10 **Abstract**

11 A lot of radionuclides were released into the environment from Fukushima Daiichi  
12 Nuclear Power Plant (FDNPP) accident on March 11, 2011. Because of the long half-life  
13 (30.12 years) and high-concentration deposition about  $^{137}\text{Cs}$ , the study regarding on the  
14 distribution of  $^{137}\text{Cs}$  in aerosol samples and the understanding carriers of  $^{137}\text{Cs}$  became a hot  
15 topic in the recent decade. However, even nine years after FDNPP accident, the explanation  
16 for the fluctuations of  $^{137}\text{Cs}$  and their carriers in the atmosphere remains elusive. In this study,  
17 a small fluctuation within  $0.0002 \text{ Bqm}^{-3}$  from January to April and a slightly higher level of  
18 atmospheric  $^{137}\text{Cs}$  from May to September was still observed in the aerosol samples obtained  
19 in Namie in a heavily contaminated area of Fukushima prefecture in 2019. Therefore, new  
20 observations, obtaining by fluorescent upright microscope and scanning electron  
21 microscopes (SEM) equipped with an energy dispersive X-ray spectrometer (EDS),  
22 quantitatively demonstrated that the carriers of  $^{137}\text{Cs}$  were the combination of C-particles and  
23 Al-particles (Al-particles was dominated with the percentage of 68%) in early May;  
24 meanwhile the predominate carriers of  $^{137}\text{Cs}$  were carbonaceous particles with the average

25 percentage of 88% in late May and September. Significantly, small particles (less than 2  $\mu\text{m}$ )  
26 and medium particles (2-8  $\mu\text{m}$ ) of carbonaceous particles had a higher level in the aerosol  
27 samples of May and September. Specially, little particles (less than 1  $\mu\text{m}$ ), bacteria (1-1.8  
28  $\mu\text{m}$ ), and spores (1.8-10  $\mu\text{m}$ ) had a linear relationship with the distribution of atmospheric  
29  $^{137}\text{Cs}$  in the aerosol samples of September. In addition, the temperature and the precipitation  
30 were the main impact factors on the distribution of  $^{137}\text{Cs}$  and its carriers.

## 31 **1 Introduction**

### 32 **1.1 The Fukushima Daiichi Nuclear Power Plant accident**

33 The Fukushima Daiichi Nuclear Power Plant (hereinafter referred to as FDNPP, 37°25'  
34 N, 141°02' E, which is located on the north-eastern Pacific Ocean coast of Honshu, about  
35 200 km far from north-east of Tokyo) was one of the nuclear power plants of the Tokyo  
36 Electric Power Holding Company (TEPCO). At 14:46 on March 11, 2011, a large-scale  
37 earthquake (also named as the Great East Japan Earthquake) with a magnitude of 9.0 occurred  
38 in the Tohoku region (Herp, 2021). At the moment of the disaster, Units 1 to 3 were normally  
39 operating, and Units 4 to 6 were shut down in the scheduled maintenance plan (Tepco, 2011a).  
40 The shaking caused by the earthquake and the following disaster of flooding caused by the  
41 tsunami resulted in the loss of the electricity of FDNPP, which was needed to run and cool  
42 the reactors and spent-fuel-pools normally (Tepco, 2011b). Therefore, a large amount of  
43 hydrogen gases was generated by the reaction of uncontrollable residual heat with metal in  
44 the units. Although the venting and water-injecting operations were performed in Units 1-3,  
45 the hydrogen explosions were not avoided in Unit 1 and Unit 3. Thus, a great many of the  
46 radionuclides were released into the atmosphere and deposited on the land and into the Pacific  
47 ocean (Iaea, 2015).

### 48 **1.2 Deposition and distribution of $^{137}\text{Cs}$**

49 There were various radionuclides released into the atmosphere and deposited in the

50 terrestrial and oceanic environment, which could cause health and environmental pollution,  
 51 such as contamination problems of soil surfaces, water, agricultural products, and animals  
 52 by-products, etc. The main radioactive radionuclides were iodine 131 ( $^{131}\text{I}$ ), cesium 134  
 53 ( $^{134}\text{Cs}$ ), cesium 137 ( $^{137}\text{Cs}$ ), and xenon 133 ( $^{133}\text{Xe}$ ). As shown in Table 1, the estimated  
 54 amount of radionuclides released from the FDNPP accident were published by JAEA on  
 55 April 12, 2011, and NISA on May 12, 2011, respectively (Ohara et al., 2011). Especially,  
 56  $^{137}\text{Cs}$  has a longer half-life of approximately 30 years, which has attracted much more  
 57 attention of researchers than other short half-life radionuclides, for example,  $^{131}\text{I}$  and  $^{133}\text{Xe}$   
 58 (which has a short half-life of 8 days and 5 days, respectively) (Christoudias and Lelieveld,  
 59 2013). Additionally, the physicochemical properties of  $^{137}\text{Cs}$  are similar to potassium.  
 60 Therefore, the soluble  $^{137}\text{Cs}$  was readily absorbed by animals and plants. When  $^{137}\text{Cs}$  was  
 61 entered into the body of animals, it was mainly retained in bone and muscle tissue (Sato et  
 62 al., 2016). Thus, it is particularly significant to conduct the long-term monitoring and analysis  
 63 of  $^{137}\text{Cs}$  for understanding the fate of  $^{137}\text{Cs}$  in the aerosol samples.

64 Table 1. Radionuclides released from FDNPP accident modified from report of Ohara et al., 2011.

Radionuclide	Half-life	Released amount (Bq)	
		Japan Atomic Energy Agency (JAEA) 2011/5/12	Nuclear and Industrial Safety Agency (NISA) 2011/4/12
$^{131}\text{I}$	$8.040 \pm 0.001$ days	$1.5 \times 10^{17}$	$1.6 \times 10^{17}$
$^{132}\text{I}$	$2.30 \pm 0.03$ hours	—	$4.7 \times 10^{14}$
$^{133}\text{I}$	$20.8 \pm 0.2$ hours	—	$6.8 \times 10^{14}$
$^{134}\text{Cs}$	$2.062 \pm 0.005$ years	—	$1.8 \times 10^{16}$
$^{137}\text{Cs}$	$30.17 \pm 0.05$ years	$1.3 \times 10^{16}$	$1.5 \times 10^{16}$
$^{106}\text{Ru}$	$368.0 \pm 1.6$ days	—	$2.1 \times 10^9$
$^{129\text{m}}\text{Te}$	33.61 days	—	$3.3 \times 10^{15}$
$^{132}\text{Te}$	$78.2 \pm 0.8$ hours	—	$7.6 \times 10^{14}$
$^{144}\text{Ce}$	$284.4 \pm 0.3$ days	—	$1.1 \times 10^{13}$
$^{133}\text{Xe}$	$5.25 \pm 0.02$ days	—	$1.1 \times 10^{19}$

