**Abstract.** Surface ozone monitoring sites in the tropics are limited, despite the risk that surface ozone poses to human health, tropical forest, and crop productivity. Atmospheric chemistry models allow us to assess ozone exposure in unmonitored locations and evaluate the potential influence of changing policies and climate on air quality, human health, and ecosystem integrity. Here, we utilise in situ ozone measurements from ground-based stations in the pan-tropics to evaluate ozone from the UK Earth system model, UKESM1, with a focus on remote sites. The study includes ozone data from areas with limited previous data, notably Tropical South America, central Africa, and tropical North Australia. Evaluating UKESM1 against observations beginning in 1987 onwards, we show that UKESM1 is able to capture changes in surface ozone concentration at different temporal resolutions, albeit with a systematic high bias of 18.1 nmol mol<sup>-1</sup> on average. We use the Diurnal Ozone Range (DOR) as a metric for evaluation and find that UKESM1 captures the observed DOR (mean bias of 2.7 nmol mol<sup>-1</sup> and RMSE of 7.1 nmol mol<sup>-1</sup>) and the trend in DOR with location and season. Results from this study demonstrate the applicability of hourly output from UKESM1 for human and ecosystem health-based impact assessments, increase confidence in model projections, and highlight areas that would benefit from further observations. Indeed, hourly surface ozone data has been crucial to this study, and we encourage other modelling groups to include hourly surface ozone output as a default.

## 35 1. Introduction

Surface level ozone is an air pollutant with detrimental effects on human and plant health (Emberson, 2020; Ainsworth et al., 2012), of which tropical forests are particularly important ecosystems that are vulnerable to climate change and anthropogenic disturbances (Artaxo et al., 2022, Andreae et al., 2015). Despite rising ozone precursor emissions across tropical cities (Sicard et al., 2023), and predicted damage to crop yields and tropical forest health (Kittipornkul et al., 2023; Hayes et al., 40 2020), measurements of surface ozone concentrations in tropical areas are sparse, and few pollution controls have been implemented. Models are therefore essential to provide information on ozone concentrations in areas with sparse observations and to understand the drivers of ozone formation. In addition, they are needed to evaluate intended and unintended impacts of pollution mitigation policies on air quality, human health and ecosystems and to produce more accurate assessments of future impacts. Comparison of model output to recent observations are essential to validating models and understanding biases or 45 missing processes. Here, we focus on evaluating surface ozone concentrations from the UK Earth system model, UKESM1 (Williams et al., 2018; Sellar et al., 2019; Archibald et al., 2020a; Mulcahy et al., 2020), with emphasis on remote areas of the tropics.

Data from ground-level ozone monitoring stations are commonly used to evaluate modelled surface ozone, as they provide data at a high temporal frequency whilst remaining in a fixed location (Sofen et al., 2016a). This is compared to aircraft 50 campaigns and ozonesondes, which are infrequent in time and sparse in space (Chang et al., 2020), and satellite products, which do not sample the lower troposphere well (Vieira et al., 2023). Although there are many ground-level stations in Europe, North America and East Asia allowing for detailed analysis (Chang et al., 2017; Akimoto et al., 2015; Hickman et al., 2022), there has until recently been only a limited number of stations in South America and central Africa, leaving the tropical forests almost entirely unobserved (Sofen et al., 2016b). This presents challenges to performing impact analysis in these locations, for 55 example in examining the extent that El Niño Southern Oscillation (ENSO) signals play in driving surface ozone concentrations (Sofen et al., 2016b) and in understanding ozone effects on tropical forest health (Sitch et al., 2007). Since 2019, several more monitoring stations have been set up, increasing the number of monitored tropical locations compared to previous evaluations by Young et al. (2018) and Gaudel et al. (2018) to include the Congo basin (Sibret et al., 2022), Panama and the wet tropics bioregion of northeast Queensland, Australia.

Tropospheric ozone is not emitted into the atmosphere directly. Ozone is instead formed in-situ from reactions involving 60 precursors of nitrogen oxides (NO<sub>x</sub>) and volatile organic compounds (VOCs). Ozone production can be considered NO<sub>x</sub>-limited or VOC-limited depending on which reagent is limiting the rate of ozone production (Archibald et al., 2020b; Wild and Palmer, 2008), or ozone photochemistry can be suppressed by aerosols (Ivatt et al., 2022). Whilst the remote tropics are mostly NO<sub>x</sub>-limited (Liu et al., 2022), cities can often be VOC-limited (e.g. Nakada and Urban, 2020; Dantas et al., 2020), 65 and even include conditions under which 'NO<sub>x</sub> titration' occurs, a process whereby large local sources of nitric oxide (NO) react with and thereby remove ozone. Over Southeast Asia, an aerosol-inhibited regime may be the dominant process due to high levels of particle pollution (Ivatt et al., 2022). Tropical forests have high biogenic VOC emission rates, of which the most

abundant is isoprene (Yáñez-Serrano et al., 2015), as well as more limited NO<sub>x</sub> sources, which include fires (Jaeglé et al., 2005, Pope et al., 2020), lightning (Verma et al., 2021; Bond et al., 2002) and soils (Weng et al., 2020). Many tropical locations  
70 show a strong seasonality in precursor emissions, with elevated NO<sub>x</sub> concentrations during months with high proximate biomass burning (van der A et al., 2008). The diversity of ozone regimes across the tropics and mix of natural and anthropogenic sources of ozone precursors provides a good test space for a variety of model processes (Nascimento et al., 2022).

UKESM1 is considered to have a positive bias compared to ground-level observations in the tropics, over-representing the  
75 annual mean ozone concentrations by approximately a factor of 2 (Archibald et al., 2020a, Fig. 6). A positive bias is not unique to UKESM1, with the latest evaluation of models contributing to the Coupled Model Intercomparison Project (CMIP6) reporting a multi-model mean bias of 6 nmol mol<sup>-1</sup> at the remote tropical site of Cape Matatula, American Samoa (14.2° S, 170.6° E.) (Griffiths et al., 2021). This bias is partly attributed to the coarse spatial resolution of the model (Wild and Palmer, 2008), which calculates ozone over a 1.875 x 1.25 degree horizontal and 40 m vertical resolution at the lowest model level. In  
80 reality, NO<sub>x</sub> emissions often occur as subgrid-scale plumes and ozone concentrations decline sharply towards the surface, but the coarse resolution does not allow this to be resolved and tends to cause overestimation of ozone production (Jaffe and Wigder, 2012; Pfister et al., 2006; Neal et al., 2017), for example by reducing highly localised NO<sub>x</sub> titration. Some consequences of changing resolution are indirect; Wild and Prather (2006) showed that ozone deposition rates increased at higher resolution as ozone was redistributed to areas of lower boundary layer resistance. Further causes of bias may include  
85 missing processes, incorrect/incomplete parameterisations or errors in simulation of small-scale transport and dynamics.

