## 28 **1 Abstract**

29 The budget of reactive nitrogen species, which play a central role in atmospheric chemistry (e.g.  
30 in photochemical O<sub>3</sub> production), is poorly understood in forested regions. In this study, Tthrough  
31 observations of NO, NO<sub>2</sub>, NO<sub>x</sub> and O<sub>3</sub> in the Rambouillet forest near Paris, France, ~~(as part of~~  
32 ~~the ACROSS campaign, 2022)~~ we have ~~examined~~gained insight into nighttime processes  
33 controlling NO<sub>x</sub> in an anthropogenically impacted forest environment. O<sub>3</sub> mixing ratios displayed  
34 a strong diel profile at the site, which was driven by a variable but generally rapid deposition to  
35 soil and foliar surfaces. The O<sub>3</sub> diel profile was strongly influenced by relative humidity, ~~which~~  
36 ~~impacted the surface resistance to uptake,~~ and temperature inversion, ~~which influenced the rate of~~  
37 ~~entrainment of O<sub>3</sub> from above the canopy.~~ Only when the O<sub>3</sub> mixing ratio was sufficiently low  
38 (and thus the NO lifetime sufficiently long), were sustained NO peaks observed above the  
39 instrumental detection limit, enabling derivation of average NO emission rates from the soil of  
40 ~1.4 ppbv h<sup>-1</sup>. Observations of the lack of increase in NO<sub>2</sub> at night, despite a significant production  
41 rate from the reaction of NO with O<sub>3</sub>, enabled an effective lifetime of NO<sub>2</sub> of ~0.5-3 h to be  
42 derived. As the loss of NO<sub>2</sub> was not compensated by the formation of gas- or particle-phase  
43 reactive nitrogen species it was presumably driven by deposition to soil and foliar surfaces, or any  
44 products formed were themselves short-lived with respect to deposition. By comparison, the  
45 daytime lifetime of NO<sub>2</sub> with respect to loss by reaction with OH is about 1 day. Our results  
46 indicate~~We conclude~~ that the nighttime deposition of NO<sub>2</sub> is a major sink of boundary layer NO<sub>x</sub>  
47 in this temperate forest environment.

48

## 49 **2 Introduction**

50 Nitrogen oxides (NO<sub>x</sub> = NO + NO<sub>2</sub>) are pollutant trace gases, which play a key role in the  
51 atmosphere by producing or destroying tropospheric ozone (O<sub>3</sub>), which can cause respiratory  
52 illness (Ciencewicki and Jaspers, 2007) and damage to plants (Emberson et al., 2018). Photolysis  
53 of nitrogen dioxide (NO<sub>2</sub>) (R1) is the primary source of tropospheric ozone (O<sub>3</sub>), and the nitric  
54 oxide (NO) product is oxidized back to NO<sub>2</sub> either by O<sub>3</sub> (R2) or by organic peroxy radicals (RO<sub>2</sub>,  
55 under formation of alkoxy radicals (RO)) or hydroperoxyl radicals (HO<sub>2</sub>) (R3, R4) (Lightfoot et  
56 al., 1992). The latter results in formation of the hydroxyl radical (OH) radical, and R3 and R4 thus  
57 represent routes to recycle the most important atmospheric radical initiator of oxidation (Hens et  
58 al., 2014). It is, therefore, essential to understand the sources and sinks of NO<sub>x</sub> in the atmosphere.

63 The dominant global sources of  $\text{NO}_{x,x}$  are anthropogenic in the form of combustion of fossil fuels  
64 and to a lesser degree biomass burning and agricultural soils. The natural sources, which include  
65 lightning (Schumann and Huntrieser, 2007), wildfires (Val Martin et al., 2008), and unperturbed  
66 soil emissions from microbial activities (Davidson and Kinglerlee, 1997), are important in regions  
67 remote from anthropogenic sources.  $\text{NO}_2$  and  $\text{NO}$  both react with peroxy radicals in the atmosphere  
68 to produce organic nitrates (R5-R6), including peroxy nitrates ( $\text{RO}_2\text{NO}_2$ ) and alkyl nitrates  
69 ( $\text{RONO}_2$ ), which are important precursors for the formation of secondary organic aerosols (SOA)  
70 (Hallquist et al., 2009; Kanakidou et al., 2005; Kiendler-Scharr et al., 2016).  $\text{NO}_2$  also reacts with  
71  $\text{OH}$  radicals,  $\text{O}_3$  and nitrate radicals ( $\text{NO}_3$ ) to form nitric acid ( $\text{HNO}_3$ ) (R7),  $\text{NO}_3$  radicals (R8), and  
72 dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ) (R9), respectively.  $\text{N}_2\text{O}_5$  is in thermal equilibrium with  $\text{NO}_2$  and  $\text{NO}_3$   
73 and can interact with aqueous aerosol or moist surfaces to form  $\text{HNO}_3$  (R10) (Kane et al., 2001)  
74 or nitryl chloride ( $\text{ClNO}_2$ ) (Phillips et al., 2013; Phillips et al., 2012). Organic nitrates, SOA, and  
75  $\text{HNO}_3$  are all removed from the boundary layer through dry and wet deposition which thereby  
76 removes  $\text{NO}_{x,x}$  from the atmosphere.

83 In the planetary boundary layer,  $\text{NO}_2$  is also lost through dry deposition to surfaces such as soil  
84 and leaves. Deposition takes places both at nighttime and daytime, but is expected to be more  
85 efficient during daytime due to increased mixing through turbulence. When  $\text{NO}_2$  deposits onto  
86 humid surfaces, it can lead to the production of nitrous acid ( $\text{HONO}$ ), which can be released to the  
87 atmosphere (Meusel et al., 2016; Elshorbany et al., 2012).  $\text{NO}_2$  uptake on leaves takes place  
88 through stomatal and non-stomatal processes, which have been reported to depend on multiple  
89 factors such as stomata aperture and relative humidity. Stomatal uptake primarily occurs at  
90 daytime when the stomata are open, leading to increased  $\text{NO}_2$  loss compared to nighttime, when  
91 the stomata are not fully open (Delaria et al., 2020; Delaria et al., 2018; Chaparro-Suarez et al.,  
92 2011). Non-stomatal uptake occurs through the cuticles, though the importance of cuticular uptake  
93 has been reported to be small compared to the stomatal uptake (Delaria and Cohen, 2020; Delaria  
94 et al., 2020).  $\text{NO}_2$  uptake to leaves is reported to be enhanced in the presence of water films, which  
95 may exist when the relative humidity is  $>70\%$  (Thoene et al., 1996; Weber and Rennenberg, 1996;  
96 Burkhardt and Eiden, 1994). There is, however, no consensus on this process, as other studies have  
97 not observed this effect (Gessler et al., 2000). Most recent work shows that the interactions with  
98 foliar surfaces is uni-directional, i.e. emissions are negligible (Delaria et al., 2020).

99 At nighttime, NO<sub>2</sub> photolysis ceases and as a consequence, in the absence of combustion sources,  
100 the main sources of NO are emissions from soils (Jaeglé et al., 2005). Since NO is oxidised  
101 efficiently by O<sub>3</sub> at night, its concentration will be highest at the surface and will decrease with  
102 altitude. The vertical profile of O<sub>3</sub> is the opposite owing to its physical loss due to deposition near  
103 the surface and through chemical reaction with NO and/or alkenes combined with entrainment  
104 from the nocturnal residual layer. As NO<sub>2</sub> is produced from the reaction between NO and O<sub>3</sub>, its  
105 vertical gradient is expected to be weaker than those of NO and O<sub>3</sub> (Geyer and Stutz, 2004; Stutz  
106 et al., 2004).

107 In this study we use measurements from the ACROSS (Atmospheric ChemistRy Of the Suburban  
108 foreSt) campaign to investigate the nighttime sources and sinks of NO<sub>x</sub> in a temperate forest. O<sub>3</sub>  
109 measurements are used to explain the observed NO features and measurements of NO<sub>2</sub> and total  
110 gas-phase nitrogen species (NO<sub>y</sub>) and particulate nitrate are used to investigate the lifetime and  
111 fate of NO<sub>x</sub> in the forest environment.