### 65 **1.3 Resuspension of radiocesium**

66 In the report (Onda et al., 2020), there were about 2.7 PBq of  $^{137}\text{Cs}$  deposited on the  
67 ground, and 60%-67% of them were deposited in the forest. These deposited  $^{137}\text{Cs}$  and their  
68 carriers were readily the secondary contamination sources. Specifically, in the report (Hirose,  
69 2013), the monthly deposition speed of  $^{137}\text{Cs}$  decreased with an apparent half-life of 11-14  
70 days during the period of March-June 2011. Also, the second peak of monthly  $^{137}\text{Cs}$   
71 deposition was observed in February-April 2012, which may be ascribed to the resuspension  
72 of  $^{137}\text{Cs}$ -bearing-particle (CsMPs) (Tang et al., 2022). In addition, most of FDNPP-deriving  
73  $^{137}\text{Cs}$  deposited on the topsoil, which remained in the soil surface layer as a potential  
74 secondary source of atmospheric  $^{137}\text{Cs}$  (Hirose, 2020). The resuspension process of  
75 radiocesium could be defined as the redistribution of deposited radioactive cesium into the  
76 atmosphere by wind or anthropogenic processes (Igarashi et al., 2003; Igarashi, 2009; Kajino  
77 et al., 2016). For bare soil surfaces and forest ecosystems, the respective resuspension rates  
78 of  $^{137}\text{Cs}$  were estimated as  $1 \times 10^{-6} \text{ day}^{-1}$  and  $2 \times 10^{-6} \text{ day}^{-1}$ , which reported by Kajino et al.  
79 (Kajino et al., 2016), and revealed a seasonal change that the high level of  $^{137}\text{Cs}$  could be  
80 observed in warm seasons and the low could be obtained in cold seasons. Also, the  
81 resuspension of  $^{137}\text{Cs}$  may be derived from the decontamination process in heavily  
82 contaminated areas (Steinhauser et al., 2015). However, based on above-mentioned studies,  
83 the resuspension of radiocesium and the carriers in the atmosphere has not been fully or  
84 accurately understood. Even nine years after FDNPP accident, it was still found a small  
85 fluctuation within  $0.0002 \text{ Bqm}^{-3}$  from January to April and a slightly higher level of  
86 atmospheric  $^{137}\text{Cs}$  from May to September in the aerosol samples obtained in Namie in a  
87 heavily contaminated area of Fukushima prefecture in 2019. This work, for the first time,  
88 quantitatively demonstrated that the carriers of  $^{137}\text{Cs}$  in early May were the combination of C-  
89 particles and Al-particles (Al-particles was dominated with the percentage of 68%);

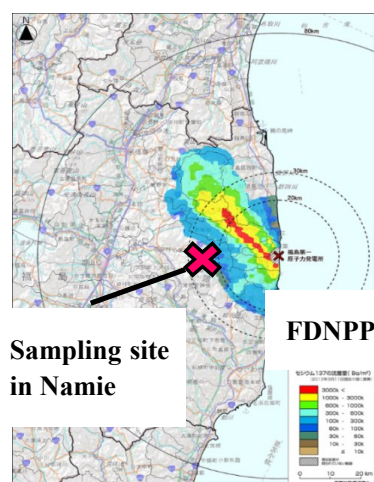

90 meanwhile the predominate carriers of  $^{137}\text{Cs}$  in late May and September were carbonaceous  
91 particles with the average percentage of 88%. In addition, the effect of weather conditions  
92 (precipitation, air temperature, relative humidity, wind speed, and gust wind speed) on the  
93 concentration of  $^{137}\text{Cs}$  and their carriers was also discussed. Obviously, the temperature and  
94 the precipitation were the main impact factors on the distribution of  $^{137}\text{Cs}$  and its carriers.

## 95 2 Experimental sections

### 96 2.1 Sampling site

97 The sampling site was a school ground (37°33'44"N, 140°46'07"E, about 30 km far from  
98 FDNPP) located in Namie in a heavily contaminated area of Fukushima Prefecture, as shown  
99 in Figure 1. It was surrounded by forests, mainly dominated by deciduous forest. Due to the  
100 heavy contamination, residents have been evacuated from these contaminated areas.  
101 Therefore, the sampling site was free of residential activities, except for decontamination  
102 activities and regular research monitoring. As shown in Figure 1, this research site was  
103 located at the boundary of the most contaminated area, about  $1 \text{ MBqm}^{-2}$ .

104

105 Figure 1. Distribution of deposited  $^{137}\text{Cs}$  obtained from the Ministry of Education, Culture, Sports, Science  
106 and Technology (MEXT) converted on March 11, 2013 (Mext, 2013), also the sampling site was marked

107 in a red cross.

108 Table 2. The information of samples in May and September 2019 giving the name and the sampling time.

109 **2.2 Sampling**

Sample name	Starting time		Ending time	
	Year/Month/Day	a.m./p.m.	Year/Month/Day	a.m./p.m.
NHVA-20190501-D-Q	2019/4/26	6:00 p.m.	2019/4/27	6:00 a.m.
NHVA-20190501-L-Q	2019/4/30	6:00 p.m.	2019/5/1	6:00 a.m.

110 High-volume aerosol samplers (HV-1000R, Sibata, Japan) equipped quartz fiber filter  
111 (2500QAT-UP, Pallflex, USA) were used to collect atmospheric aerosol samples. The  
112 sampling flow rate was set to 1000 Lmin<sup>-1</sup>, and the sampling period was a short-term of 12  
113 hours. The daytime and nighttime samples were respectively collected in May and September

114 2019, with day-time sampling from 6:00 a.m. to 6:00 p.m. and night-time sampling from 6:00  
115 p.m. to 6:00 a.m. of the next day, as detailed given in Table 2. The absent samples in late  
116 May and early September 2019 were ascribed to the sampling plan and summer vacation.  
117 The quartz filter samples collected by HV aerosol samplers in Namie were stored in the  
118 laboratory.

### 119 2.3 Meteorological monitoring

120 Regular meteorological monitoring of the sampling location was also carried out, which  
121 was located approximately 800 m far from HV aerosol samplers. The pressure (mbar), solar  
122 radiation ( $Wm^{-2}$ ), wind direction ( $\theta$ ), moisture content ( $m^{-3}m^{-3}$ ), precipitation (mm), air  
123 temperature ( $^{\circ}C$ ), relative moisture (RH, %), wind speed ( $ms^{-1}$ ), and speed of gust wind ( $ms^{-1}$ )  
124 were simultaneously measured per minute. The detailed instrumental settings are shown in  
125 Table 3.

126 Table 3. Several instrumental specifications of meteorological monitoring modified from Appendix of  
127 Ishizuka et al., 2017.