Although there are several model evaluations of how well Earth System Models (ESMs) capture seasonality (Young et al., 2018; Griffiths et al., 2021; Brown et al., 2022; Turnock et al., 2020) there are limited studies on the ability of ESMs to replicate the diurnal cycle (Pacifico et al., 2015). Whilst seasonal cycles are important to determine average ozone concentrations, seasonal changes in ozone regime and trends over time, hourly or sub-daily resolution are key to assessing peak and duration  
90 exposure metrics for both human health and vegetation uptake (Lefohn et al., 2018). Given the pivotal role of sunlight in ozone formation and the short lifetime of ozone at the surface, ozone concentrations vary over the diurnal cycle, typically from lower values at night, to peak values in the early afternoon (Piikki et al., 2009). For plants, this diurnal cycle directly affects stomatal ozone uptake as leaf-conductance also changes over the day (Felzer et al., 2007) with the highest stomatal conductance coinciding with the highest daytime ozone concentrations. Thus, the ability of models to reproduce the observed diurnal cycle  
95 is critical to ecosystem impact assessments.

This study evaluates UKESM1 on its ability to reproduce hourly, daily, seasonal and annual trends in ozone concentration across the tropics, with a focus on remote sites. By evaluating ozone concentrations from UKESM1 against different sites in the tropics over a range of time resolutions, we provide a starting point for further systematic evaluation of ozone-forming processes and their sensitivity in the tropics.

## 100 2. Methods

### 2.1 Station data

The monitoring station data used in this study comprise freely available data collected from the TOAR I database (Schröder, et al., 2021; Schultz et al., 2017). Further data have been provided by the CongoFlux eddy-flux tower located in Yangambi DR Congo (Sibret et al., 2022), a canopy access crane at James Cook University’s Daintree Rainforest Observatory Australia (Liddell et al., 2007), and an eddy-flux tower station located on Barro Colorado Island, Panama (Detto and Pacala, 2022). Data from 3 urban stations in Darwin, Australia are also publicly available from the Northern Territory Environment Protection Authority (<http://ntepa.webhop.net/NTEPA/>).

Monitoring stations (n=53, Table S1) are aggregated into 13 distinct sites (Fig.1) for model evaluation, of which 8 are remote. The sites are described in the Supplementary Information. We use ‘station’ to refer to an individual instrument dataset and ‘site’ to refer to the collection of station data that are combined for comparison to UKESM1. Stations were discarded if a diurnal cycle was not available. The temporal range and completeness of the data within this range are shown in Fig. S1. UKESM1 was evaluated at the gridcell level by comparing model output to the site, an average of all stations within the gridcell. Station networks that were geographically close but crossed adjacent gridcells were combined into one site and compared with the average of the corresponding grid cells: the urban air quality network in Bogotá spans 3 gridcells, São Paulo spans 2 gridcells and Jakarta spans 2 gridcells.

Data has been cleaned to remove erroneously high and low values; the highest 20 hourly values from each station were checked and data points removed if there were sudden jumps between hours that were more than double the values for the preceding and succeeding hours. This was largely to remove extreme outliers, for example, a random hourly measurement of 1000 nmol mol<sup>-1</sup> where all other data are below 200 nmol mol<sup>-1</sup> will affect the DOR. Periods of 24 hours or more with ozone values at 0 – 1 nmol mol<sup>-1</sup> were also removed since this was an indication that the instrument was not working correctly. This occurred at the Daintree and Panama sites, which had known issues with their ozone monitors.

**Table 1: Information on ozone measurement stations and sites used in this study. The first 8 rows are remote sites. Latitude and longitude refer to the gridcell centre, locations of individual stations are given in Table S1.**

## 2.2 UKESM1

130 Hourly surface ozone concentrations were modelled by UKESM1 as part of the CMIP6 historical simulations (Tang et al., 2019), a core experiment of CMIP6, that covers the historical period from 1850 to 2014 including anthropogenic, solar and volcanic forcings (Eyring et al., 2016). One of the major purposes of the experiment was model evaluation.

135 UKESM1 is a combination of the physical climate model HadGEM-GC3.1 (Williams et al., 2018) with additional Earth system components including land and atmospheric chemistry (Sellar et al., 2019). The UK Chemistry and Aerosol scheme (UKCA) contains stratospheric and tropospheric chemistry (Archibald et al., 2020a) combined with the GLOMAP-mode aerosol microphysics scheme (Mulcahy et al., 2020, 2018). The lowest vertical model level of UKESM1 represents an altitude of 0 – 40 m with a layer midpoint height of 20 m above orography/ground and the horizontal resolution is 1.25° latitude by 1.875° longitude (~140 km at mid latitudes).

140 Anthropogenic and biomass burning emissions, including the ozone precursors VOCs, NO<sub>x</sub> and CO, are prescribed at a monthly resolution (Hoesly et al., 2018; Van Marle et al., 2017). Lightning NO<sub>x</sub> is calculated using the parameterisation of Price and Rind (1992), which calculates a lightning flash density based on cloud-top height. Soil NO<sub>x</sub> is prescribed as a spatially explicit model output according to Yienger and Levy (1995), scaled to give an annual flux of 12 Tg. CH<sub>4</sub> is prescribed as

annual mean surface concentrations based on observations over the historical period (Meinshausen et al., 2017). Emissions of isoprene and monoterpenes are generated by the interactive biogenic VOC (iBVOC) emission model (Pacifico et al., 2011).

145 Other biogenic emissions are prescribed as monthly mean climatologies based on the years 2001–2010 (Sindelarova et al., 2014; Guenther et al., 2012).

UKCA includes 84 chemical tracers used to simulate chemical cycles of Ox, HOx, and NOx, as well as oxidation reactions of CO, CH<sub>4</sub>, and NMVOCs.

### 2.3 Analysis

150 This study looks in detail at remote sites (8 of 13) across the tropics (Table 1), with the rural site in Watukosek classed as remote for the purpose of this study. Urban sites (5 of 13) are also included for annual mean calculations to identify trends across sites. Where possible, years of data from UKESM1 are matched to each site, and where observations are outside of the model period, the years 2005 – 2015 are used (Table 1). As UKESM1 is free running, i.e. it simulates its own weather and climate, the meteorology in each year does not necessarily reflect the conditions at the time but should reflect the variability and the average over the decade. Archibald et al. (2020) show that the temperature sensitivity of ozone in the chemistry scheme of UKESM1 is on the order of 1 ppb K<sup>-1</sup> in the absence of feedbacks from the land surface, meaning climate trends are unlikely to cause a significant difference in ozone between the different periods. Changes in climate at the relevant sites are given in Fig. S3 and show the model period differs from the observation period by 0.5 K on average. Additionally, prescribed emissions are specific to the year, so where the modelled and observed periods do not match, there may be differences in ozone concentrations due to emissions changes. The major source of air pollution in the Darwin, Daintree and Congo sites is from biomass burning. Figure S3 shows that whilst regional biomass burning emissions are decreasing, emissions closest to the Congo and Darwin sites are increasing so it is difficult to predict how precursor emissions at each site may differ between model and observations. The error bars in Figs. 2, 3, 5 and 6 are intended to suggest how sensitive the model may be to changes in meteorology and emissions.