112

### 113 **3 The ACROSS Campaign**

114 The ACROSS campaign (13<sup>th</sup> of June 2022 to 25<sup>th</sup> of July 2022) was conducted in multiple  
115 locations in and around Paris, France (Cantrell and Michoud, 2022). Here we present  
116 measurements from the Rambouillet forest supersite located approximately 50 km southwest of  
117 Paris (48.687, 1.704). The forest consists of approximately 70% oak, 20% pine, and small  
118 contributions from beech and chestnut. The top of the forest canopy around the supersite was  
119 around 20-25 m. Several instrumented containers were placed in a clearing (~697 m<sup>2</sup>) together  
120 with a 41 m measurement tower. Most of the instruments used in this study were located in two  
121 different containers (MPIC and Orléans). The sampling inlets of the two containers were  
122 approximately 17 m apart and the tower was approximately 9 m from the MPIC container and 16  
123 m from the Orléans container. The soil measurements were carried out at the bottom of the tower,  
124 approximately 13 m from the MPIC container and approximately 17 m from the Orleans container.  
125 All the instruments used in this study are described briefly below.

126

#### 127 **3.1 Measurements**

##### 128 **3.1.1 Ground**

129 NO<sub>2</sub> was measured using two different cavity ringdown spectroscopy (CRDS) instruments with  
130 co-located inlets sampling from a high-volume-flow stainless steel tube (10 m<sup>3</sup> min<sup>-1</sup>; 15 cm  
131 diameter, 0.2 s residence time) taking air from a height of 5.4 m above ground. One of the  
132 instruments (5CH-CRDS) consists of 3 cavities operated at 408 nm to measure NO<sub>2</sub> and, via their  
133 thermal dissociation to NO<sub>2</sub>, total peroxy nitrates (ΣPNs, 448 K) and total alkyl nitrates (ΣANs,  
134 648 K). Two additional cavities, operated at 662 nm, measured NO<sub>3</sub> and (via thermal dissociation  
135 to NO<sub>3</sub>, 373 K) N<sub>2</sub>O<sub>5</sub> (Sobanski et al., 2016). During this campaign, the NO<sub>2</sub> cavity had a limit of  
136 detection (LOD) of 9.7 pptv for 1 min averaging (3σ). The second instrument (k-NO3) primarily

137 measures the NO<sub>3</sub> reactivity, but also has a cavity operated at 405 nm for the measurement of NO<sub>2</sub>  
138 (Liebmann et al., 2018).

139 Another CRDS instrument was used to measure NO<sub>x</sub>, NO<sub>y</sub>, and particulate nitrate (pNO<sub>3</sub>) from  
140 co-located inlets near the high-volume-flow stainless steel tube. NO<sub>x</sub> was measured by adding  
141 O<sub>3</sub> to the ambient sample, thereby oxidizing NO to NO<sub>2</sub>, which was measured with CRDS at 405  
142 nm (Friedrich et al., 2020). A judicious choice of O<sub>3</sub> and reaction time ensured that minimal (>1%)  
143 of NO<sub>2</sub> was oxidized to NO<sub>3</sub>. At times with low (or zero) NO, NO<sub>x</sub> concentrations were in close  
144 agreement with both NO<sub>2</sub> measurements. NO<sub>y</sub> was measured by passing ambient air through a  
145 quartz inlet at ~ 900 K which quantitatively converts reactive nitrogen trace-gases to NO or NO<sub>2</sub>.  
146 Exceptions are N<sub>2</sub>O, HCN and NH<sub>3</sub>, which are not detected. In this location, NO<sub>y</sub> is expected to  
147 consist mainly of NO<sub>x</sub> + NO<sub>3</sub> + N<sub>2</sub>O<sub>5</sub> + HNO<sub>3</sub> + PNs + ANs + HONO + ClNO<sub>2</sub> + particulate  
148 nitrates (pNO<sub>3</sub>).

149 Particulate nitrates (both organic and inorganic) were separately measured (as NO<sub>y</sub>) after  
150 denuding gas-phase reactive nitrogen species (Friedrich et al., 2020). To achieve this, problems  
151 involving the ineffective trapping of gas-phase NO<sub>x</sub> by the denuder was eliminated, as will be  
152 described in a forthcoming technical paper.

153 O<sub>3</sub> was measured from the high-volume-flow stainless-steel tube with a commercial instrument  
154 (2B Technologies model 205) using UV absorption at 254 nm. The LOD is 2 ppbv for 10 s  
155 averaging time.

156 A spectral radiometer (metcon GmbH) was installed near the co-located inlets on top of the MPIC  
157 container to measure actinic fluxes, which were used to calculate photolysis frequencies as  
158 described elsewhere (Meusel et al., 2016).

159 NO was measured from the Orléans container using a commercial chemiluminescence instrument  
160 (Ecophysics CLD 780 TR, henceforth CLD) with an LOD of 10 pptv for 1 min averaging time.  
161 The sampling height for NO measurements was about 0.6 and 3.2 m above the container top and  
162 the ground surface, respectively. The NO measurements required correction due to a change in the  
163 CLD sensitivity during the campaign caused by an interruption in the instrument's oxygen supply.  
164 The corrections and the corrective procedure are described in the SI.

165 HONO was measured by a commercial long-path absorption photometer (LOPAP-03, QUMA  
166 GmbH, Germany) with a sampling height of 2.0 m above the ground level. Details about the  
167 LOPAP instrument can be found elsewhere (Heland et al., 2001; Kleffmann et al., 2006). During  
168 the campaign, the LOPAP was calibrated by diluted nitrite when changing any supporting  
169 solutions. Zero calibration by measuring synthetic air was conducted 2-3 times per day. The  
170 detection limit is < 5 pptv.

171 The sum of peroxy radicals, XO<sub>2</sub>=HO<sub>2</sub>+RO<sub>2</sub>, was measured by their conversion to H<sub>2</sub>SO<sub>4</sub> in  
172 presence of NO and SO<sub>2</sub> and detection of the generated H<sub>2</sub>SO<sub>4</sub> using NO<sub>3</sub><sup>-</sup> CIMS (Kukui et al.,  
173 2008). The calibration coefficient is determined using N<sub>2</sub>O actinometry and OH/RO<sub>2</sub> generation

174 in a turbulent flow reactor by photolysis of N<sub>2</sub>O or H<sub>2</sub>O at 184.9 nm. The calibration of HO<sub>2</sub>,  
175 CH<sub>3</sub>O<sub>2</sub> and other RO<sub>2</sub> is performed by adding into the calibration reactor CO, CH<sub>4</sub> (or other RO<sub>2</sub>  
176 precursors) converting OH to RO<sub>2</sub>. The overall estimated calibration accuracy (2σ) for XO<sub>2</sub> is  
177 about 30%, although the uncertainty of the XO<sub>2</sub> measurements is typically higher due to  
178 uncertainty in ambient air XO<sub>2</sub> composition. The lower limit of detection for XO<sub>2</sub> radicals at S/N=3  
179 and a 4 minute integration time is 2×10<sup>6</sup> molecule cm<sup>-3</sup>.

180 Time series of the most relevant measurements can be found in Figure S1-2. Due to missing total  
181 NO<sub>x</sub> and NO<sub>y</sub> measurements prior to June 25<sup>th</sup> and NO after July 18<sup>th</sup>, the data analysis is  
182 focused on the time period in between these dates.

183

### 184 3.1.2 Tower

185 Measurements at 41 m were conducted with instruments located on the tower as well as through a  
186 manifold with an inlet at the top of the tower. The manifold was built from glass tubing (4.9 cm  
187 inner diameter, Borodrain) with a residence time in the manifold of 2.1 s. NO<sub>2</sub> was measured using  
188 a cavity attenuated phase shift (CAPS) instrument on the tower with an LOD of 40 pptv, which  
189 was zeroed every 1-2 hours. NO and O<sub>3</sub> were both measured from the manifold using a  
190 chemiluminescence instrument with a LOD of 30 pptv and a HORIBA (APOA370) with an LOD  
191 of 2.5 ppbv, respectively. The NO measurements were corrected for losses due to the reaction of  
192 NO with O<sub>3</sub> in the manifold and the sampling line (total 5.5 s), with corrections ranging from 1-  
193 28%. Time series of all three measurements are plotted in Figure S3.

194

### 195 3.1.3 Meteorology and Soil

196 Ambient temperature was measured at four different heights on the tower; 5 m, 13 m, 21 m, and  
197 41 m using temperature sensors from Atexis (PT1000) and Thermoest (PT100). Relative humidity  
198 was measured at 5 m using a Vaisala humidity sensor (HMP45A). Soil temperature and moisture  
199 were measured at 5 cm, 10 cm, and 30 cm below the surface using probes from Thermoest (PT100)  
200 and Delta T (Thetaprobe ML2X), respectively. Wind speed and direction were measured at 41 m  
201 using a wind monitor from Young Company. Time series of all the meteorological and soil  
202 measurements are shown in Figure S4-5.