Monitoring Object	Instrument	Manufacture	Model
Precipitation	Tipping bucket rain gauge	Takeda Keiki Kougyou	TKF-1
Humidity (RH)	Capacitive chip	Vaisala Corp.	HMP155D
Wind speed	Three cups anemometer	R. M. Young	3102
Gust wind speed	Sonic anemometer	R. M. Young	81000
Air temperature	Pt resistance thermometer	Vaisala Corp.	HMP155D
Moisture	ADR sensor	Delta-T Devices Ltd.	Theta probe ML2x

## 128 3 Radioactivity measurement and observations of samples

### 129 3.1 Radioactivity measurement

130 The radioactivity of  $^{134}Cs$ ,  $^{137}Cs$  was measured at the peak gamma-ray at 605 keV and

131 662 keV, respectively, using coaxial Ge semiconductor equipped with computerized  
132 spectrum analyzer in the Meteorological Research Institute (MRI) and the University of  
133 Tsukuba. The atmospheric radioactive concentration of  $^{137}\text{Cs}$  was calculated by

$$134 \quad C_{\text{filter}} = Q_{\text{filter}} / V_{\text{filter}} \quad (1)$$

135 where  $C_{\text{filter}}$  ( $\text{Bqm}^{-3}$ ) was the atmospheric radioactive concentration of  $^{137}\text{Cs}$ ,  $Q_{\text{filter}}$  (Bq)  
136 was the radioactive intensity of  $^{137}\text{Cs}$  in quartz fiber measured by coaxial Ge semiconductor,  
137 and  $V_{\text{filter}}$  ( $\text{m}^3$ ) was the volume of the sampling air.

### 138 **3.2 Microscope observations**

139 Two pieces of  $\Phi 33$  mm were taken out from the HV aerosol filter sample ( $8 \times 10$  inches)  
140 for DAPI (4',6-diamidino-2-phenylindole) staining: one piece (a) was obtained in the middle  
141 area and the other piece (b) was obtained in the edge area from the same aerosol filter sample.  
142 The rest of the aerosol filter sample was sealed and stored for other experiments. Then, one  
143 piece of  $\Phi 12$  mm was taken out from each piece of  $\Phi 33$  mm for further treatment. Finally,  
144 two pieces of  $\Phi 12$  mm were obtained and the rest of each piece of  $\Phi 33$  mm was sealed and  
145 stored for backup. For all samples, the two pieces of  $\Phi 12$  mm filters were firstly fixed by  
146 formaldehyde solution, and then dried for 2 hours. Formaldehyde solution was used for  
147 preserving or fixing tissues or cells due to its functions of embalming, fixing cadavers,  
148 disinfection, and bleaching. DAPI for fluorescent staining, because DAPI could penetrate the  
149 cell membrane and strongly fix the DNA in the nucleus (Maki et al., 2013). After staining,  
150 the samples were rinsed with ultrapure water and dried, in the end, the samples were stored  
151 in dark light. For fluorescence observation, the DAPI-stained cells were able to be labeled  
152 with blue fluorescence, after excitation by UV light with the wavelength of 360-400 nm,  
153 using the fluorescent upright microscope (BS-2040TF, Bio Tools Inc., Gunma, Japan). The  
154 dark particles (all particles) could be observed with the reflected-light mode, and the colored  
155 particles (carbon-containing particles) could be observed in the fluorescence-mode because

156 the DAPI-stained particles could be shown blue or yellow fluorescence illuminated by UV  
157 light under the fluorescent upright microscope. Five sites of each  $\Phi 12$  mm sample were used  
158 for observations using fluorescent upright microscope. Each site was photographed with a  
159 CCD camera in reflected-light mode and in fluorescent-light mode, respectively. Finally, all  
160 images were saved for the analysis of the size and morphology of aerosol particles. A total  
161 of 10 images were taken for each  $\Phi 12$  mm sample, and a total of 20 images were taken for  
162 each sample collected in our sampling site. The images (the number and Feret's diameter of  
163 particles) were analyzed by a free professional software of Image J (Kita et al., 2020). The  
164 morphology, the elemental compositions and distribution of the aerosol particles was  
165 characterized by a SEM (SU3500, Hitachi High-Technologies Co., Tokyo, Japan) equipped  
166 with an EDS (X-max, Horiba Ltd., Kyodo, Japan) in MRI.

## 167 **4 Results and discussion**

### 168 **4.1 Variations of $^{137}\text{Cs}$ in aerosol filters sampled in 2019**

#### 169 **4.1.1 Annual variations of atmospheric $^{137}\text{Cs}$**

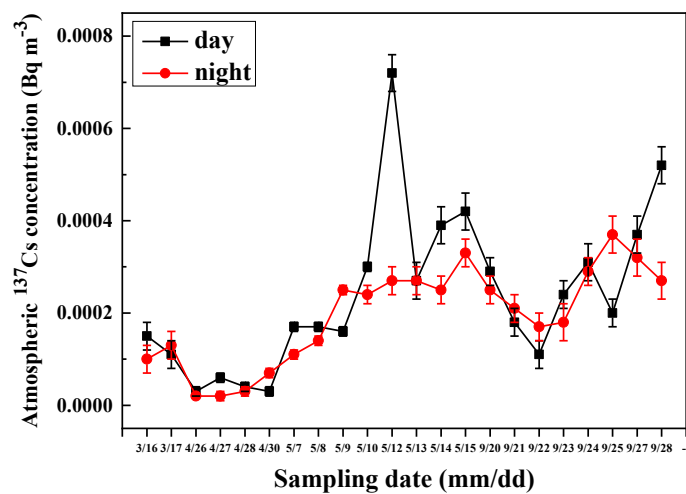

170 The annual variations of  $^{137}\text{Cs}$  in the HV aerosol filters sampled in 2019 were shown in  
171 Figure 2 (the absent samples were ascribed to the sampling plan and vacations). It could be  
172 found a small fluctuation of atmospheric  $^{137}\text{Cs}$  within  $0.0002 \text{ Bqm}^{-3}$  from January to April. It  
173 was obvious that a slightly higher level of  $^{137}\text{Cs}$  could be observed from May to September.  
174 Moreover, it can be obtained the seasonal variation of the atmospheric  $^{137}\text{Cs}$  that the level of  
175  $^{137}\text{Cs}$  was higher in the warm season (from May to September) and lower in the cold season  
176 (from January to April). Significantly, there were two peaks that appeared in May (about  
177  $0.00072 \text{ Bqm}^{-3}$ ) and September (about  $0.00052 \text{ Bqm}^{-3}$ ). These two peaks may be caused by  
178 the resuspension of aerosol particles carrying  $^{137}\text{Cs}$ , which will be discussed later in detail.  
179 Thus, in the following section, variations of atmospheric  $^{137}\text{Cs}$  for HV filter samples collected  
180 in May and September were mainly discussed.

181

182

Figure 2. Annual variations of  $^{137}\text{Cs}$  in aerosol filters sampled in 2019.

183

184 Figure 3. Diurnal variations of  $^{137}\text{Cs}$  in the aerosol filters sampled in the day-period/night-period in 2019.

185 The sampling date defined as mm/dd. Blackline represents variations of  $^{137}\text{Cs}$  concentration in the day-

186 period. Redline was the variations of the samples obtained in the night-period.