165 To calculate mean values in Figs. 2, 3, 5 and 6, station data are converted to a monthly climatological data composite at each site before averaging all stations within the same gridcell. This removes biases if some stations have a longer period of recording than other stations in the same gridcell, or if some months have limited measurement data. To calculate year-to-year variability, data from all stations within a site are averaged to create a monthly time series. For Figs. 2 and 3, standard deviations are then taken using annual means for years with 11 or more months of data, regardless of the number of stations contributing.

170 For Figs. 5 and 6, standard deviations are taken for each month. Figure S2 shows the total number of days of data contributing to the analysis in each month. Diurnal cycle data from the TOAR I database is only available as a monthly mean climatology, so no standard deviation is available for the observations in Figs. 3 and 6 for these sites. To evaluate how well UKESM1 captures trends among sites or months, we calculate a Pearson's coefficient of determination ( $r^2$ ) and/or root mean square error (RMSE).

175 This study applies the Diurnal Ozone Range (DOR) metric to quantitatively evaluate the model's ability to capture the increase  
in ozone concentration during the day compared to the night at different locations and seasons (Piikki et al., 2009). The DOR  
is the difference between the minimum and maximum ozone concentrations measured over a diurnal cycle. Although the time  
that the minimum and maximum occur varies with season and latitude, the DOR is independent of the time of these  
minima/maxima. Studies in remote locations have shown that the DOR is related to the diurnal temperature range and is highest  
180 inland, lower to the ground and in valleys (Klingberg et al., 2012). For example, above the canopy, ozone concentrations tend  
to show less diurnal variation than closer to the canopy; downdrafts of ozone from the free troposphere occur throughout the  
night because of a contracted planetary boundary layer (PBL), and there are fewer deposition processes than within the canopy,  
leading to higher ozone concentrations overnight and therefore less diurnal variability. In polluted regions, the DOR can also  
depend on entrainment and circulation of ozone-rich air masses (Klumpp et al., 2006). The ability of UKESM1 to capture the  
185 DOR reflects the ability of the model to accurately reproduce the diurnal ozone cycle for varying environmental conditions.

### 3. Results

#### 3.1 Average ozone concentrations at each site

UKESM1 overestimates ozone concentrations at all sites by an average of 18.1 nmol mol<sup>-1</sup>, a factor of 2, but the bias varies  
from 8.8 nmol mol<sup>-1</sup> to 33.2 nmol mol<sup>-1</sup> across sites (Fig. 2). The positive bias indicates that UKESM1 overestimates ozone  
190 concentrations at surface level where it is relevant to human and ecosystem health.

Despite the positive bias, UKESM1 captures the relationship in average ozone concentrations between sites, except in  
Indonesia (Fig. 2b). Excluding Bukit Koto, Jakarta and Watukosek, the mean bias is 13.0 ( $r^2 = 0.61$ ,  $p = 0.01$ ). Grouping by  
region, the mean bias (and mean % bias) in South America is 12.1 nmol mol<sup>-1</sup> (91.2 %), in Indonesia is 28.5 nmol mol<sup>-1</sup> (212.5  
)%, in Australia is 12.4 nmol mol<sup>-1</sup> (60.0 %), and in Africa is 11.1 nmol mol<sup>-1</sup> (70.9 %). The limited number of sites in each  
195 region creates uncertainty in the regional pattern, but from the data available, the bias in Indonesia is significantly different to  
the other sites ( $p = 0.0001$  when using a student's t-test to compare the bias for sites in Indonesia against all other sites). There  
are no statistically significant differences between the magnitudes of the bias in remote compared to urban areas when groups  
are compared using a student's t-test, nor a significant correlation between the magnitude of the ozone concentration and the  
bias. The observed annual means are within a range of 5 to 25 nmol mol<sup>-1</sup>, with 11 of the 13 sites within a range of 10 to 20  
200 nmol mol<sup>-1</sup> whereas annual means in UKESM1 range from 20 to 50 nmol mol<sup>-1</sup>.

205 **Figure 2: Mean annual ozone concentration at each site compared to in the corresponding gridcell of UKESM1 (a) for each site and (b) showing the correlation between model and observations. Bars represent 1 standard deviations using annual means. Missing bars in the observations are due to insufficient data.**

### 3.2 The diurnal cycle of ozone at remote sites

Analysis of the diurnal cycle reveals that the positive bias in the annual mean is due to a systematic overestimation of ozone concentrations across all hours of the day, so UKESM1 performs similarly during day and night (Fig. S4). As expected, UKESM1 predicts an increase in ozone concentrations at sunrise, a peak in the mid-afternoon and decline into the night, although the exact shape of the diurnal cycle varies at each site. At Daintree, for example, night-time ozone concentrations drop by only a few nmol mol<sup>-1</sup> whereas at Watukosek the annual mean diurnal cycle ranges from 4.2 nmol mol<sup>-1</sup> to 30.9 nmol mol<sup>-1</sup> (Fig. S4). Qualitatively, UKESM1 captures the trends in the diurnal cycle at the Amazon sites (Fig. S4a – S4c) and the Congo site (Fig. S4d) but performs less well at the Daintree site (Fig. S4g). The very shallow diurnal cycles modelled at Daintree and Panama is likely due to the coastal nature of the site. The ozone deposition rate over ocean is low, which results in a diminished diurnal variation because ozone is not removed efficiently overnight.

To quantify whether the model is able to capture the magnitude of the changes in diurnal cycle, we examine the DOR from each site (Fig. 3). The observations show an average DOR of 17.1 nmol mol<sup>-1</sup> with individual sites ranging from 2.2 nmol mol<sup>-1</sup> at the Daintree site to 30.3 nmol mol<sup>-1</sup> at the São Paulo site (Fig. S3a). Comparing the annual mean DOR between model and observation, we confirm that UKESM1 is able to capture the DOR with high accuracy. The mean bias is 2.7 nmol mol<sup>-1</sup> with a range of -11.6 to 15.1 nmol mol<sup>-1</sup> across different sites so, unlike the absolute ozone concentrations, UKESM1 does not exhibit a systematic high bias in the DOR (Fig. S3b). As a percentage, the mean bias across all sites is 16.0 % and UKESM1 is also able to capture the differences in the DOR between sites ( $r^2 = 0.64$ ,  $p=0.005$ ). The overall RMSE of 7.1 nmol mol<sup>-1</sup> over

all sites is largely driven by urban sites Jakarta and Darwin, whereas selecting only remote sites gives an RMSE of 4.8 nmol  
 225 mol<sup>-1</sup>.