203

## 204 3.2 HYSPLIT

205 To identify different air masses, 48-hour back trajectories were simulated every hour at a  
206 terminating height of 40 m using the Hybrid Single-Particle Lagrangian Integrated Trajectory  
207 model (HYSPLIT, version 4, 2019) (Draxler and Rolph, 2011). The back-trajectories were  
208 modelled using meteorological data from the Global Data Assimilation System (GDAS) at a  
209 resolution of 1 degree. This led to the separation of the data into two periods, 25<sup>th</sup> of June to 2<sup>nd</sup> of  
210 July and 3<sup>rd</sup> of July to 18<sup>th</sup> of July, which are plotted in Figure 1. The first phase is dominated by  
211 clean air from over the Atlantic Ocean (henceforth called “Atlantic”). Back trajectories indicated  
212 that the vast majority of air masses were transported within the boundary layer prior to reaching

213 the site and thus may have reasonably fresh “marine influence”. The second phase is dominated  
214 by air that has passed over urban locations including Paris, Brussels and the Ruhr area within the  
215 last 48 hours (henceforth called “Continental”).

216

#### 217 **4 Results and Discussion**

218 Two 24-hour periods of temperature (at 4 different heights), NO, O<sub>3</sub>, relative humidity (RH), NO<sub>2</sub>,  
219 and NO<sub>2</sub> photolysis rate constant (JNO<sub>2</sub>) are plotted in Figure 2. The left panels show 24 hours  
220 with Atlantic air and the right panels 24 hours with continental air. Immediately apparent in these  
221 datasets (and in Fig S1) is the large diel cycle in O<sub>3</sub> mixing ratios, with net daytime production  
222 resulting in mid-afternoon mixing ratios between ~30 and 90 ppbv. In contrast, very low O<sub>3</sub> mixing  
223 ratios (often approaching zero) were observed at nighttime.

224 In the lowermost panels (JNO<sub>2</sub> measurements), the nighttime is shown in dark grey and the two  
225 light grey areas show the time before sunset (about 5 hours) and after sunrise (about 4.5 hours)  
226 when very little direct sunlight reaches the ground of the site due to shading by the trees. This  
227 leaves about 6.5 hours centred around midday when direct sunlight reaches the ground. The  
228 shading results in radiative cooling of the ground in the late afternoon and associated temperature  
229 inversions begin to form prior to sunset as can be observed in the right panels of Figure 2 and in  
230 more detail in Figure S6. The temperature inversions begin approximately at the same time as the  
231 ground temperature at 5 cm below the surface starts to decrease (see Figure S6). These conditions  
232 of insolation were relatively consistent throughout the campaign.

233 Clear temperature inversions were observed for both nights shown in Figure 2, the beginning and  
234 end of which are indicated by dashed lines. Vertical mixing can be reduced significantly during a  
235 temperature inversion, which is apparent from the O<sub>3</sub> and RH measurements in the right-hand  
236 panel. In both examples, O<sub>3</sub> decreases at the ground level (5.4 m) at the beginning of the  
237 temperature inversion and increases as the inversion breaks down in the morning. This behaviour  
238 is understood in terms of O<sub>3</sub> loss to soil surfaces and through stomatal and non-stomatal uptake on  
239 leaves (Zhou et al., 2017; Rannik et al., 2012; Altimir et al., 2006; Ganzeveld and Lelieveld, 1995)  
240 as well as through chemical reactions with e.g. NO, NO<sub>2</sub> and unsaturated (biogenic) organics  
241 (Kurpius and Goldstein, 2003). Reduced vertical mixing means that during the inversion, O<sub>3</sub> is  
242 only slowly replenished by downward mixing of air masses above the canopy where higher O<sub>3</sub>  
243 levels are observed. In contrast, the RH behaves in the opposite sense as the air above the inversion  
244 is drier than close to the ground, where evapotranspiration contributes to enhanced water vapour  
245 concentrations.

246 If the only source of NO was the photolysis of NO<sub>2</sub>, NO mixing ratios would be expected to follow  
247 the NO<sub>2</sub> photolysis rate during the day and tend to zero at night as NO is oxidized on a time scale  
248 of minutes (for O<sub>3</sub> > 10 ppb) to NO<sub>2</sub> by O<sub>3</sub>. This was not always the case during ACROSS. A  
249 pronounced NO peak (up to ~2 ppbv) was observed at ground level between 00:00 and 06:00 UTC  
250 (02:00 and 08:00 local time) during the phase dominated by Atlantic air, shown in Figure 2, which  
251 is absent in the phase dominated by continental air. The peak occurs prior to sunrise and is only  
252 observed by the ground-level measurements suggesting a non-photolytic source of NO close to the

253 ground, which is discussed further below. Very low (0-5 ppbv) O<sub>3</sub> mixing ratios coincide with the  
254 sustained nighttime NO peak observed, which is never reached in the example from the continental  
255 phase, although in both cases clear temperature inversions were seen. Additional examples of  
256 sustained NO peaks (i.e. lasting several hours at level between 1 and 2 ppbv) at night during the  
257 first phase are shown in Figure S7. Examples of additional nights with temperature inversions  
258 during phase 2, where NO mixing ratios remained close to zero, are shown in Figure S8.

259

#### 260 4.1 Nighttime Ozone Loss

261 For each night between June 17<sup>th</sup> and July 22<sup>nd</sup> the net O<sub>3</sub> loss rate constant,  $k_L(\text{O}_3)$  was derived  
262 by fitting exponential expressions to the data for periods of 4.5 to 8 hours.  $k_L(\text{O}_3)$  was highly  
263 variable, with values between  $1.8 \times 10^{-5} \text{ s}^{-1}$  and  $3.0 \times 10^{-4} \text{ s}^{-1}$ , depending on the strength of the  
264 temperature inversion and the relative humidity (see discussion below). These values of  $k_L(\text{O}_3)$   
265 correspond to lifetimes of 1-15 hours for O<sub>3</sub> at nighttime. Chemical losses of O<sub>3</sub> occur through  
266 reactions with NO, NO<sub>2</sub>, and unsaturated BVOCs (Zhou et al., 2017). Rate coefficients of reactions  
267 of O<sub>3</sub> with NO ( $1.9 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 298 K), NO<sub>2</sub> ( $3.5 \times 10^{-17} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 298  
268 K), limonene (a reactive terpene,  $2.2 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 298 K),  $\beta$ -caryophyllene  
269 (sesquiterpene,  $1.2 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 298 K) are low such that mixing ratios in excess  
270 of 1 ppbv for NO and  $\beta$ -caryophyllene would be required to explain the O<sub>3</sub> loss rate constant  
271 (IUPAC, 2024). Required mixing ratios of terpenes or NO<sub>2</sub> would be even larger (60-300 ppbv).  
272 As such high mixing ratios of NO and NO<sub>2</sub> were not observed continuously and such levels of  
273 BVOC are unlikely, we assume that chemical losses of O<sub>3</sub> are insignificant compared to deposition  
274 as previously observed (Zhou et al., 2017). Ignoring entrainment from other heights, we can then  
275 equate  $k_L(\text{O}_3)$  to  $(2V_d/h)$ , where  $V_d$  is the deposition velocity and  $h$  is the boundary layer height;  
276 the factor 2 is used to account for a positive vertical gradient (Shepson et al., 1992). Using a  
277 boundary layer height of 20 m (arbitrarily set equal to the top of the canopy) gives net deposition  
278 velocities varying between 0.018 and 0.3 cm s<sup>-1</sup>. These values for  $V_d$  are in broad agreement with  
279 other studies in temperate forests, where deposition velocities for O<sub>3</sub> at nighttime have been  
280 reported to be around 0.07-0.3 cm s<sup>-1</sup> (Padro, 1996, 1993; Finkelstein et al., 2000; Wu et al., 2016).