#### 187 **4.1.2 Diurnal variation of $^{137}\text{Cs}$**

188 The comparison of daytime and nighttime variation of atmospheric  $^{137}\text{Cs}$  was shown in  
189 Figure 3. There were 22 groups of  $^{137}\text{Cs}$  in HV filter samples collected in the day-period and  
190 night-period, respectively. Clearly, it can be found that the concentration of  $^{137}\text{Cs}$  in the  
191 daytime samples were slightly higher than that sampled in the nighttime. Specifically, among  
192 the 22 groups of  $^{137}\text{Cs}$ , 15 groups had a positive differences in atmospheric  $^{137}\text{Cs}$  between  
193 daytime and nighttime samples. Also, it can be noticed that the concentrations of  $^{137}\text{Cs}$   
194 sampled in the day-period on the 12 May and on 28 September were about 3 times and 2  
195 times higher than that of those samples collected in the night-period, respectively. Especially,  
196 the diurnal variations of  $^{137}\text{Cs}$  were similar to the seasonal variation of  $^{137}\text{Cs}$  as mentioned  
197 above in the annual variations of  $^{137}\text{Cs}$ . Specifically, the maximum of  $^{137}\text{Cs}$  concentration  
198 was  $0.00072 \text{ Bqm}^{-3}$  sampled in a day-period on 12 May and the minimum was  $0.00002$   
199  $\text{Bqm}^{-3}$  sampled in the night-period on 26 April and 27 April. In Autumn (late September),  
200 the maximum of  $^{137}\text{Cs}$  concentration was  $0.00052 \text{ Bqm}^{-3}$  sampled a day-period on 28  
201 September, and the minimum was  $0.00011 \text{ Bqm}^{-3}$  sampled a day-period on 22 September.

#### 202 **4.2 Possible carriers of $^{137}\text{Cs}$ in May and September**

##### 203 **4.2.1 Possible carriers of $^{137}\text{Cs}$ for the HV samples collected in May 2019**

204 SEM observations of the HV filter sample (#NHVA2019-0511-J-Q) were shown in  
205 Figure 4. Comparative analysis of the observations was shown in Figure 4a in backscattered  
206 electrons mode, BSE, and Figure 4b in low-vacuum mode. Clearly, there were some grey-  
207 white particles with diameters of 20-35  $\mu\text{m}$ , which could be easily identified as pollen  
208 particles. Meanwhile, there were also some small, clear, white, elliptic-shaped particles and  
209 they were mapped by EDS, as shown in Figure 4c, 4b, and 4d. Significantly, the several large  
210 carbon-containing particles could be pollens as shown in Figure 4c, and some small particles  
211 may be organic matters (such as fungal cells and/or debris, sporangia or ascospores or other

212 microorganisms). In Figure 4d and 4e, it can be found that there were a lot of small  
213 aluminum-containing and iron-containing particles, which may be mineral particles or soil  
214 dusts. Overall, in Spring, more iron/aluminum-containing mineral particles of 2-5  $\mu\text{m}$  and  
215 some scattered pollens and/or organic particles can be observed, indicating that main possible  
216 carriers of  $^{137}\text{Cs}$  in HV filters collected were the mineral particles.

219 Figure 4. SEM images and elemental distribution maps of the HV filter named #NHVA2019-0511-J-Q: a)  
220 SEM image obtained in backscattered electrons mode; b) SEM image got in low-vacuum mode; c)  
221 Elemental distribution of carbon; d) Elemental distribution of aluminum; e) Elemental distribution map of  
222 iron.

223 In the typical optical microscopy photograph (Figure 5a) and fluorescent micrograph  
224 (Figure 5c) of 4,6-diamidino-2-phenylindole (DAPI) staining particles in the HV filter  
225 sample (#NHVA2019-0523-J-Q), it can be found a lot of bioaerosol particles. After treatment

226 by Image J software, equivalent projected images were used for counting and classifying  
227 particles in the reflected-light mode (Figure 5b) and fluorescent-light mode (Figure 5d),  
228 respectively. It is easy to distinguish some pollen particles with a size larger than 20  $\mu\text{m}$   
229 (Figure 5a). Based on the fluorescent color and morphology of the lighted particles, the  
230 fluorescent aerosol particles could be classified into different bioparticles. Specifically, in  
231 Figure 5c, it could be found that the most abundant fluorescent aerosol particles were 1) big  
232 elliptic blue particles (diameter  $>20 \mu\text{m}$ , indicating pollens or aggregated particles), 2)  
233 spindly yellow and blue particles ( $10 \mu\text{m} < \text{diameter} < 20 \mu\text{m}$ , microbial particles of sporangia  
234 or ascospores), 3) elliptic yellow and blue particles (diameter  $< 10 \mu\text{m}$ , identified as bacteria  
235 or basidiospore), and 4) white particles indicated other organics.

236  
237 Figure 5. Microscope images (BS-2040TF) and processed equivalent projected images by Image J in the  
238 same site of a HV filter sample (#NHVA2019-0523-J-Q) collected in May 2019: (a) microscope image in  
239 reflected-light mode; (b) equivalent projected area image of Figure 5a; (c) microscope image in  
240 fluorescent-light mode; (d) equivalent projected area image of Figure 5c.

241 The classifications of fluorescence highlighted particles were consistent with that of the  
 242 reference (Igarashi et al., 2019b). Additionally, only particles with sizes larger than 0.65  $\mu\text{m}$   
 243 were counted in this study. Particularly, it is observed that numerous particles with multiple  
 244 septa, which were most possible the fungal spores of the phylum Ascomycota. More  
 245 bioaerosol particles are observed in September than in May (based on the comparison in  
 246 Figure 5c and 8c). It was possibly due to a seasonal change in the bioaerosol source or rainy  
 247 weather on the sampling days in September, which has also been discussed in the report of  
 248 Kita et al. (Kita et al., 2020). As a consequent, after analyzing all particles, large particles  
 249 (such as ascospores, pollens, fragments, aggregated particles), small particles (such as  
 250 bacteria), and medium particles (such as basidiospores) could be observed and classified.  
 251 Therefore, the abovementioned six types of particles were discussed in the following section.

252

253

Figure 6. Variation of  $^{137}\text{Cs}$ , C% and Al%.

254

255

256

257

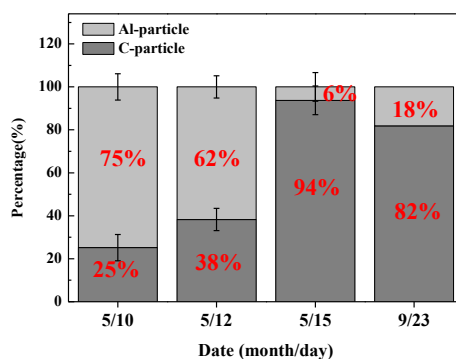

258

259

Based on the SEM observations (Figure 4), it could be obtained that many small mineral particles were also found in HV filter samples collected in May. Meanwhile, the optical microscope images (Figure 5) also exhibited many dispersed organic large particles, such as pollen particles. Thus, it was assumed that the carriers of  $^{137}\text{Cs}$  in the filter samples collected in May can be alternated during this sampling period, because May was just located in the alternate period of spring and summer. In addition, four HV filter samples collected in May

260 were analyzed by SEM/EDS for estimating the elemental mass percentage. The variation of  
 261  $^{137}\text{Cs}$  and elemental mass percentage of Al and C with sampling time were shown in Figure  
 262 6. The black points were the concentration of  $^{137}\text{Cs}$ , the red and the blue symbol represented  
 263 the percentage of C and Al, respectively. It was obvious that the variation of  $^{137}\text{Cs}$   
 264 concentration was consistent with the trend of Al%. Specifically, the gradual increase of  $^{137}\text{Cs}$   
 265 concentration and Al% was observed from 26 April to 12 May, reaching the peak on 12 May.  
 266 After 12 May, Al% showed a clear downward trend. In contrast, the variation of C% was  
 267 always in a slowly increasing trend. There would be a period for  $^{137}\text{Cs}$  carrier's transition  
 268 from mineral particles (aluminum-containing particles) to carbonaceous particles. Therefore,  
 269 it could be assumed that the mineral particles or soil dusts could be the main carriers of  $^{137}\text{Cs}$   
 270 in early Spring. On the other hand, the carbon-containing particles may be the dominated  
 271 carriers of  $^{137}\text{Cs}$  in the late Spring, but more data and further discussion are still needed.