230 **Figure 3: Mean Diurnal Ozone Range (DOR) at each site compared to in the corresponding gridcell of UKESM1 (a) for each site and (b) showing the correlation between model and observations. Bars represent 1 standard deviations using annual means. Missing**  
 235 **bars in the observations are due to insufficient data.**

We also validate whether the model captures the time of maxima and minima in the diurnal cycle (Fig. 4). To the nearest hour,  
 the minimum value occurs slightly earlier than observed and the maximum occurs later. The Bukit Koto and Daintree sites  
 235 have a diurnal cycle with a small amplitude (Fig. S4e, S4g), which causes the minimum hour to be misrepresented, but at all  
 other sites the model and observations differ by 2 hours or less (Fig. 4).

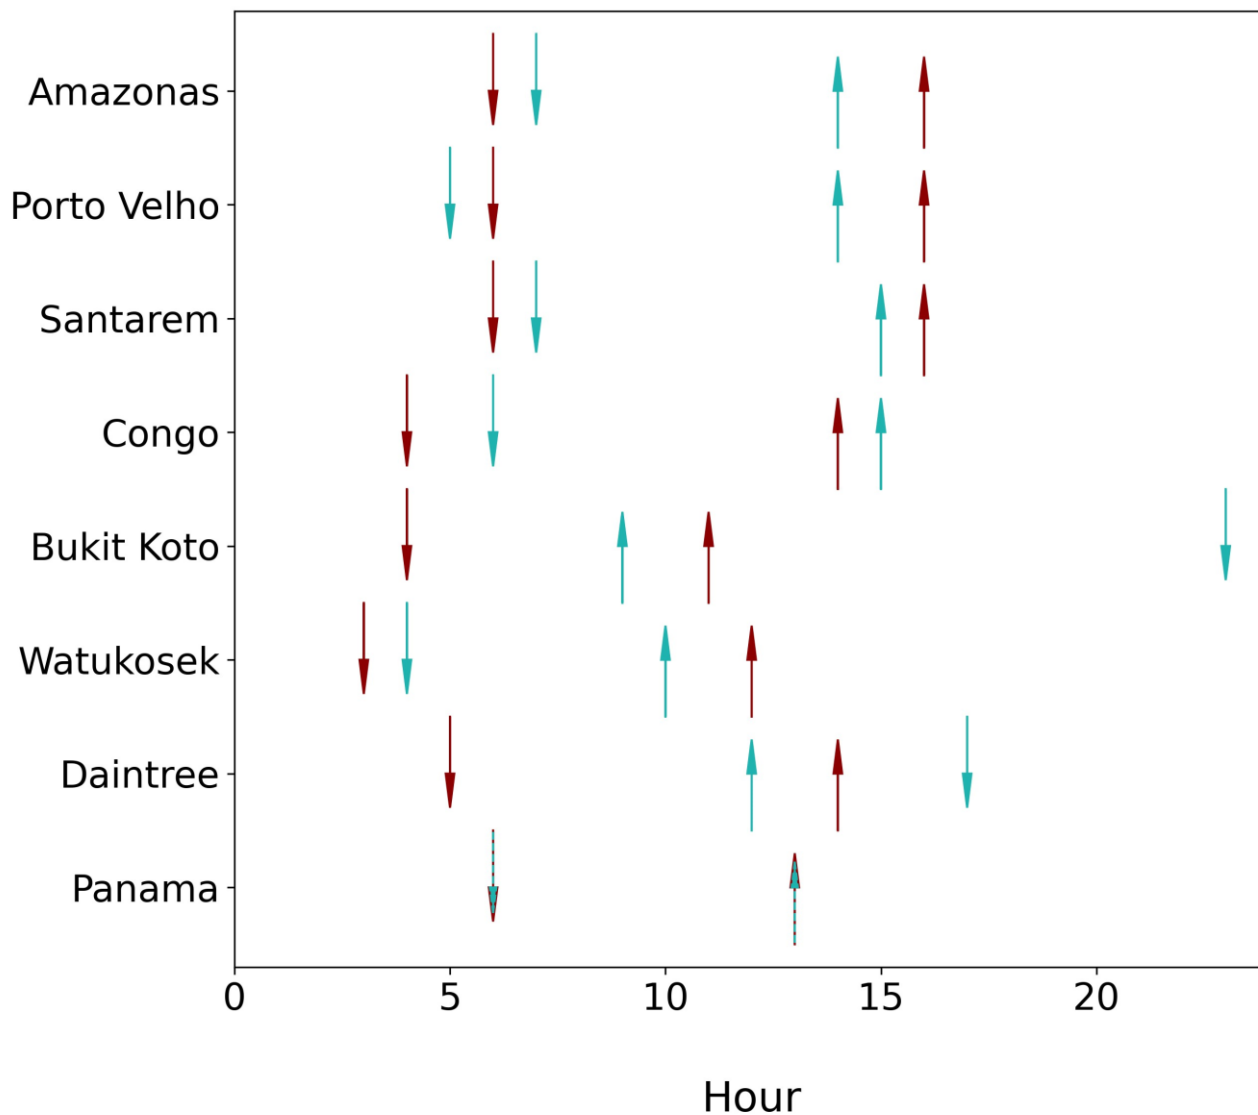

Figure 4: The hours in the diurnal cycle that show the minimum (down arrow) and maximum (up arrow) ozone concentrations from observations (blue) and UKESM1 (red). The minimum and maximum values at the Panama site are the same for both observations and UKESM1.

240

### 3.3 Daily ozone variation

Figure S5 shows a histogram of the monthly detrended daily mean ozone concentration. A broader distribution indicates higher variability in day-to-day ozone anomalies. Most remote sites show daily deviations of up to 10 nmol mol<sup>-1</sup> from the monthly mean and a few (Congo, Watukosek and Bukit Koto) show days with ca. 20 nmol mol<sup>-1</sup> differences compared to the monthly

245 mean (Fig. S5c, S5d, S5e). UKESM1 overestimates the frequency of these events at Bukit Koto and Watukosek, as well as in Porto Velho (Fig. S5b, S5d, S5e).

Comparing the standard deviation, skew and kurtosis of the daily distribution plots, UKESM1 reproduces the variability in daily ozone concentration in several locations (Table S2). The model standard deviation is within 50 % of observations at 9 out of 13 sites, but is overestimated at Bukit Koto, Watukosek, Porto Velho and São Paulo. Some patterns in the standard deviation between sites are captured, such as the broader distribution in Africa compared to South America but, the overall relationship between different sites does not resemble observations ( $r^2 = 0.34$ ,  $p=0.05$ ). The kurtosis describes the tailedness of the distribution; positive values indicate a higher number of days with large deviations from the monthly mean compared to a normal distribution. UKESM1 tends to overestimate the kurtosis of the distributions, exemplified at the Porto Velho site (Fig. S5b). The skew describes whether the distribution is shifted to one side relative to the zero value. The observational data shows that a positive skew is present at all the sites except the Daintree site, indicating that events with substantially higher ozone than the monthly mean are more common than events with substantially lower ozone. UKESM1 displays a positive skew of a similar magnitude to that observed at all sites (a mean of 0.58 compared to 0.66 in observations) but cannot capture the relationship between sites ( $r^2 = 0.07$ ,  $p=0.39$ ).