281 In Figure 3 the O<sub>3</sub> production rate ( $J\text{NO}_2 \times [\text{NO}_2]$ ), RH, temperature at 4 different heights and O<sub>3</sub>  
282 mixing ratio have been plotted for two nights with high average RH to illustrate the impact of  
283 temperature inversions on the net O<sub>3</sub> loss-rate constants. The production rate of O<sub>3</sub> is used to  
284 identify periods in which production is negligible. In the left panel a night without a temperature  
285 inversion is plotted, where the average RH for the period used to fit the exponential decay is  $93 \pm$   
286  $3 \%$ . These conditions resulted in a net O<sub>3</sub> loss-rate constant of  $6.0 \times 10^{-5} \text{ s}^{-1}$ . In contrast, the night  
287 depicted in the right panel has the same average RH ( $92 \pm 3 \%$ ) and a very clear temperature  
288 inversion, which gives a net O<sub>3</sub> loss-rate constant of  $3.0 \times 10^{-4} \text{ s}^{-1}$ . This gives a factor of 5 between  
289 these two net O<sub>3</sub> loss-rate constants depending on whether a temperature inversion is observed or  
290 not. This can be understood in terms of the O<sub>3</sub> being replenished from above when there is no (or  
291 a weak) inversion, which is not the case when there is an inversion. Bearing this in mind, the use  
292 of  $k_L(\text{O}_3)$  (a *net* O<sub>3</sub> loss constant) must result in a lower limit to  $V_d$  unless strong temperature  
293 inversions (preventing O<sub>3</sub> entrainment from above) are present. The O<sub>3</sub> loss rate will also be

294 enhanced under conditions of strong inversion if trace-gases that are reactive towards O<sub>3</sub> are  
295 released into a very shallow boundary layer. However, as indicated above, chemical losses are not  
296 expected to compete with physical losses.

297 To investigate the impact of RH on the net O<sub>3</sub> loss-rate constants, two nights with temperature  
298 inversions are plotted in Figure S9; one with high RH ( $92 \pm 3$  %) and one with a lower RH ( $63 \pm$   
299  $6$  %). Here we see a large decrease in  $k_L(\text{O}_3)$  from  $3.0 \times 10^{-4} \text{ s}^{-1}$  to  $4.5 \times 10^{-5} \text{ s}^{-1}$ , when going from  
300 high to lower RH. The individually determined O<sub>3</sub> loss-rate constants are plotted as a function of  
301 RH in Figure 4 and coloured depending on whether a temperature inversion is observed or not  
302 during the time period which was used for the exponential decay fit. A clear increase in O<sub>3</sub> loss-  
303 rate constants can be observed when RH increases above 70-80% when a temperature inversion  
304 was observed. A small increase at RH higher than 70-80% was also observed when temperature  
305 inversions were absent. The observed dependence of  $k_L(\text{O}_3)$  on relative humidity is consistent with  
306 previous studies in forested regions, which have reported an increase in O<sub>3</sub> loss above 60-70% RH  
307 (Altimir et al., 2006; Rannik et al., 2012; Zhou et al., 2017). Altimir et al. (2006) suggested an  
308 enhancement factor which is humidity dependent above 70% RH; 1 at 70% RH, 2 at 85% RH and  
309 a sharp increase to over 5 when moving towards 100% RH. In a boreal forest these observations  
310 have been explained by the formation of a “wet skin” on leaves which enhances surface O<sub>3</sub> losses  
311 by modifying (reducing) the surface-resistance to uptake (Zhou et al., 2017). This is in broad  
312 agreement with our observations during nights with a temperature inversion (see Figure 4), and  
313 the discrepancies between the studies could be explained e.g. by different tree types, the height of  
314 the boundary layer, strength of the inversion and temperature.

315 The faster net rate of O<sub>3</sub> loss on nights with high relative humidity and well-defined temperature  
316 inversions explain the differences observed in the O<sub>3</sub> mixing ratios at night during the Atlantic and  
317 continental phases. The average nighttime (20:00-04:00 UTC) RH for the Atlantic phase was  $87.4$   
318  $\pm 7.6$  (1 $\sigma$ ) % compared to  $68.4 \pm 12.7$  (1 $\sigma$ ) % for the continental phase, indicating that on nights  
319 with temperature inversions higher loss-rate constants would be expected for the Atlantic phase.  
320 The high RH combined with the significantly lower average peak O<sub>3</sub> mixing ratio in the Atlantic  
321 phase ( $34.5 \pm 6.0$  (1 $\sigma$ ) ppbv between 14:00-15:00 UTC) compared to the continental phase ( $52.7$   
322  $\pm 13.6$  (1 $\sigma$ ) ppbv between 14:00-15:00 UTC) explains why on nights with temperature inversions  
323 during the Atlantic phase the O<sub>3</sub> was essentially completely depleted as shown in Figure 2 and S7.

324

## 325 **4.2 Nitrogen Oxide Soil Emissions**

326 Figure 2 (left panel) and S7 show nighttime periods in which NO was observed when O<sub>3</sub> was  
327 depleted during the Atlantic phase. The several hours duration of the period when NO was above  
328 the LOD excludes very local combustion as the source, leaving soil emissions resulting from  
329 microbial activity (Davidson and Kinglerlee, 1997) as the most likely source of NO. At 293 K and  
330 2 ppbv of O<sub>3</sub>, the lifetime of NO towards reaction with O<sub>3</sub> is around 20 minutes. It is therefore  
331 reasonable to assume that NO is close to steady-state when there is 2 ppbv or more of O<sub>3</sub> available.  
332 The NO emission rate ( $E_{\text{NO}}$ ) can therefore be equated to the loss rate of NO as described in equation  
333 (1) assuming all peroxy radicals (XO<sub>2</sub>) react with the same rate coefficient as HO<sub>2</sub>:

334 
$$E_{\text{NO}} = k_{\text{NO}+\text{O}_3}[\text{NO}][\text{O}_3] + k_{\text{NO}+\text{HO}_2}[\text{XO}_2][\text{NO}] \quad (1)$$

335 where  $k_{\text{NO}+\text{O}_3}$  and  $k_{\text{NO}+\text{HO}_2}$  are the temperature-dependent rate constants for the reaction between  
336 NO and O<sub>3</sub> and HO<sub>2</sub>, respectively, (IUPAC, 2024) and [NO], [O<sub>3</sub>] and [XO<sub>2</sub>] are the measured  
337 concentrations of NO, O<sub>3</sub> and XO<sub>2</sub>, respectively. In Figure 5, NO and E<sub>NO</sub> (when O<sub>3</sub> > 2 ppbv) at  
338 nighttime ( $J\text{NO}_2 < 10^{-5} \text{ s}^{-1}$ ) are separated by air masses and plotted against O<sub>3</sub>, where the outliers  
339 are defined as being outside  $1.5 \times$  interquartile range (IQR). While the nighttime NO mixing ratio  
340 increased rapidly when O<sub>3</sub> tended towards 0 ppbv during the Atlantic phase, O<sub>3</sub> was never depleted  
341 to less than 5 ppbv during the Continental phase and therefore no sustained periods of enhanced  
342 NO were observed at nighttime. In contrast, no significant trend is found when plotting E<sub>NO</sub> against  
343 O<sub>3</sub> for either of the phases, which shows that the calculated soil emission of NO is not dependent  
344 on O<sub>3</sub>. This indicates that while the soil is an important but variable source of NO, sustained  
345 nighttime NO peaks are only observed above the instrument LOD when O<sub>3</sub> is almost totally  
346 depleted so that the lifetime of NO is long enough to allow its concentration to build-up  
347 sufficiently.

348 Water content and temperature have previously been shown to impact the emission rate of NO  
349 from soil (Pilegaard, 2013; Rosenkranz et al., 2006). Rosenkranz et al. (2006) found a positive  
350 correlation between soil moisture and NO emission up to 40% water-filled pore space (WFPS) and  
351 an optimum between 12.5 and 15 °C soil temperature in a sessile oak forest in Hungary. In Figure  
352 6, NO and E<sub>NO</sub> are plotted against the soil temperature and moisture at 5 cm below the surface.  
353 The measured NO mixing ratios peak towards the highest soil moisture and lowest soil temperature  
354 measured during this campaign, however, as with O<sub>3</sub>, there is no significant trend in the NO  
355 emission rates with soil moisture. At the low (11.5-12.5 °C) and high (19.5-20.5 °C) nighttime soil  
356 temperatures very few measurements were made (around 2 hours combined) compared to the rest  
357 of the temperature intervals. Across the remaining temperature intervals, no significant trend was  
358 observed in the estimated NO emission.