272

273 Figure 7. Comparative percentage variations of carbon- and aluminum- containing particles.

274 In Figure 7, the comparative variation of carbon-containing particles and aluminum-  
 275 containing particles estimated from SEM-EDS observations was provided. It could be  
 276 noticed that the percentage of carbon-containing particles gradually increased, on the  
 277 contrary, the percentage of aluminum-containing particles gradually decreased from 10 May  
 278 to 15 May, which is consistent with the assumption that the mineral particles or soil dusts

279 could be the main carriers of  $^{137}\text{Cs}$  in early Spring and the carbon-containing particles could  
280 be the dominated carriers of  $^{137}\text{Cs}$  in the late Spring. Moreover, a close higher-level  
281 percentage of carbon-containing particles was found in the samples collected on 15 May and  
282 23 September with the percentage of carbon-containing particles of 92%, and 82%,  
283 respectively, which indicated that the main carriers of  $^{137}\text{Cs}$  may be carbon-containing  
284 particles. This result was consistent with our previous master's research (Kimura, 2019a) that  
285 the bio-particles gradually became the dominant carriers of  $^{137}\text{Cs}$ . These results were also  
286 consistent with the speculation that the mineral particles or soil dusts could be the main  
287 carriers of  $^{137}\text{Cs}$  in early Spring and the carbon-containing particles could be the gradually  
288 dominated carriers of  $^{137}\text{Cs}$  in the late Spring.

289  
290 Figure 8. Microscope images (BS-2040TF) and processed equivalent projected images by Image J in the  
291 same site of a HV filter sample (# NHVA2019-0923-L-Q) collected in September 2019: (a) microscope  
292 image in reflected-light mode; (b) equivalent projected area image of Figure 8a; (c) microscope image in  
293 fluorescent-light mode; (d) equivalent projected area image of Figure 8c.

294 **4.2.2 Possible carriers of  $^{137}\text{Cs}$  for the HV samples collected in September 2019**

295 As shown in the typical optical microscopy photograph (Figure 8a) and fluorescent  
296 micrograph (Figure 8c) of DAPI staining particles in the HV filter sample (#NHVA2019-  
297 0923-L-Q), it was easily observed that there were more bio-particles with different  
298 morphology and size, which were consistent with report that bio-particles could be the main  
299 carriers of  $^{137}\text{Cs}$  in autumn (Kimura, 2019b; Igarashi et al., 2019b).

302 Figure 9. SEM images and elemental distribution maps: a) SEM image obtained by BSE model; b) SEM  
303 image got by UVD; c) Compositional map of C; d) Compositional map of Al; e) Compositional map of  
304 Fe. Sample name is #NHVA2019-0929-B-Q. The bar is 100  $\mu\text{m}$ .

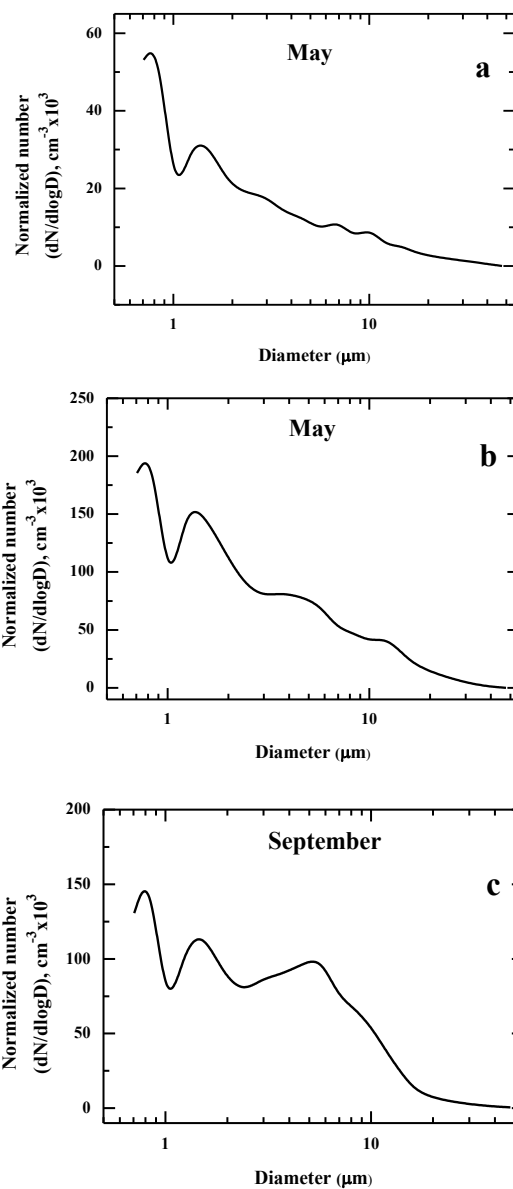

305 SEM observations of the HV filter sample (#NHVA2019-0929-B-Q) were shown in  
306 Figure 9. Compared with Figure 9c, 9d, and 9e, there were a higher level of carbonaceous

307 particles and fewer aluminum-containing and iron-containing particles, which indicates  
308 carbon-containing particles could be the dominated carriers of  $^{137}\text{Cs}$  in September. It was  
309 also consistent with the results of microscope observations, as shown in Figure 8.

### 310 **4.3 Bioaerosol particles and their size distributions**

311 According to the observations of optical, fluorescent microscope, and SEM-EDS,  
312 aerosol particles in the aerosol filter samples collected in May and September 2019 were  
313 mainly analyzed. Diameter was described as the Feret diameter (along the selection boundary,  
314 the longest distance between any two points, also known as maximum caliper), which was  
315 obtained from the microscope images using Image J. Figure 10a and 10b were the size  
316 distributions of bioaerosol particles in the HV filter samples collected in May 2019. It could  
317 be easily noticed that the particles with the diameter ( $d < 1 \mu\text{m}$ ) were predominant. The  
318 second peak represented the particles with a diameter less than 2  $\mu\text{m}$ . Similarly, the size  
319 distribution of bioaerosol particles in the HV filter samples collected in September 2019 was  
320 given in Figure 10c. A wider diameter range of the bioaerosol particles could be found in  
321 three peaks ( $d < 1 \mu\text{m}$ ,  $d < 2 \mu\text{m}$ , and  $d < 8 \mu\text{m}$ ). In addition, bioaerosol particles with a  
322 diameter less than 1  $\mu\text{m}$  were also predominant. Quantitatively, from Figure 10a (early May)  
323 to Figure 10b (late May), the normalized number of particles had increased nearly 3 times  
324 (obtained by the value of first peak), which was consistent with the SEM observations as  
325 shown in Figure 7. Similarly, from Figure 10b (late May) to Figure 10c (September), the  
326 normalized number of particles had no apparent change. Overall, although the size  
327 distribution appeared bimodal or multi-peaked in Figure 10b and 10c, the bioaerosol particles  
328 with the diameter ( $< 2 \mu\text{m}$ ) could be the predominant possible carriers of  $^{137}\text{Cs}$ .