### 3.4 The seasonal ozone cycle at remote sites

260 As with the diurnal cycle, UKESM1 captures the seasonal cycle at several sites (Fig. 5) but overestimates ozone concentrations in absolute terms (RMSE = 18.5 nmol mol<sup>-1</sup>). Often, the monthly means predicted by UKESM1 are greater than the daily maximum ozone recorded in each month (Fig. 5, blue dots).

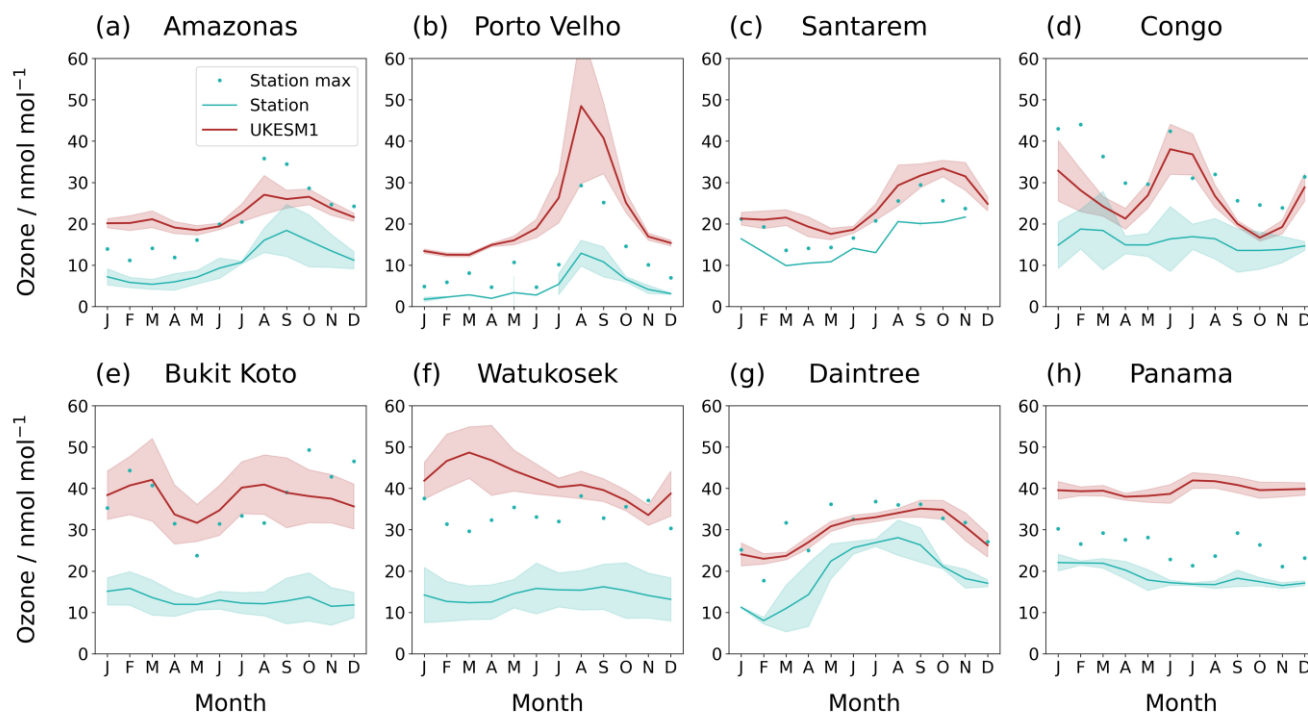

In South America (Fig. 5a – 5c), UKESM1 correctly captures an increase in ozone concentrations during biomass burning months July – October, however the increase is overestimated at the Porto Velho site. Porto Velho, in the arc of deforestation, records concentrations of less than 5 nmol mol<sup>-1</sup> during the wet season (December – May), lower than other sites in South America, followed by an increase to 12.9 nmol mol<sup>-1</sup> during the burning season. UKESM1 captures this trend but the magnitude of the increase in the burning season is 4 times larger than observed.

In Africa, the biomass burning season occurs in June – July in central Africa, and December – February in northern Africa. The Congo site sits between these biomass burning areas and ozone is expected to be transported to the site by seasonal circulation patterns. UKESM1 predicts much larger increases in ozone concentration during these months than is observed at the Congo site (Fig. 5d); the range of observed monthly means is 5.2 nmol mol<sup>-1</sup> compared to 21.4 nmol mol<sup>-1</sup> in the model. Surprisingly, the seasonal pattern predicted by UKESM1 is similar to the measured daily maximum ozone concentration in each month, which have a range of 20.1 nmol mol<sup>-1</sup> (from 23.9 nmol mol<sup>-1</sup> to 44.0 nmol mol<sup>-1</sup>; Fig. 5d, blue dots). This suggests that, although ozone concentrations can be much higher on specific days during biomass burning seasons compared to other months, these high ozone events are not frequent enough to generate the large seasonal variation predicted by UKESM1. Similar features are seen at the Bukit Koto site in Indonesia (Fig. 5e); UKESM1 predicts a seasonal cycle that follows the

variation in the observed daily maximum, which was  $23.8 \text{ nmol mol}^{-1}$  in May but reached  $49.3 \text{ nmol mol}^{-1}$  in October, rather than the monthly means, which are below  $20 \text{ nmol mol}^{-1}$ .

The bias at the Bukit Koto, Congo and Porto Velho sites may be considered as factors rather than absolute values, meaning the modelled seasonal cycle has larger monthly changes in ozone than the observations. Applying a bias correction multiplier of 0.33, 0.55 and 0.25 for Bukit Koto, Congo and Porto Velho, respectively, brings the magnitude of the monthly means and the seasonal variation closer to observations (Fig. S6). The seasonal cycle at these sites is dominated by changes in biomass burning, suggesting that the model overestimates ozone formed from burning due to either incorrect emissions or process representation. At the other remote sites, the bias is consistent between months and therefore the annual means in Fig. 2 represent the biases sufficiently well, or the seasonal cycle is not well represented. In these cases, scaling the model output as in Fig. S6 does not improve the match to observations.

At Watukosek, the seasonal cycle from UKESM1 is completely different to observations (Fig. 5f), where monthly mean ozone concentrations are between 10 and  $20 \text{ nmol mol}^{-1}$  with only a small seasonal variation. Analysis of the surrounding area shows that the observed seasonal trend is captured by UKESM1 in adjacent ocean gridcells to the south (Fig. S7). The gridcell chosen contains the measurement station, but also the city of Surabaya, whereas the station may only be recording clean air outside of the city and therefore would be better represented by an adjacent gridcell.

**Figure 5: Mean monthly ozone concentration at each station (blue solid line) compared to in the corresponding gridcell of UKESM1 (red solid line). Shading covers 1 standard deviation. Blue circles indicate the maximum ozone concentration recorded in each month using daily means.**

Figure 6 shows the seasonal cycle in the DOR, which is captured more accurately at remote sites than the monthly mean ozone concentrations ( $r^2 = 0.56$ ,  $p=4 \times 10^{-18}$  and  $RMSE = 6.3 \text{ nmol mol}^{-1}$ ), indicating that the relative change in ozone concentration over the day is well represented by UKESM1 across different seasons.