359 The average NO emission rate derived for the two phases is identical with values of  
360  $1.45 \pm 1.61 \text{ ppbv h}^{-1}$  ( $1\sigma$ , median =  $1.27 \text{ ppbv h}^{-1}$ ) and  $1.42 \pm 5.68 \text{ ppbv h}^{-1}$  ( $1\sigma$ , median =  $0.71$   
361  $\text{ppbv h}^{-1}$ ) for the Atlantic and Continental phases, respectively, when using data where O<sub>3</sub> > 2  
362 ppbv. The Continental phase show much higher variability resulting from more spikes in the data  
363 during that period. When O<sub>3</sub> is completely depleted during the Atlantic phase, the increase in NO  
364 per hour results in NO emission rates of 0.3-1.8 ppbv h<sup>-1</sup>, which is in reasonable agreement with  
365 the averages across each of the two phases when there is still O<sub>3</sub> present. By assuming a mixed  
366 nocturnal boundary layer (NBL) with a height of 20 m (top of the canopy), the average emission  
367 rates can be converted to NO emission fluxes of  $16.6 \pm 18.5$  ( $1\sigma$ ) and  $16.2 \pm 65.0$  ( $1\sigma$ )  $\mu\text{g N m}^{-2} \text{ h}^{-1}$ ,  
368 respectively. These values are within the range of previous measurements in different European  
369 forests with similar tree types to those found in the Rambouillet forest (see Table 1). The  
370 measurements by Pilegaard et al. (2006) and Rosenkranz et al. (2006) were all performed using  
371 the chamber technique, whereas Schindlbacher et al. (2004) measured the emission from soil  
372 samples collected in the field and exposed to different temperatures and humidity in the laboratory.  
373 The chamber-derived emission rates are all either lower or, within combined uncertainties, equal  
374 to the values determined in this study, while emission rates from the soil samples were higher than

375 (or, within combined uncertainties, equal to) the values derived in the present study. Davidson and  
376 Kingerlee (1997) modelled the global NO emission inventory from soil depending on the biome  
377 (e.g. temperate forest, agriculture, and savanna), and split the temperate forest category into  
378 regions affected by nitrogen deposition or not. For temperate forests not affected by nitrogen  
379 deposition, those authors estimated a flux of 0.0-0.2 kg N ha<sup>-1</sup> yr<sup>-1</sup> (0.0-2.3 μg N m<sup>-2</sup> h<sup>-1</sup>), which is  
380 in good agreement with the lower measurements by Pilegaard et al. (2006). In contrast, the  
381 temperate forests impacted by nitrogen deposition had estimated fluxes of 1.1-5.0 kg N ha<sup>-1</sup> yr<sup>-1</sup>  
382 (12.6-57.1 μg N m<sup>-2</sup> h<sup>-1</sup>), which is in good agreement with our measurements at Rambouillet where  
383 nitrogen deposition is enhanced by pollution arriving from Paris and other surrounding urbanized  
384 / industrialized areas. While noting that our fluxes are broadly consistent with previous  
385 measurements, we recognise that the calculations are based on the assumptions of a well-mixed  
386 boundary layer of fixed height arbitrarily set at 20 m and should not be over-interpreted.

387

### 388 **4.3 Nitrogen Dioxide Losses**

389 At nighttime, in the absence of its photolysis, NO<sub>2</sub> may be expected to increase in concentration  
390 (via R2) when a constant NO source exists (e.g. from soil, as observed here) and when O<sub>3</sub> is  
391 present. For both the Atlantic and the Continental phases an average diel profile between 20.00  
392 and 04.00 UTC of NO<sub>2</sub> (black) is plotted in Figure 7. No obvious increase in NO<sub>2</sub> can be observed  
393 in the Atlantic phase and an average increase of around 1 ppbv can be observed in the Continental  
394 phase. The expected NO<sub>2</sub> resulting from the NO + O<sub>3</sub> reaction if there were no loss mechanisms  
395 of NO<sub>2</sub> is plotted in red. This is determined using the NO<sub>2</sub> measured at 20.00 UTC and  
396 incrementing this value by the NO<sub>2</sub> that would have been produced through NO oxidation by O<sub>3</sub>  
397 and peroxy radicals in each time step. In both phases, the simple assumption of nighttime NO<sub>2</sub>  
398 production through NO + O<sub>3</sub> and NO + XO<sub>2</sub> and no NO<sub>2</sub> loss results in significant generation of  
399 NO<sub>2</sub> with an overestimation of 10-12 ppbv of NO<sub>2</sub> at the end of the night compared to the measured  
400 NO<sub>2</sub>. A loss mechanism of around 1.4 ppbv h<sup>-1</sup> of NO<sub>2</sub> is therefore necessary to explain the  
401 observed (lack of increase in) NO<sub>2</sub>.

402

#### 403 **4.3.1 Chemical Losses**

404 While during the daytime NO<sub>2</sub> is removed in a largely irreversible process through reaction with  
405 OH radicals to form HNO<sub>3</sub>, this is unlikely to represent a significant sink at nighttime. In the  
406 absence of photochemical formation pathways, OH is generated at night in the ozonolysis of  
407 olefins and in the reaction of HO<sub>2</sub> with NO<sub>3</sub> and NO.

411 In the forested environment in summer, the emissions of biogenic volatile organic compounds  
412 (BVOC) (e.g. olefinic terpenoids) will favour R11 and simultaneously disfavour R12 as NO<sub>3</sub> will  
413 be reduced in concentration through its reactions with BVOCs. During the ACROSS campaign

414 ground NO<sub>3</sub> levels were generally below instrument detection limits of 2 pptv and we can  
415 reasonably ignore R12. Measurements of OH in forested environments are sparse, though they  
416 indicate that nocturnal OH levels are low, with concentrations generally lower than  $1 \times 10^5$   
417 molecule cm<sup>-3</sup>. Combining the rate coefficient for reaction of OH with NO<sub>2</sub> of  $\sim 1 \times 10^{-11}$  cm<sup>3</sup>  
418 molecule<sup>-1</sup> s<sup>-1</sup> (IUPAC, 2024) at ambient pressure and  $\approx 300$  K with an upper limit (confirmed by  
419 measurements) to the OH concentration of  $1 \times 10^6$  molecule cm<sup>-3</sup> results in a NO<sub>2</sub> loss constant of  
420  $1 \times 10^{-5}$  s<sup>-1</sup>, or (at the average nighttime NO<sub>2</sub> = 1650 pptv) a loss rate of  $\sim 60$  ppt h<sup>-1</sup>, clearly  
421 insufficient to explain the observations.

422 NO<sub>2</sub> is also lost via its reaction with O<sub>3</sub> to form the NO<sub>3</sub> radical (R8). In an upcoming paper, we  
423 will show that the majority of NO<sub>3</sub> formed in the forest will react with BVOCs rather than with  
424 NO (to re-form NO<sub>2</sub>) and, to a good approximation, R8 represents an irreversible loss of NO<sub>2</sub> as  
425 the alkyl nitrates will not release nitrogen in the form of NO<sub>2</sub> at nighttime. However, the rate  
426 coefficient for this process ( $3.5 \times 10^{-17}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> at 298 K, (IUPAC, 2024)) is very small  
427 and with average nighttime O<sub>3</sub> levels reduced by deposition (see above) to 23 ppbv, the lifetime  
428 of NO<sub>2</sub> with respect to this reaction is 14 hours and the loss-rate (at the average nighttime NO<sub>2</sub> =  
429 1650 pptv) is  $\sim 120$  pptv h<sup>-1</sup>, again too slow to contribute significantly to the apparent loss rate of  
430 NO<sub>2</sub>.

431 The chemical loss of NO<sub>2</sub> via reaction with OH or via formation of NO<sub>3</sub> and its further reactions  
432 with BVOC to form alkyl nitrates is expected to result in the conversion of NO<sub>x</sub> to NO<sub>y</sub>. As  
433 described in section 3.1.1, during the ACROSS campaign we operated a NO<sub>y</sub> instrument to  
434 measure NO<sub>y</sub> both in the gas- and particle-phases. Figure 8 displays the average diel profiles of  
435 NO<sub>z</sub> (NO<sub>y</sub>-NO<sub>x</sub>) and pNO<sub>3</sub> during the Atlantic and Continental phases. For both NO<sub>z</sub> and  
436 pNO<sub>3</sub> the diel profiles show either a decrease or stable mixing ratio across the period in which  
437 losses of 10-12 ppbv of NO<sub>2</sub> are required to explain the observations. Clearly, the loss of NO<sub>2</sub> at  
438 nighttime is not balanced by the formation of other forms of reactive nitrogen that were long lived  
439 enough to be detected. Trace gases such as HNO<sub>3</sub> or alkyl nitrates may be lost via deposition to  
440 surfaces, especially at high relative humidity and lifetimes for biogenic alkyl nitrates of a few  
441 hours have been reported (Liebmann et al., 2019; Farmer and Cohen, 2008; Browne et al., 2013;  
442 Romer Present et al., 2019). However, as shown above, the limiting step in the formation of organic  
443 nitrates is the slow reaction of NO<sub>2</sub> with O<sub>3</sub>, which will not convert sufficient NO<sub>2</sub> to NO<sub>z</sub>  
444 to explain our observations. Formation of organic nitrates that do not require the intermediacy of NO<sub>3</sub>  
445 (i.e. peroxy nitrates formed from RO<sub>2</sub> + NO<sub>2</sub>) would also have been detected by the NO<sub>y</sub>  
446 instrument and can thus also be ruled out as major reservoirs of NO<sub>x</sub>.

