a  
496 permafrost-dominated landscape to one with evolving and then stabilizing morainal topography. This landscape  
497 instability with reworking of glacial sediments may have led to the stratigraphy interpreted by Young et al. (2020) as  
498 primary tills in contact with logs dating to 13 ka (Fig. 7). Both the Dragonfly and Little Protection sites have  
499 intervals with increased wood deposition between 14 and 13 ka and future work could investigate the source of these  
500 woody intervals to further investigate the results from Young et al. (2020).

501

## 502 6 Conclusion

503 We present 41 new macrofossil-based radiocarbon ages from kettle basin infills in western New York. We  
504 find that the lowest radiocarbon ages from Unit 3 (15,000-15,400 and 13,600-14,000 cal BP) are 5 kyr younger than  
505 our OSL age constraints on moraine deposition of  $19.8 \pm 2.6 - 20.6 \pm 2.9$  ka and the oldest radiocarbon age from  
506 Unit 2 of 19,350-19,600 cal BP from the Kent Moraine. The lowest Unit 3 ages are 2 kyr younger than our estimated  
507 age of Lake Escarpment Moraine deposition from moraine correlations. We interpret this offset to be due to a cold  
508 climate in western New York during Heinrich Stadial 1 supporting persistent buried ice which inhibited kettle basin  
509 formation until regional warming that took place during the Bølling. Our results do not support a re-advance of the  
510 LIS over the Lake Escarpment Moraine ~13 ka (c.f. Young et al., 2020). The lag time between ice sheet retreat and  
511 moraine stabilization in western New York may present an alternate explanation for inconsistencies between basal  
512 ages in sediment cores and other dating methods in central New York (Kozłowski et al., 2018) and eastern New  
513 York (Peteet et al., 2012).

514 Future work could target features that are stable during ice retreat even where permafrost is present, such as  
515 outcrops of pro-glacial and ice-walled lake plane deposits (e.g., Curry et al., 2018), or perhaps moraines that are not  
516 hummocky in nature. This limitation may not be as necessary in environments where climate more quickly  
517 ameliorated, such as appears to have been the case in southern Ohio (Glover et al., 2011). Additionally, it may be  
518 important to consider the coring equipment. The GeoProbe coring device enabled us to collect stiff mineral-rich  
519 sediments lower than otherwise possible with the Livingstone and Russian Peat coring devices. This meant that our

520 coring did not stop at first contact with stiff minerogenic sediment that could mistakenly be interpreted as primary  
521 glacial in origin.

522

523

524 **Data availability:** Table 2 provides the data to calculate the radiocarbon ages from this study. Table 3 and Table A1  
525 provide the data to calculate OSL ages from this study.

526

527 **Author contributions:** JPB and KKP conceptualized the study. ALK and KKP provided funding for fieldwork and  
528 lab analyses. KKP, JPB, CKW, BMC, and EPY collected sediment cores. KKP, BMC, EPY and JPB conducted  
529 downcore analyses and radiocarbon sampling. CKW collected OSL samples and TMR conducted lab analyses and  
530 calculated the ages. KKP compiled and recalculated the radiocarbon ages. KKP, JPB, ALK, CKW, and BMC  
531 interpreted the results. KKP wrote the first draft of the manuscript and all authors contributed to editing. KKP and  
532 TMR developed the figures and tables.

533

534 **Competing interests.** The authors declare that they have no conflict of interest.

535

536 **Acknowledgements:** We thank the Vincent, Songster, Gebhard, and Bohall families for the access to their property,  
537 as well as their enthusiasm and friendship. We thank Joseph Tulenko, Brandon Graham, Elizabeth Thomas, Kurt  
538 Lindberg, Owen Cowling, Fiona Ellsworth, Joshua Charlton, Liza Wilson, Jason Parsons, Will Phillips, and George  
539 Thomas for their help in the field (it takes a village!). We thank the National Ocean Sciences Accelerator Mass  
540 Spectrometry and W. M. Keck Carbon Cycle Accelerator Mass Spectrometer laboratories for radiocarbon analyses.  
541 We thank the Luminescence Lab at Utah State University for OSL analyses.

542

543 **Funding sources:** This research was supported by the United State Geological Survey Great Lakes Geological  
544 Mapping Coalition grant #G20AC00418, the NSF/GSA Graduate Student Geoscience grant # 13056-21, which was  
545 funded by NSF Award # 1949901, and the Mark Diamond Research Fund of the Graduate Student Association of  
546 the State University of New York at Buffalo.