At Porto Velho, the seasonal cycle in the DOR is captured significantly better than the monthly means (Fig. 5b) but UKESM1 still has a positive bias of  $6.0 \text{ nmol mol}^{-1}$ , with the largest overestimation of  $16.9 \text{ nmol mol}^{-1}$  occurring in biomass burning months August and September (Fig. 6b). However, the standard deviation (shading) is large during August – September in model and observations so is clearly very sensitive to yearly variability.

Similarly, at the Congo site, the observed seasonal variation of  $14.3 \text{ nmol mol}^{-1}$  to  $25.0 \text{ nmol mol}^{-1}$  is still overestimated by UKESM1 during the June – July biomass burning months, giving a modelled seasonal variation of  $14.3 \text{ nmol mol}^{-1}$  to  $31.9 \text{ nmol mol}^{-1}$  (Fig. 6d). This is improved compared to the monthly mean concentrations, but again highlights biomass burning months as periods with worse model performance.

At Bukit Koto, there is very little variation in the DOR by month, and UKESM1 overestimates by  $5.1$  to  $10.6 \text{ nmol mol}^{-1}$  (Fig. 6e). As with the monthly means, the model fails to capture the seasonal cycle in the DOR at Watukosek, displaying a very different pattern in April – August compared to the observed DOR (Fig. 6f).

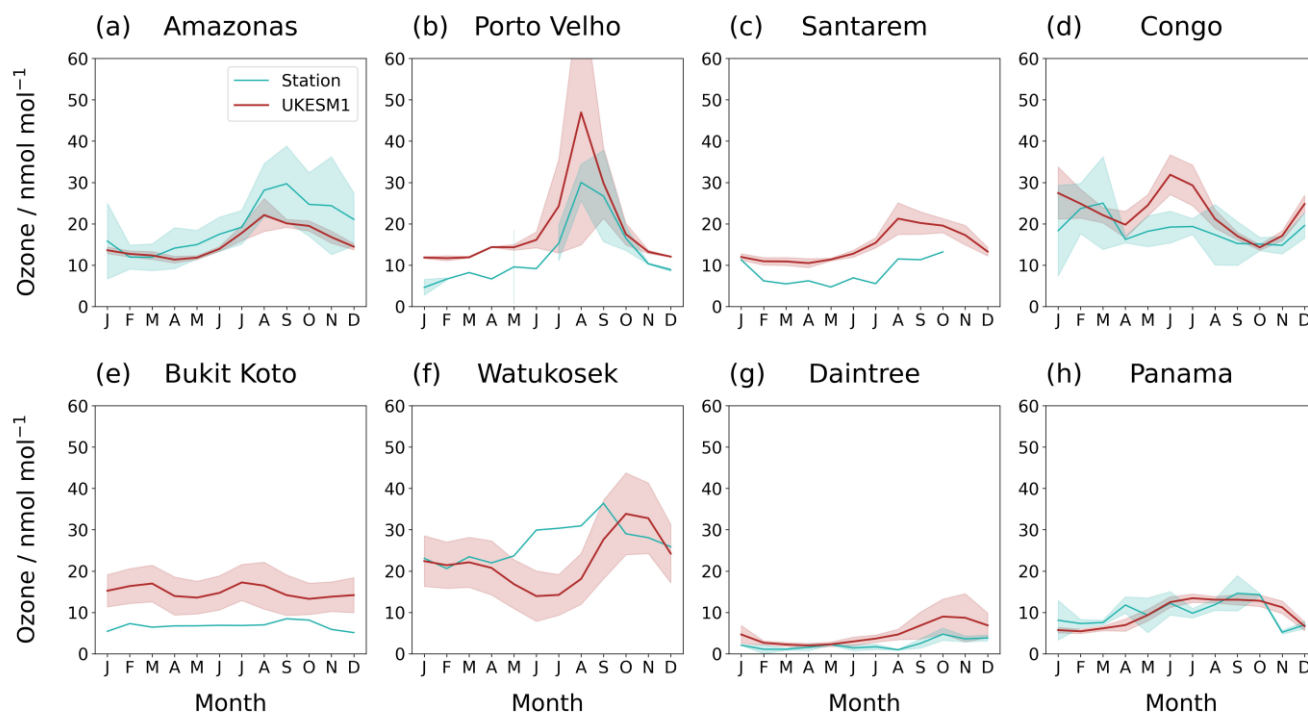

Figure 6: Mean monthly Diurnal Ozone Range (DOR) at each station (blue solid line) compared to in the corresponding gridcell of UKESM1 (red solid line). Shading covers 1 standard deviation except at the TOAR I sites (Santarem, Bukit Koto, Watukosek) where diurnal cycle data was only available as a monthly climatology.

## 4. Discussion

### 4.1 Does UKESM1 reproduce surface ozone in the tropics?

UKESM1 overestimates ozone in the tropics by a mean of  $18.1 \text{ nmol mol}^{-1}$  at 13 sites (Fig. 2) covering environments such as remote forests, urban areas and coastal locations (Fig. 1). In relative terms, we find that UKESM1 overestimates ozone concentrations by ca. a factor of 2, in agreement with Archibald et al. (2020). The pattern in ozone concentrations among sites are captured reasonably well although there is a large bias ( $+28.5 \text{ nmol mol}^{-1}$ ) at the Indonesian sites (Watukosek, Jakarta, Bukit Koto). More promisingly, the Diurnal Ozone Range (DOR) is reproduced with much smaller biases (RMSE =  $7.1 \text{ nmol mol}^{-1}$ ) (Fig. 3) and seasonal patterns in the DOR are captured at most remote sites (Fig. 6). In conjunction with a good representation of the shape of the diurnal cycle (Fig. 4, Fig. S4), the ability to model the DOR shows that UKESM1 can reproduce the increase in ozone concentration from its night-time minimum, including how it changes with season and location. This gives confidence in the ability of UKESM1 to represent the behaviour of surface ozone in the tropics.

From comparison of the seasonal cycle, we show that the bias at remote sites is largest during biomass burning seasons (Fig. 5) and bias correction at sites where the seasonal cycle is controlled by biomass burning was best applied by using a scaling factor, whereas at other sites the bias is a constant value across all months (Fig. 5, Fig. S6). Similarly, although UKESM1 reproduces the seasonal cycle in the DOR at remote sites (RMSE =  $6.3 \text{ nmol mol}^{-1}$ ), performance is worse during months strongly impacted by biomass burning. This is true at both the Porto Velho and the Congo sites, possibly indicating that either the emission factors or the altitude of emission from biomass burning is incorrect in the model. Regardless, the magnitude of the seasonal cycle is captured better in the DOR than the absolute ozone concentrations. This suggests that there is a systematic error, for example from an incorrect emission factor, a missing process or unresolved subgrid-scale processes, and further work is needed to identify the cause of the systematic bias. Causes of model bias are discussed in more detail in Sect. 4.2 and 4.3.