447 NO<sub>2</sub> deposited to humid surfaces can be converted to HONO and released to the atmosphere  
448 (Elshorbany et al., 2012; Meusel et al., 2016). A time series of HONO can be found in Figure S2  
449 which reveals increases in HONO at nighttime. However, the HONO mixing ratios can account  
450 for only a small fraction of the NO<sub>2</sub> loss described above. This may reflect the fact that, if formed  
451 at a moist surface, (soluble) HONO is unlikely to desorb quantitatively into the gas-phase. The  
452 low HONO mixing ratios measured during the Atlantic phase compared to the Continental phase,  
453 could potentially be explained by the difference in soil humidity, however, the factors influencing

454 the formation and release of HONO are complex. The HONO observations will be analysed in  
455 detail in a separate publication from the ACROSS campaign.

456 In the absence of other known gas-phase mechanisms for the removal of NO<sub>2</sub> at night and the fact  
457 that very little other reactive nitrogen trace-gases or nitrate particles are formed during the night,  
458 we conclude that physical removal of NO<sub>2</sub> (i.e. deposition) is responsible for its lack of build-up  
459 at night during ACROSS and that any transformation of NO<sub>2</sub> at the surface does not lead to  
460 quantitative release into the gas-phase

461

### 462 4.3.2 Physical Losses

463 NO<sub>2</sub> is known to be lost through dry deposition to surfaces such as soil and leaves, the latter  
464 depending on whether the stomata are open (daytime) or not fully open (nighttime) (Delaria et al.,  
465 2020; Delaria et al., 2018; Chaparro-Suarez et al., 2011). As for O<sub>3</sub>, dry deposition of NO<sub>2</sub> to  
466 surfaces can be described by an exponential decay with a first-order decay rate constant,  $k_L(\text{NO}_2)$   
467 =  $(V_d/h)$ , where  $V_d$  is the deposition velocity and  $h$  is the boundary layer height. This expression  
468 applies when gradients within the boundary layer are weak, as expected for NO<sub>2</sub> (see above) even  
469 though vertical mixing is very slow at night. The net production (or loss) of NO<sub>2</sub> is given by Eq.  
470 (2) where the first term on the right-hand side is the NO<sub>2</sub> production rate from the reaction of NO  
471 with O<sub>3</sub> or XO<sub>2</sub> (which is identical to the NO soil emission rate) and the second term is the loss  
472 rate assuming only depositional losses (see above) and ignoring entrainment of NO<sub>2</sub> from other  
473 heights. This will give an upper limit of the NO<sub>2</sub> deposition rate as a small fraction (<10%) of NO<sub>2</sub>  
474 is lost through chemical reactions with O<sub>3</sub> and OH (see above).

$$475 \frac{d[\text{NO}_2]}{dt} = E_{\text{NO}} - k_L(\text{NO}_2)[\text{NO}_2]_0 \quad (2)$$

476 [NO<sub>2</sub>]<sub>0</sub> is the NO<sub>2</sub> mixing ratio at 20.00 UTC. The NO<sub>2</sub> concentration at any subsequent time can  
477 then be calculated as described in Eq. (3) with variation of  $k_L(\text{NO}_2)$  in order to match the observed  
478 NO<sub>2</sub> mixing ratio.

$$479 [\text{NO}_2]_t = \int_0^t \frac{d[\text{NO}_2]}{dt} + [\text{NO}_2]_0 \quad (3)$$

480 In Figure 7 the grey lines symbolize the calculated NO<sub>2</sub> mixing ratios at nighttime using values of  
481  $k_L(\text{NO}_2)$  between  $1.0 \times 10^{-4}$  and  $4.0 \times 10^{-4} \text{ s}^{-1}$ . As expected, no single value of  $k_L(\text{NO}_2)$  can explain  
482 all the measurements as the height of the BL will not be invariant during the whole night. However,  
483 for the Continental and Atlantic phases the observed NO<sub>2</sub> can be explained with  $k_L(\text{NO}_2) = (2.0 \pm$   
484  $1.0) \times 10^{-4} \text{ s}^{-1}$  and  $k_L(\text{NO}_2) = (2.75 \pm 1.25) \times 10^{-4} \text{ s}^{-1}$ , respectively, which results in lifetimes of ~  
485 1-3 h and ~ 40-110 min for NO<sub>2</sub> at nighttime. As deposition of NO<sub>2</sub> in this environment represents  
486 a permanent loss of NO<sub>x</sub> from the gas phase, this lifetime can be compared to e.g. the lifetime of  
487 NO<sub>x</sub> with respect to its conversion to HNO<sub>3</sub> via reaction of NO<sub>2</sub> with OH which is ~ 1 day  
488 (assuming average [OH] =  $1 \times 10^6 \text{ molecule cm}^{-3}$ ). The low aerosol surface area during ACROSS  
489 combined with the low uptake coefficient for NO<sub>2</sub> renders losses due to heterogeneous processes

490 insignificant (IUPAC, 2024). Clearly, only depositional losses of NO<sub>2</sub> in a forested environment  
491 contribute substantially to its lifetime at night and to the NO<sub>x</sub> budget.

492 If we continue to assume the nocturnal boundary layer at the forest site is at the top of the canopy  
493 (20 m), then the NO<sub>2</sub> loss-rate constants we determined can be converted to a deposition velocity  
494 of  $0.4 \pm 0.2 \text{ cm s}^{-1}$  and  $0.55 \pm 0.25 \text{ cm s}^{-1}$  for the Continental and Atlantic phase, respectively.  
495 These are comparable to previous measurements of NO<sub>2</sub> deposition velocities of  $0.15 \text{ cm s}^{-1}$   
496 (Dewald et al., 2022),  $0.1\text{-}0.57 \text{ cm s}^{-1}$  (Rondón et al., 1993),  $0.098 \text{ cm s}^{-1}$  (Breuninger et al., 2013),  
497  $0.2\text{-}0.5 \text{ cm s}^{-1}$  (Horii et al., 2004),  $0.02\text{-}0.64 \text{ cm s}^{-1}$  (Puxbaum and Gregori, 1998), for a mountain  
498 observatory surrounded by coniferous trees, boreal coniferous forests, a temperate coniferous  
499 forest, a temperate mixed deciduous forest, and a temperate oak forest, respectively, where a  
500 combination of soil and foliage deposition is measured. Horii et al. (2004) saw an increase in  
501 deposition velocity with increasing NO<sub>2</sub> mixing ratio; from  $0.2 \text{ cm s}^{-1}$  at 1 ppbv to  $0.5 \text{ cm s}^{-1}$  at 30  
502 ppbv. Puxbaum and Gregori (1998) reported monthly averages of  $0.02\text{-}0.64 \text{ cm s}^{-1}$ , however, their  
503 nighttime deposition velocities averaged below  $0.05 \text{ cm s}^{-1}$ . The deposition velocities determined  
504 here are a factor of 5-40 higher than what has been measured for nighttime foliage deposition  
505 velocities to the leaves of different trees native to California (Delaria et al., 2020; Delaria et al.,  
506 2018), but in good agreement with measurements for daytime. It is, however, important to note  
507 that the deposition velocities estimated here are upper limits as the estimation of the NO emission  
508 rate is an upper limit and chemical loss of NO<sub>2</sub> is not taken into account. Using an average  
509 nighttime NO<sub>2</sub> mixing ratio of 1650 and 1450 pptv for the Continental and Atlantic phase,  
510 respectively, results in NO<sub>2</sub> deposition rates of  $13.6 \pm 6.8 \mu\text{g N m}^{-2} \text{ h}^{-1}$  and  $18.7 \pm 8.5 \mu\text{g N m}^{-2} \text{ h}^{-1}$ ,  
511 which are in reasonable agreement with that measured for soil NO<sub>2</sub> deposition in a sessile oak  
512 forest of  $9.67 \pm 1.92 \mu\text{g N m}^{-2} \text{ h}^{-1}$  during the summer (Rosenkranz et al., 2006). The estimated NO  
513 soil emission rate and NO<sub>2</sub> deposition rate are, within the uncertainties, identical, which means the  
514 Rambouillet forest is not a significant direct source or sink of NO<sub>x</sub>.