329

330

331

332 Figure 10. Normalized particle number size distributions of bioaerosol particles in the HV filter samples

333 collected in May (a: # NHVA2019-0501-G-Q, b: # NHVA2019-0523-J-Q) and September (c, #

334 NHVA2019-0923-J-Q) in 2019.

#### 335 **4.4 Relation between aerosol particles and $^{137}\text{Cs}$**

336 In Figure 11a, the unstained particles represented mainly mineral particles and some  
337 bioaerosol particles, which were difficult to stain in the DAPI staining experiment. In Figure  
338 11b, the stained particles referred to mainly bioaerosol particles, which could be observed in  
339 blue/yellow/white lighted particles under fluorescent light. The blue points and the red points  
340 represented the correlation between the concentration of atmospheric  $^{137}\text{Cs}$  and the  
341 concentration of aerosol particles, which were respectively estimated from the HV aerosol  
342 filter samples collected in May 2019 (there were ten samples,  $n=10$ ) and in September 2019  
343 (there were eight samples,  $n=8$ ), respectively. It was obviously found that the unstained  
344 particles of mainly mineral particles had a strong positive correlation with the concentration  
345 of atmospheric  $^{137}\text{Cs}$  both in May and September 2019, as shown in Figure 11a. As mentioned  
346 in Figure 7-10, it was consistent with the assumption that the combination of mineral particles  
347 and bio-particles could be the main possible carriers of  $^{137}\text{Cs}$  in May 2019.

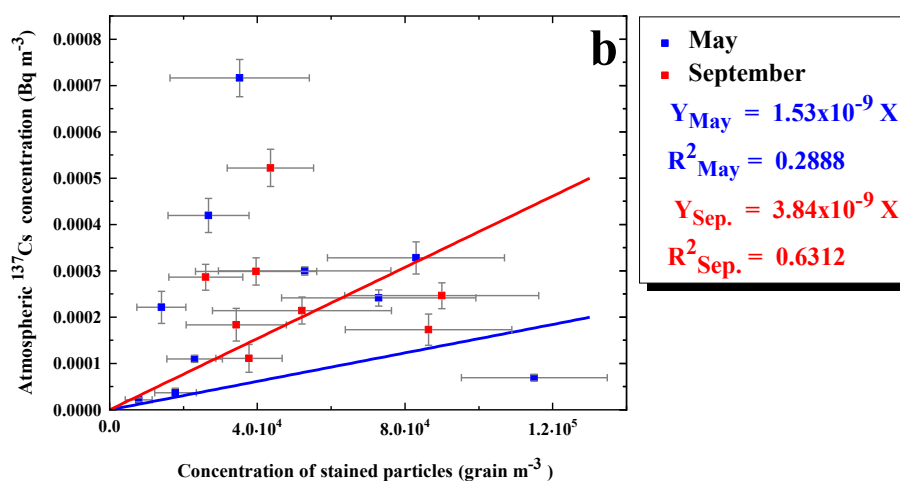

348 In Figure 11b, the stained particles also had a positive correlation distribution with  $^{137}\text{Cs}$   
349 in September 2019, reconfirming that the bioparticles could be predominant carriers of  $^{137}\text{Cs}$   
350 (which was also consistent with the results in Figure 8 and 9). In contrast, in May, the  $^{137}\text{Cs}$   
351 concentration did not have a good linear relation with concentration of colorless particles,  
352 which may be caused by the fact that the combination of mineral particles and bioparticles  
353 could be the main carriers of  $^{137}\text{Cs}$  in May 2019. Namely, the dominant carriers of  $^{137}\text{Cs}$  could  
354 be mineral particles in early May and bio-particles in late May (as shown in Figure 5 and 7).  
355 It seems to be consistent with other studies (Kinase et al., 2018; Igarashi et al., 2019b) that  
356 there were different resuspension mechanisms in May and September. Namely, it was  
357 generally believed that there was a much lower concentration of  $^{137}\text{Cs}$ , and the main carriers  
358 could be mineral particles in the Spring. In Summer and Autumn, there were relatively higher  
359 concentration of  $^{137}\text{Cs}$ , and the bioaerosol particles could be predominant in the aerosol

360 particles, which also implied that the bioaerosols were more possible to be the carriers of  
 361  $^{137}\text{Cs}$  in September (Kita et al., 2020).

362

363

364 Figure 11. The concentration variations of atmospheric  $^{137}\text{Cs}$  with the concentration of aerosol particles,

365 which were respectively estimated from the HV aerosol filter samples collected in May 2019 (there were

366 ten samples,  $n=10$ , highlighted in blue points) and in September 2019 (there were eight samples,  $n=8$ ,

367 highlighted in red points).

368 Table 4. Classification of bioaerosol particles based on different sizes. AR (Aspect Ratio) represented the

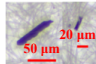

369 ratio of the major to the minor. The major and the minor were the primary and secondary axes of the

370 best fitting ellipse. Circularity was defined as  $4\pi \times (\text{area}) / (\text{squared circumference})$ . When the value of

371 circularity was 1, representing the particle that could be regarded as a perfect circle. If the value

372 approached 0, it indicated that the shape of the particle was elongated. When the AR was greater than 4

373 and the circularity was less than 0.45, the particle was defined as a fragment.

Species	Parameter		Size		References	Appearance Examples
	AR	Circularity	Major	Minor		
Fragment	>4	<0.45				
Little particle	<4	>0.45	0.65-1.0µm	0.65-1.0µm		
Bacteria	<4	>0.45	1.0-1.8µm	1.0-1.8µm	Hoorman et al. (2011)	
Basidiospore	<4	>0.45	1.8-10µm	1.8-5µm	Yamamoto et al. (2012)	
Ascospore	<4	>0.45	10-60µm	5-15µm	Stanley and Linskins (1974); Kelly et al. (2002)	
Pollen	<4	>0.7		>15µm		
Others						

374

375 Igarashi et al. reported a strong relationship between carbon-bearing particles and <sup>137</sup>Cs

376 concentration (Igarashi et al., 2019b). Also, combining the abovementioned discussion, the

377 main carriers of <sup>137</sup>Cs were mineral particles in early May, and the predominant carriers of

378 <sup>137</sup>Cs were bioaerosol particles in late May and in September 2019. Therefore, it was

379 necessary to quantify the relation between bioaerosol concentration and <sup>137</sup>Cs concentration

380 to estimate the predominant contribution of the specific type of bioaerosol particles to the

381 atmospheric <sup>137</sup>Cs. According to the classification, as shown in Table 4, there were several

382 common types of bioaerosol particles (Stanley and Linskins, 2012; Kelly et al., 2002;

383 Yamamoto et al., 2012; Hoorman, 2011). Then, a multiple linear regression was used to  
 384 estimate the kinds of bio-particles varied with the dominant carriers of  $^{137}\text{Cs}$ , as follows:

$$385 \quad I = \sum_i a_i * A_i + b_0 \quad (2)$$

386 Where  $I$  (Bq) was the total radioactivity of  $^{137}\text{Cs}$  in the HV aerosol filter samples,  $i$  was a  
 387 serial number,  $i = 1, 2, 3, 4, 5, 6$  (little particle, bacteria, spore, ascospore, pollen, fragment)  
 388 and so on,  $a_i$  was the coefficient ( $\text{Bq } \mu\text{m}^{-2}$ ),  $A_i$  is the area of the HV filter samples ( $183.2 \text{ mm}$   
 389  $\times 234 \text{ mm}$ ), and  $b_0$  was residual radioactivity of  $^{137}\text{Cs}$  of the HV filter (Bq).