### 4.2 Resolution as a cause of model bias

The coarse resolution of UKESM1 provides a different type of information when comparing a gridcell average to only a few measurement stations. Station measurements may not be representative of the gridcell as a whole, especially if there is spatial heterogeneity in precursor sources or meteorological features (e.g., from mountains) within the gridcell (Young et al., 2018). Many sites in this study have a limited duration of measurements and contain only one measurement station (Table 1), exacerbating the discrepancy between model and observations without necessarily indicating a model weakness (Schutgens et al., 2017). In several cases, observations were only available outside of the model time range, which ended in 2014. Although the meteorology is shown to be representative of the present day, prescribed emissions such as those from biomass burning are not identical between model and observations (Fig. S3), which is especially important if there is a trend over time. Lack of long term monitoring means that there is no clear idea of temporal trends in surface ozone concentrations in the tropics, although observations at American Samoa do not detect any significant change in background ozone over the period 1975 to

2014 (Griffiths et al., 2020). At the site level, local changes in emissions such as decreasing fire activity in African savannah and increasing deforestation fires (van Marle et al., 2017) are likely to cause some differences between model and observations.  
350 Continued monitoring and evaluation of ozone concentrations at recently established stations will be instrumental to furthering understanding of ozone in the tropics.

To demonstrate how ozone concentrations can vary considerably within a gridcell, we can use the Amazonas site as an example. This site contains 4 monitoring stations, among which the average ozone concentration differs from the gridcell average by 9.2 % to 23.3 % and individual monthly mean values vary by up to 94.9 % from the gridcell monthly mean (Fig. S8). These differences can come from the altitude of the measurement station as well as numerous other reasons including proximity to precursor emissions sources, prevailing air flow direction and surface type. At the Amazonas site, stations T2 and T3 are in clearings close to the ground and downwind of Manaus city, whereas T0z is above the canopy and upwind of Manaus. As ozone concentrations decrease rapidly within the canopy (Sörgel et al., 2020), measurement stations capturing air that has been depleted of ozone from in-canopy loss processes are incongruous with model data, which represent ozone concentrations above the canopy. In general, measurement stations are located above the canopy, although future studies may consider adjusting modelled concentrations to match the measurement height more precisely.

Several sites in this study are coastal (the model gridcell is split between ocean and land). Due to a low deposition velocity of ozone over water (Sarwar et al., 2016; Luhar et al., 2018) and limited oceanic emission sources, concentrations of ozone over the ocean in UKESM1 are  $\sim 20 \text{ nmol mol}^{-1}$ , and minimal diurnal variation is present. The gridcell chemistry and deposition velocities along coasts will be an average of the land and ocean, implying that the gridcell ozone concentration may not be representative of the site and the DOR is likely to be lower.

The resolution of UKESM1 can also introduce biases because emissions that, in reality, often occur as small, concentrated plumes are spread homogeneously across the whole gridcell volume. The formation of ozone depends critically on relative concentrations of precursors, so this effect can dramatically change rates of production and loss (e.g. Archibald et al., 2020). Dilution of NO<sub>x</sub> spatially and temporally due to coarse resolution can increase its ozone production efficiency and alter its lifetime (Wild and Prather, 2006; Chatfield and Delany, 1990). In the horizontal, Wild and Prather (2006) show that diluting point sources of NO<sub>x</sub> over a large gridcell can bring NO<sub>x</sub> into contact with BVOCs more immediately as the separation of clean and polluted regions is unable to be resolved. In the vertical, coarse resolution can prevent build-up of NO<sub>x</sub> at the surface, which decreases surface deposition processes and NO<sub>x</sub> titration (Nassar et al., 2009; Chatfield and Delany, 1990). Both processes lead to increased ozone concentrations in source regions, so it is likely that coarse resolution partially contributes to the larger biases in biomass burning regions (Fig. 4b). In this simulation, NO<sub>x</sub> emissions (except from interactive lightning) are provided as monthly means, thereby also diluting emissions over time, which has been similarly shown to increase ozone production (Chatfield and Delany, 1990). Changes in temporal resolution may be more pronounced for emissions with high temporal variability such as biomass burning. On the other hand, prescribing monthly emissions of NO<sub>x</sub> did not seem to reduce the ability of UKESM1 to simulate the daily variability in ozone (Fig. S5, Table S2), which is governed by interactive processes including BVOC emissions, lightning NO<sub>x</sub> and meteorology. This emphasises that interactive natural precursor sources are

highly important for tropical ozone formation, with BVOCs dominating tropical forest emissions and intense lightning activity occurring in several areas, especially near the Congo site in central Africa.

#### 4.3 Knowledge gaps as a cause of model bias

385 To calculate ozone concentrations, chemistry models must necessarily parameterise and simplify the atmospheric chemistry and deposition processes that lead to ozone formation. This includes, among other simplifications, grouping VOCs by their size, reactivity or functional groups and parameterising stomatal and non-stomatal deposition (Hardacre et al., 2015; Archibald et al., 2020a). A semi-mechanistic process in UKESM1 determines biogenic emissions of isoprene and monoterpenes (Pacifico et al., 2012) which, although it agrees with the global average estimate (Sindelarova et al., 2022), is poorly constrained by  
390 observations. To lead to ozone formation, isoprene undergoes several other chemical reactions. This process has considerable uncertainty, especially with regards to recycling of OH and NO<sub>x</sub> (Lee et al., 2013; Fiore et al., 2005), and is challenging to validate (Schwantes et al., 2020; Horowitz et al., 2007). Furthermore, the reactions determining the fate of isoprene and other VOCs are too numerous, and the lack of detailed reaction-kinetic information is an obstacle to include them explicitly in the model (Archibald et al., 2010). However, studies which include a more detailed suite of organic oxidation products and explicit  
395 HO<sub>x</sub> recycling mechanisms have been shown to further increase the bias in UKESM1, especially over tropical forests, suggesting this bias is due to other processes (Archer-Nicholls et al., 2021; Weber et al., 2021).

As for NO<sub>x</sub>, it is possible that UKESM1 overestimates NO<sub>x</sub> concentrations in the boundary layer as NO<sub>x</sub> is injected at the surface rather than at different vertical levels, with the exception of aircraft emissions (Archibald et al., 2020a). Leung et al., (2007) show that varying injection altitudes of biomass burning emissions resulted in increases in ozone further above the PBL  
400 and greater transport of NO<sub>x</sub> to remote regions. Comparing to our study, ozonesondes at Watukosek record lower tropospheric ozone concentrations greater than 60 nmol mol<sup>-1</sup> during biomass burning season (Adedeji et al., 2020; Komala et al., 1996), which is similar to the ozone concentrations predicted by UKESM1 but larger than the measurement station (10 – 20 nmol mol<sup>-1</sup>) (Fig. 5f). However, there are many other uncertainties associated with biomass burning such as emission factors of both NO<sub>x</sub> and organic compounds (Schultz et al., 2008), and subsequent chemistry (Young et al., 2018) that may contribute to  
405 biases. The NO<sub>x</sub> emission factors for savannah and grassland fires used in CMIP6 (van Marle et al., 2017) are at the upper end of the range used by other inventories (Jin et al., 2021) and isoprene emission factors from C4 grasses are likely to have been overestimated in this set up of UKESM1 (Weber et al., 2023). An overestimation of either or both of these factors could contribute to model bias during biomass burning seasons, especially in the Congo where most burning occurs in the savannah biome, and are likely to be adapted for CMIP7.