515

## 516 **5 SummaryConclusions:**

517 Measurements of NO, NO<sub>2</sub>, NO<sub>x</sub>, and O<sub>3</sub> during the ACROSS campaign (June-July 2022) in the  
518 Rambouillet forest southwest of Paris, France, have been used to gain insight into nighttime  
519 processes controlling NO<sub>x</sub> in an anthropogenically impacted forest environment. Based on  
520 HYSPLIT back trajectories, two phases of the campaign were identified; one dominated by air  
521 originating over the Atlantic Ocean (“Atlantic”), which on average had high relative humidity and  
522 low O<sub>3</sub> mixing ratios, and one dominated by continental air masses from different  
523 urban/industrialized regions (“Continental”), which on average had a lower relative humidity than  
524 the Atlantic phase and higher O<sub>3</sub> mixing ratios. Strong diel profiles were observed in the O<sub>3</sub>  
525 measurements across the campaign with daytime peak mixing ratios varying from ~30 to 90 ppbv  
526 and nighttime tending towards 0-10 ppbv. The daily variation was driven by a variable but  
527 generally rapid O<sub>3</sub> deposition to soil and foliar surfaces, with a strong influence of relative  
528 humidity (influencing the surface resistance to uptake) and inversion (influencing the rate of  
529 entrainment of O<sub>3</sub> from above the canopy).

530 During the Atlantic phase, periods of sustained NO above the instrumental detection limit was  
531 observed at nighttime when O<sub>3</sub> was sufficiently low (i.e. the NO lifetime sufficiently long). This  
532 enabled the derivation of an average NO emission rate from the soil (E<sub>NO</sub>) of ~1.4 ppbv h<sup>-1</sup>, which  
533 was confirmed by the approximately linear increase in NO observed in the absence of O<sub>3</sub> in the  
534 Atlantic phase. The estimated E<sub>NO</sub> is in broad agreement with previous measurements in other  
535 European temperate forests with tree types as found in the Rambouillet forest. The uncertainty in  
536 the estimated NO emission rate is determined from the uncertainties in NO and O<sub>3</sub> at 3-5 m above  
537 ground, which leads to higher relative uncertainties at low NO and O<sub>3</sub> mixing ratios. Measurements  
538 of either NO fluxes or highly resolved height profiles of NO and O<sub>3</sub> will improve the NO emission  
539 rate estimate during future field campaigns.

540 An increase in NO<sub>2</sub> at night would be expected when having a constant NO emission rate of  
541 ~1.4 ppbv h<sup>-1</sup> in the presence of O<sub>3</sub> as observed in this study, however, this was not the case. The  
542 lack of increase in NO<sub>2</sub> was used to estimate first-order decay constants of  $(2.0 \pm 1.0) \times 10^{-4} \text{ s}^{-1}$   
543 and  $(2.75 \pm 1.25) \times 10^{-4} \text{ s}^{-1}$  resulting in an effective lifetime of NO<sub>2</sub> of ~0.5-3 h. The loss of NO<sub>2</sub>  
544 at nighttime is presumably driven by deposition to soil and foliar surfaces since the lifetime of  
545 NO<sub>2</sub> towards its reactions with OH and O<sub>3</sub> at night is >28 and 14 h, respectively. By comparison,  
546 the daytime lifetime of NO<sub>2</sub> with respect to loss by reaction with OH is about 1 day. We conclude  
547 that the nighttime deposition of NO<sub>2</sub> is a major sink of boundary layer NO<sub>xx</sub> in this forested  
548 environment.

549

## 550 **6 Data Availability:**

551 All data can be found on <https://across.aeris-data.fr/catalogue/>.

552

## 553 **7 Author contribution:**

554 All authors contributed with measurements. Data analysis was conducted by STA with  
555 contributions from JNC and PD. CC and VM organized the field campaign with contributions from  
556 the individual group leads. STA and JNC developed the manuscript with contributions from all  
557 authors.

558

## 559 **8 Competing Interests:**

560 At least one of the (co-)authors is a member of the editorial board of Atmospheric Chemistry and  
561 Physics

562

## 563 **9 Acknowledgements:**

564 STA is thankful to the Alexander von Humboldt foundation for funding her stay at MPIC.

565 PD gratefully acknowledges the Deutsche Forschungsgemeinschaft (project “MONOTONS”,  
566 project number: 522970430).

567 The ACROSS project has received funding from the French National Research Agency (ANR)  
568 under the investment program integrated into France 2030, with the reference ANR-17-MPGA-  
569 0002, and it was supported by the French National program LEFE (Les Enveloppes Fluides et  
570 l'Environnement) of the CNRS/INSU (Centre National de la Recherche Scientifique/Institut  
571 National des Sciences de l'Univers). Data from the ACROSS campaign are hosted by the French  
572 national center for Atmospheric data and services AERIS.

573 IMT Nord Europe acknowledges financial support from the CaPPA project, which is funded by  
574 the French National Research Agency (ANR) through the PIA (Programme d'Investissement  
575 d'Avenir) under contract ANR-11-LABX-0005-01, the Regional Council “Hauts-de-France” and  
576 the European Regional Development Fund (ERDF).

739 deposition model, *Atmos. Chem. Phys.*, 17, 1361-1379, 10.5194/acp-17-1361-2017, 2017.

740

741 **11 Figures:**

742

743 Figure 1: 48-hour back trajectories from the Rambouillet forest supersite using the Hybrid Single-  
744 Particle Lagrangian Integrated Trajectory model (HYSPLIT, version 4, 2019).

745  
 746 Figure 2: Measurements of temperature, NO, O<sub>3</sub>, RH, NO<sub>2</sub>, and JNO<sub>2</sub> for two different nights  
 747 during the campaign; one during the Atlantic phase (left panels) and one during the continental  
 748 phase (right panels). The different colours symbolize four different heights; red = 3–6 m, grey =  
 749 13 m, orange = 21 m, and black = 41 m, and the blue shows the RH at 5 m. The grey shaded areas  
 750 in the JNO<sub>2</sub> plots shows the time the MPIC container was in shade during the afternoon and  
 751 morning (light grey) and nighttime (dark grey). The vertical black dashed lines indicate the  
 752 beginning and end of the observed temperature inversions in the top panels.

753

754

755 Figure 3: The production of O<sub>3</sub> (JNO<sub>2</sub> × [NO<sub>2</sub>]), temperature, RH, and O<sub>3</sub> plotted for two nights  
 756 with high average RH; one without a temperature inversion (left panels) and one with a  
 757 temperature inversion (right panels). The different colours symbolize four different heights; red =  
 758 5-5.4 m, grey = 13 m, orange = 21 m, and black = 41 m, and the blue shows the RH at 5 m. The  
 759 net nighttime O<sub>3</sub> loss is fitted with an exponential decay curve (solid black line) in the bottom  
 760 plots. The grey shaded areas represent the nighttime.

761

762

763 Figure 4: Net O<sub>3</sub> loss-rate constants at 5.4 m plotted against the average relative humidity measured  
 764 during the time used to fit the exponential decay of O<sub>3</sub>. The error bars represent  $\pm 1\sigma$  on the average  
 765 RH. The dashed line symbolizes the observations made by Altimir et al. (2006).