390 Table 5. Each coefficient in equation (2).  $a_i$  was the coefficient of each bioaerosol, referring to the  $^{137}\text{Cs}$   
 391 radioactivity accumulated in each type of bioaerosols within each HV aerosol filter sample. The statistical  
 392 analysis was made by regression analysis for 10 samples. Asterisk (\*) indicated a significance level.

$a_i$	Coefficient value ( $\text{Bq } \mu\text{m}^{-2}$ )	$b_0$	Residual radioactivity (Bq)
$a_1$	$1.11 \times 10^{-8}$	$b_0$	0.19
$a_2$	$3.08 \times 10^{-8} *$		
$a_3$	$9.14 \times 10^{-12}$		
$a_4$	0.00		
$a_5$	0.00		
$a_6$	0.00		

393 In Figure 12, the relationship between each type of bioaerosols and  $^{137}\text{Cs}$  was obtained  
 394 by the multiple linear regression analysis. The black symbol was the measured value of  $^{137}\text{Cs}$   
 395 obtained from the coaxial Ge semiconductor detector. The red points represented the  
 396 predicted radioactivity value estimated from equation (2). The other symbols represented the  
 397 contribution of different bioaerosol particles to the radioactivity of  $^{137}\text{Cs}$ .

398 The distribution of  $^{137}\text{Cs}$  for each bioaerosol in aerosol filter samples collected in  
 399 September 2019 was given in Table 6. As a result of a multivariate analysis (performed by  
 400 least-squares) under non-negative constraints, the contribution of each species of bioaerosols

401 to the radioactivity of  $^{137}\text{Cs}$  and the residuals were calculated. Obviously, bacteria (blue  
 402 squares) had the highest contribution to radioactivity of  $^{137}\text{Cs}$  (Figure 12), which showed the  
 403 strongest correlation with the concentration of  $^{137}\text{Cs}$ , followed by the order of little particles  
 404 (wine squares), spores (violet squares), and ascospores (magenta squares) and fragment  
 405 (olive squares). It was strongly consistent with the results of the size distribution of particles  
 406 (as shown in Figure 10c), in which particles with a diameter ( $< 2 \mu\text{m}$ ) could be the  
 407 predominant possible carriers of  $^{137}\text{Cs}$ . Therefore, combining the information on the size  
 408 distribution of the particles (Figure 10), the dominant  $^{137}\text{Cs}$ -bearing particles could be  
 409 bacteria (1-1.8  $\mu\text{m}$ ), followed with little particles (less than 1  $\mu\text{m}$ ) and medium particles of  
 410 1.8-10  $\mu\text{m}$ , possibly deriving from spores.

411  
 412 Figure 12. Bioaerosol particles' radioactivity contribution to  $^{137}\text{Cs}$  radioactivity based on the multiple  
 413 linear regression equation (2). The black squares are the measured values ( $I$ ) of  $^{137}\text{Cs}$  radioactivity in each  
 414 HV aerosol filter sample. The red squares represent the estimated values ( $I$ ) from equation (2) in each  
 415 sample. The rest symbols represent their contributed radioactivity of different bioaerosol particles to the  
 416 radioactivity of  $^{137}\text{Cs}$  based on statistical predictions from the multiple linear regression equation, as

417 detailed information is summarized in Table 6.  
 418 Table 6. Contribution values of each species of bioaerosols to <sup>137</sup>Cs radioactivity. There were ten data (for  
 419 eight in September, two on 15 May, consideration of bioaerosols could be the main carriers). The observed  
 420 values (Bq) of <sup>137</sup>Cs radioactivity are obtained from the HV aerosol filter samples (183.2 mm × 234 mm).  
 421 The estimated values (Bq) are based on a prediction of equation (2) in each sample. The predicted  
 422 radioactivity (Bq) in little particles, bacteria, spores, ascospores, and fragments (without considering  
 423 pollens because of seasonality) was calculated from the statistical analysis in a multiple linear regression  
 424 equation (2). The residual values were involved in the difference between the measured value and the  
 425 estimated value.

Data number	Measured value (Bq)	Estimated value (Bq)	Little particle (Bq)	Bacteria (Bq)	Spore (Bq)	Ascospore (Bq)	Fragment (Bq)	Residual value (Bq)
1	0.2538	0.1516	0.0119	0.1395	0.0002	0.0000	0.0000	0.1023
2	0.1983	0.2812	0.0275	0.2536	0.0002	0.0000	0.0000	-0.0829
3	0.1730	0.0751	0.0083	0.0667	0.0001	0.0000	0.0000	0.0980
4	0.1490	0.1355	0.0306	0.1048	0.0002	0.0000	0.0000	0.0134
5	0.1296	0.1442	0.0118	0.1321	0.0003	0.0000	0.0000	-0.0146
6	0.0671	0.0786	0.0139	0.0645	0.0001	0.0000	0.0000	-0.0114
7	0.1045	0.1573	0.0264	0.1305	0.0004	0.0000	0.0000	-0.0528
8	0.1110	0.0980	0.0143	0.0835	0.0002	0.0000	0.0000	0.0130
9	0.1806	0.0978	0.0161	0.0817	0.0001	0.0000	0.0000	0.0828
10	0.3158	0.3139	0.0266	0.2870	0.0004	0.0000	0.0000	0.0019

426 In addition, to verify the accuracy of equation (2), a correlation analysis between the  
 427 observed and estimated radioactivity values was shown in Figure 13. The X-axis was the

428 observed value of the atmospheric radioactivity of  $^{137}\text{Cs}$ , and Y-axis was the estimated value  
429 of the atmospheric radioactivity of  $^{137}\text{Cs}$ . It was obvious that they were in a good positive  
430 linear relationship, indicating the feasibility and reasonability of equation (2).