410 Uncertainty in emissions is especially high for peat fires (Nassar et al., 2009; Christian et al., 2003), which drive the seasonal cycle in NO<sub>x</sub> and can make up the majority of fire emissions in southeast Asia (Gaveau et al., 2014) but are poorly represented in the model. In fact, UKESM1 did not perform well in Indonesia against most metrics used in this study. Further analysis of the surrounding gridcells showed large variation in the magnitude and pattern of the seasonal cycle between adjacent gridcells (Fig. S7). In Watukosek, for example, the measured seasonal cycle shows a similar pattern to the cycle over the ocean gridcells,

415 which is quite different from the pattern over land. It is likely that the station is exposed to ocean air masses whereas the gridcell contains anthropogenic emissions that change the seasonal pattern. Indonesia is a mosaic of agriculture, forest and dense megacities, in addition to having a complex meteorology affected by summer monsoon circulation, ENSO and outflow from continental Asia (biomass burning in February – April) (Permadi and Oanh, 2021). A more detailed analysis of these separate processes and their representation in UKESM1 is needed to understand the cause of the model errors.

#### 420 **4.4 Improving understanding of surface ozone in the tropics**

For this evaluation, we have synthesised real-world tropical surface ozone concentrations from more sites than previously available in the literature. Whilst modelled ozone concentrations are necessary for a range of applications, the existing observational data already reveals that surface ozone in the tropics may already be crossing safe thresholds for vegetation and human health. Although annual mean ozone concentrations are below  $20 \text{ nmol mol}^{-1}$  at all sites (Fig. 2), we show that there is large variability in ozone concentrations that can exceed  $40 \text{ nmol mol}^{-1}$  at times, even in remote tropical forests (Fig. 5). Daily mean ozone concentrations can vary by up to  $20 \text{ nmol mol}^{-1}$  from the monthly mean at the Indonesian sites and in the Congo (Fig. S5), with the highest daily mean values being more than double the monthly mean at the Amazonas, Congo, Bukit Koto and Watukosek sites (Fig. 5). In absolute terms, daily means greater than  $30 \text{ nmol mol}^{-1}$  were recorded at all sites except Santarem and the annual mean diurnal cycle peaks at over  $30 \text{ nmol mol}^{-1}$  on average at Watukosek (Fig. S4), Jakarta and Bogotá (not shown). Furthermore, over the course of a day, ozone concentrations vary by over  $20 \text{ nmol mol}^{-1}$  on average at the Watukosek, Jakarta, São Paulo and Bogotá sites (Fig. 3, Fig. S4), meaning that ozone concentrations during daylight hours are higher than annual, monthly or daily means represent. This increases the risk to ecosystems, demonstrated by Cheesman et al. (2023) who have shown that using hourly data instead of monthly means can increase modelled stomatal ozone uptake by 40 %. Since our study focuses on remote sites, further research is needed to evaluate the human health impacts at urban sites. Clearly, more studies and greater monitoring is needed to evaluate the human and ecosystem impacts in these globally important regions, with emphasis on maintaining existing sites for trend analysis and more robust datasets.

To increase understanding of ozone in the tropics, we identify a gap in monitoring of the savannah/grassland regions such as Northern and Central Africa, and Cerrado, the savannah region in Brazil. In general, Africa is underrepresented by monitoring stations, despite large variation across the continent from growing cities and seasonal variation in biomass burning and circulation. Increased monitoring of ozone over areas with large populations and of ecological importance would significantly help in assessing the environmental risk factors to human and plant health across.

Areas with poor model performance, large intermodel spread and high uncertainty in future trends would also benefit from increased observational data to help constrain model predictions. In this study, UKESM1 performed worst over Indonesia, an area previously identified as having a high intermodel standard deviation in ozone concentration (Young et al., 2013). Previous studies have also identified Southern Africa as an area of high future uncertainty due to intermodel variation of surface ozone changes in response to climate change (Brown et al., 2022) and precursor emissions (Turnock et al., 2020).

## 5. Conclusion

We show that UKESM1 can capture observed variability in surface ozone concentrations across the tropics such as increased ozone over the diurnal cycle, and during biomass burning seasons. However, UKESM1 overestimates surface ozone concentrations by a factor of 2 on average. The mean bias is  $18.1 \text{ nmol mol}^{-1}$  but this varies with location and season, with the largest positive bias of  $28.5 \text{ nmol mol}^{-1}$  occurring in Indonesia. In other locations, biases are generally largest during biomass burning seasons, which suggests emission factors from fires may need to be revised. Coarse resolution may also be responsible for some of the bias, and future studies should aim to quantify the contribution attributed to coarse resolution in order to better identify model deficiencies. Biases are substantially smaller in the Diurnal Ozone Range (DOR); UKESM1 reproduces the DOR, which represents the change in ozone concentration over the diurnal cycle, with a mean bias of  $2.7 \text{ nmol mol}^{-1}$  (15.9 %) including how it varies seasonally (RMSE =  $6.3 \text{ nmol mol}^{-1}$ ). Overall, this suggests that hourly data from models such as UKESM1 could be used for health and ecosystem impact assessments, although these may require bias correcting depending on the purpose. The magnitude of the bias in different regions and seasons, and its dependence on factors such as distance from emissions sources remains to be quantified. For this, more in situ monitoring and is instrumental.

Furthermore, the observed ozone concentrations show that tropical ozone concentrations are highly variable in space and time. Ozone concentrations on individual days can be double the monthly mean concentration, in addition to DORs that are regularly greater than  $20 \text{ nmol mol}^{-1}$  at both urban and remote sites. Further studies on human and ecosystem risks in the tropics are required and we encourage the inclusion of hourly surface ozone output from all models as a default option.

## Data availability

Processed data used to make the figures are available at DOI : [10.5281/zenodo.10252771](https://doi.org/10.5281/zenodo.10252771).

Data from UKESM1 is available from ESGF (<https://esgf-node.llnl.gov/search/cmip6/>)

The original data is also publically available for many sites:

Data for the Sao Paulo, Bukit Koto, Watukosek, Jakarta, Amazonas, Bogota, Santarem and San Lorenzo sites are available on the TOAR I database (<https://join.fz-juelich.de/>)

Data for Darwin is available at AQI (<https://www.aqi.in/uk/dashboard/australia/northern-territory/darwin>)