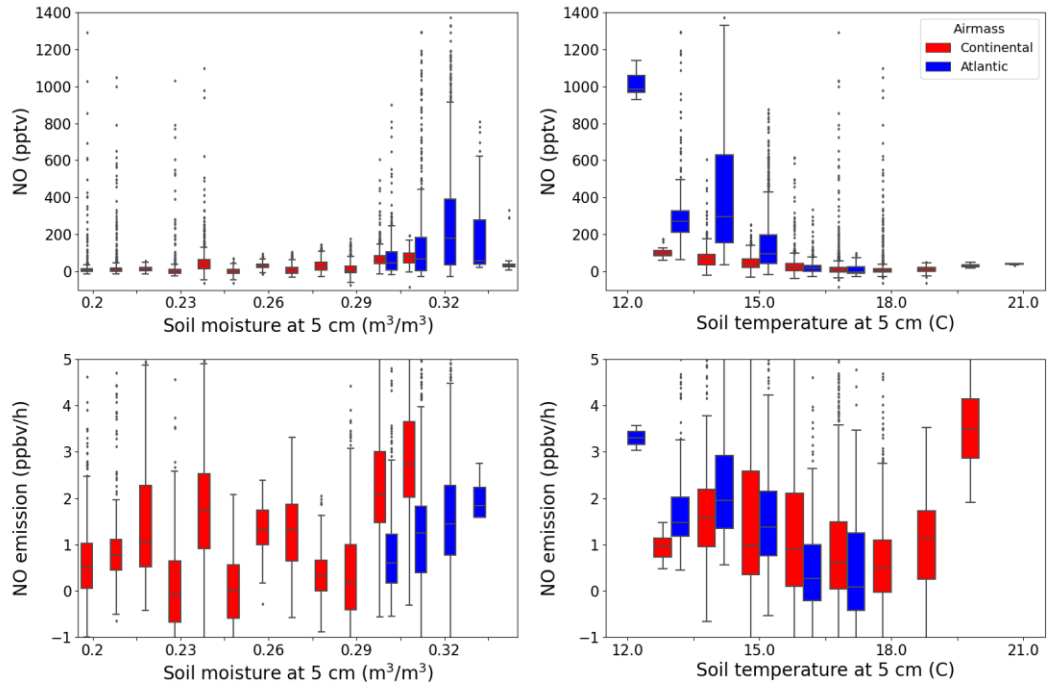

766

767 Figure 5: NO (top) and NO emission (bottom) plotted against O<sub>3</sub> in a box-and-whiskers plot, where  
 768 the outliers are defined as being outside  $1.5 \times \text{IQR}$ . The colours represent the two different air  
 769 masses.

770

771

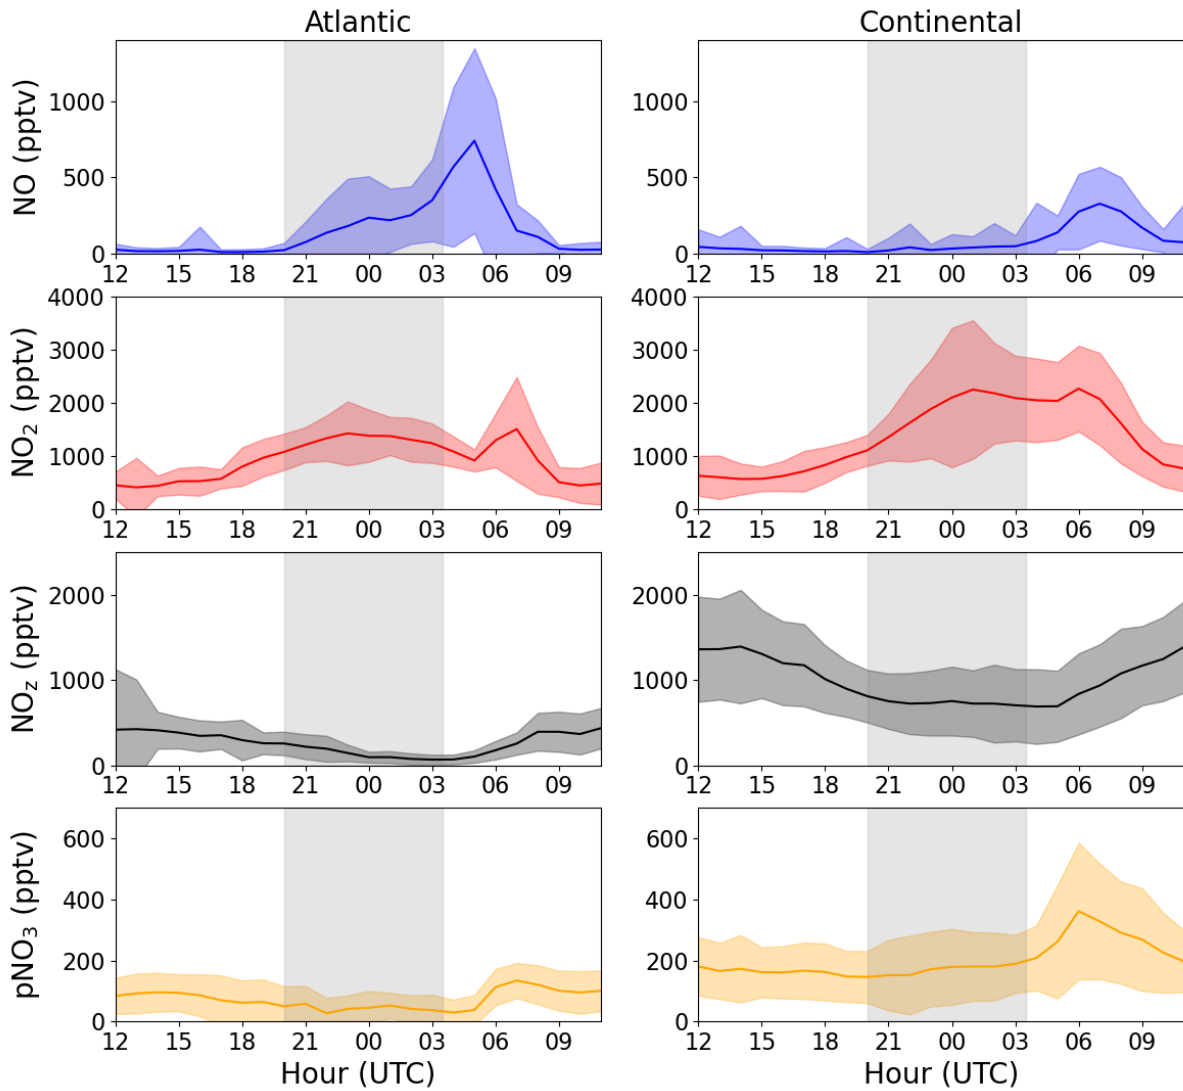

772 Figure 6: NO (top panels) and NO emission (bottom panels) plotted against soil moisture (left  
 773 panels) and temperature (right panels) at 5 cm below the surface in a box-and-whiskers plot, where  
 774 the outliers are defined as being outside  $1.5 \times \text{IQR}$ . The colours represent the two different air  
 775 masses.

776

777

778 Figure 7: Average nighttime profiles of NO<sub>2</sub> at 5.4 m for each of the two phases (black) plotted  
 779 together with the expected NO<sub>2</sub> with (grey) and without (red) NO<sub>2</sub> loss.

780

781 Figure 8: Average diel profiles of NO, NO<sub>2</sub>, total gas-phase NO<sub>z</sub>, and particulate nitrate (pNO<sub>3</sub>) at  
 782 3-6 m above ground for the Atlantic (left panels) and Continental (right panels) phases. The grey  
 783 shaded areas symbolize nighttime.

784 **12 Tables:**

785

786 Table 1: Measured NO soil emission in European forests with the same tree types as in the  
787 Rambouillet forest.

Dominant tree type	Location	NO emission ( $\mu\text{g N m}^{-2} \text{h}^{-1}$ )	Reference
Oak	Matra Mountains, Hungary	2.1	(Pilegaard et al., 2006)
		$6.0 \pm 3.3$ (summer)	(Rosenkranz et al., 2006)
		$8.4 \pm 2.4$ (autumn)	(Rosenkranz et al., 2006)
Pine	San Rossore, Italy	5.4	(Pilegaard et al., 2006)
Beech	Schottenwald, Austria	$25.5 \pm 7.5$	(Schindlbacher et al., 2004)
		4.2	(Pilegaard et al., 2006)
Beech	Klausen-Leopoldsdorf, Austria	$10.2 \pm 3.4$	(Schindlbacher et al., 2004)
		0.7	(Pilegaard et al., 2006)
Spruce-Fir-Beech	Achenkirch, Austria	$2.8 \pm 1.4$	(Schindlbacher et al., 2004)
		0.9	(Pilegaard et al., 2006)
Mixed deciduous	Ticino Park, Italy	$18.5 \pm 5.8$	(Schindlbacher et al., 2004)
		Below LOD	(Pilegaard et al., 2006)