431

432 Figure 13. Correlation between observed values and estimated values for  $^{137}\text{Cs}$  radioactivity.

#### 433 4.5 Effect estimation of weather conditions on $^{137}\text{Cs}$ and its carriers

434 Several representative items of weather conditions, such as precipitation, air temperature,  
435 relative humidity, wind speed, and gust wind speed, were selected and monitored to analyze  
436 the influence of these weather factors on the concentration of  $^{137}\text{Cs}$  and its carriers.  
437 Precipitation was obtained from a 12-hour accumulated value, and the other values were the  
438 average value, during the sampling period. Table 7 shows the effect of atmospheric  $^{137}\text{Cs}$   
439 concentration and concentration of particles in HV aerosol samples by precipitation, air  
440 temperature, RH, wind speed, and gust in May 2019, which was estimated by Pearson  
441 correlation and P-value significance tests (ten samples were used for analysis,  $n=10$ ). It could  
442 be found that the precipitation had a negative effect on both the concentration of  $^{137}\text{Cs}$  and

443 its carriers. The temperature had a positive effect on the concentration of  $^{137}\text{Cs}$  and its carriers,  
 444 which was consistent with the abovementioned speculation that the concentration of  $^{137}\text{Cs}$   
 445 was higher in the warm season and lower level in the cold season. Other weather conditions  
 446 of RH, wind speed, and gust had no significant correlations in the current research.  
 447 Table 7. The effect of atmospheric  $^{137}\text{Cs}$  and concentration of particles in HV filter samples by  
 448 precipitation, air temperature, RH, wind speed, and gust in May 2019, was estimated by Pearson  
 449 correlation and P-value significance tests (ten samples were used for analysis,  $n=10$ ).

Items	Air $^{137}\text{Cs}$ concentration( $\text{Bq m}^{-3}$ )		Particle concentration( $\text{grain m}^{-3}$ )	
	Pearson correlation	P-value	Pearson correlation	P-value
Precipitation(mm)	<b>-0.38</b>	0.28	<b>-0.52</b>	0.13
Air Temperature( $^{\circ}\text{C}$ )	<b>0.44</b>	0.20	<b>0.48</b>	0.16
Relative Humidity(%)	-0.16	0.65	-0.07	0.84
Wind Speed(m/s)	0.28	0.43	-0.05	0.90
Gust(m/s)	0.41	0.23	-0.08	0.83

450  
 451 The effect of atmospheric  $^{137}\text{Cs}$  and concentration of particles in HV filter samples by  
 452 precipitation, air temperature, RH, wind speed, and gust in September 2019 was shown in  
 453 Table 8, also estimating by Pearson correlation and P-value significance tests (eight samples  
 454 were used for analysis,  $n=8$ ). Obviously, the temperature had a positive effect on both the  
 455 concentration of  $^{137}\text{Cs}$  and its carriers, which was consistent with the results in May and the  
 456 speculation. In contrast, the precipitation had a negative impact on the concentration of  $^{137}\text{Cs}$   
 457 and a positive effect on the concentration of the particles, which was inconsistent with that  
 458 in May.

459 In the report (Kita et al., 2020), the precipitation was conducive to an increase of the  
 460 atmospheric  $^{137}\text{Cs}$  compared with the non-rainfall sampling period. In September, the  
 461 precipitation positively affected the concentration of the bioparticles. Because the rainfall  
 462 was possible and reasonable to promote spores' multiplication. Moreover, there was no doubt  
 463 that higher temperature could accelerate microbial colonization, which was able to explain

464 the positive impact on the concentration of  $^{137}\text{Cs}$  and its carriers by temperature both in May  
465 and September.

466 Table 8. The effect of atmospheric  $^{137}\text{Cs}$  concentration and concentration of particles in HV filter samples  
467 by precipitation, air temperature, RH, wind speed, and gust in September 2019, was estimated by Pearson  
468 correlation and P-value significance tests (ten samples were used for analysis,  $n=8$ ).

Items	Air $^{137}\text{Cs}$ concentration( $\text{Bq m}^{-3}$ )		Particle concentration( $\text{grain m}^{-3}$ )	
	Pearson correlation	P-value	Pearson correlation	P-value
Precipitation(mm)	<b>-0.34</b>	0.41	<b>0.34</b>	0.41
Air Temperature( $^{\circ}\text{C}$ )	<b>0.27</b>	0.52	<b>0.21</b>	0.63
Relative Humidity(%)	-0.52	0.19	0.06	0.88
Wind Speed(m/s)	-0.17	0.69	-0.26	0.53
Gust(m/s)	-0.15	0.72	-0.29	0.48

## 470 5 Conclusions

471 From the analysis of annual atmospheric concentration variation of  $^{137}\text{Cs}$  (based on the  
472 HV air filter samples collected in 2019), the atmospheric concentration of  $^{137}\text{Cs}$  had a small  
473 fluctuation within  $0.0002 \text{ Bqm}^{-3}$  from January to April and a slightly higher activity level of  
474  $^{137}\text{Cs}$  in the air could be observed from May to September. Therefore, it could be obtained  
475 that the seasonal variation of  $^{137}\text{Cs}$  was higher in the warm season (from May to September)  
476 and lower in the cold season (from January to April). Significantly, there were two peaks that  
477 appeared in May (about  $0.00072 \text{ Bqm}^{-3}$ ) and September (about  $0.00052 \text{ Bqm}^{-3}$ ). Thus, a lot  
478 of attention was given to understanding the difference of concentration variations of  $^{137}\text{Cs}$   
479 and its carriers in HV filter samples collected in May and September. By SEM/EDS and  
480 optical microscope observations, it could be obtained that the small mineral particles or soil  
481 dusts could be the main carriers of  $^{137}\text{Cs}$  in early Spring and the carbon-containing particles  
482 (some microorganisms, spores, and some other bio-particles) could be the dominated carriers  
483 of  $^{137}\text{Cs}$  in the late Spring. The bio-particles (bacteria and other small bio-aerosols particles)

484 could be dominant carriers of  $^{137}\text{Cs}$  in September.

485 According to an effect estimation of atmospheric  $^{137}\text{Cs}$  concentration and concentration of  
486 particles in HV filter samples by measuring precipitation, air temperature, RH, wind speed,  
487 and gust in May and September 2019, using Pearson correlation and P-value significance  
488 tests, it could be obtained that the temperature and the precipitation were the main impact  
489 factors of  $^{137}\text{Cs}$  and its carriers. Specifically, the temperature had a positive effect on the  
490 concentration of  $^{137}\text{Cs}$  and its carriers both in May and September 2019, which was consistent  
491 with the abovementioned speculation that  $^{137}\text{Cs}$  concentration was higher in the warm season  
492 and lower level in the cold season (Kinase et al., 2018). Moreover, the rainfall had a negative  
493 effect on both the concentration of  $^{137}\text{Cs}$  and its carriers in May 2019. In contrast, the rainfall  
494 had a negative impact on the concentration of  $^{137}\text{Cs}$  and a positive effect on the concentration  
495 of the particles in 2019, which may be resulted from the fact that the effect of precipitation  
496 on the concentration of  $^{137}\text{Cs}$  and/or bioparticles may persist for some time. For instance, the  
497 rainfall in one day may affect changes of the concentration of  $^{137}\text{Cs}$  and/or bioparticles in the  
498 following several days. Moreover, there was no decreasing trend in the concentration of  $^{137}\text{Cs}$   
499 in 2019, which means long-term monitoring was still necessary for further and deeply  
500 understanding the fate and variation of atmospheric  $^{137}\text{Cs}$  resuspended from  $^{137}\text{Cs}$  bearing  
501 microparticles (CsMPs) (Tang et al., 2022; Igarashi et al., 2019a; Higaki et al., 2020; Nihei  
502 et al., 2018) or soluble  $^{137}\text{Cs}$  (Otosaka et al., 2022) deriving from FDNPP.
