21 **Abstract**

22
23 The Sicily Channel, located in the Central Mediterranean Sea, represents a key point for the regional
24 oceanographic circulation as it is considered the sill that separates the western and eastern basins.
25 Therefore, it is considered a unique zone regarding the well-documented west-to-east
26 Mediterranean productivity gradient. Here we present a time series of settling planktonic
27 foraminifera assemblages from November 2013 to October 2014. 19 samples from the sediment
28 trap C01 deployed at a water depth of around 400 m have been used. More than 3700 individuals
29 and 15 different species have been identified. *Globorotalia inflata*, *Globorotalia truncatulinoides*,
30 *Globigerina bulloides*, *Globigerinoides ruber* and *ruber* (pink) were the five main species identified,
31 accounting for more than 85% of the total foraminifera.

32 The total planktonic foraminifera flux mean value was 630 shells m⁻² d⁻¹, with a minimum value of
33 45 shells m⁻² d⁻¹ displayed during late autumn 2013 and a maximum of 1890 shells m⁻² d⁻¹ reached
34 during spring 2014. This is likely due to the regional oceanographic configuration and the marked
35 seasonality in the surface circulation. During spring and winter, the Atlantic waters dominate the
36 surface circulation, bringing cool and nutrient enriched waters. This results in a planktonic
37 foraminifera flux increase and a dominance of western basin taxa. During summer and autumn, the
38 circulation is dominated by the eastern warm and oligotrophic Levantine water, which leads to a
39 planktonic foraminifera flux decrease and the dominance of eastern basin species. Our comparison
40 with satellite derived SST and chlorophyll-*a* data showed that *G. inflata* was associated with cool
41 and nutrient rich conditions, while both *G. ruber* morphotypes were associated with warm and
42 oligotrophic conditions. However, no trends were identified for *G. truncatulinoides* or *G. bulloides*.

43 As the latter species flux increased coincidentally with that of benthic foraminifera one, we considered
44 that this species might have a resuspended origin.

45 The comparison of the Sicily Channel data with other Mediterranean time series—located in the
46 Alboran Sea, Gulf of Lions and the Levantine basin—was carried out. Our data indicates that the
47 annualized planktonic foraminifera flux was lower than in the westernmost Alboran Sea but higher
48 than in the easternmost Levantine basin. However, The Sicily Channel species diversity was the
49 highest among the compared zones, highlighting the influence of the different basins and its
50 transitional aspect from a planktonic foraminifera population perspective.

51 Finally, we compared the settling planktonic foraminifera assemblage with the assemblages from
52 seabed sediment located in the vicinity of the Sicily Channel. The differences with the seabed
53 populations varied according to the sites studied. The deep-dwelling species dominated the settling
54 assemblages samples, while eutrophic and oligotrophic species were significantly more abundant in
55 the sediment. Finally, a high-resolution chronology comparison allowed to show that this planktonic
56 foraminifera population shift likely developed during the late Holocene prior to the industrial period,
57 however, its causes remain uncertain.

58

59 1. Introduction

60

61 Planktonic foraminifera are a group of marine calcareous single-celled protozoans with a
62 cosmopolitan distribution. Around 50 morphospecies of planktonic foraminifera have been
63 described in today's oceans (Schiebel and Hemleben, 2017), and although most of those species are
64 surface dwellers, some species can be found in waters below 2000 m (Schiebel and Hemleben,
65 2005). Their abundance and distribution are affected by a wide array of factors, such as
66 temperature, salinity, chlorophyll-*a* and nutrient concentrations, among others (Hemleben et al.,
67 1989; Schiebel and Hemleben, 2005). According to Schiebel, (2002), the production and export of
68 their calcareous shells account for 23 to 56% of the open marine CaCO₃ flux, thereby playing a key
69 role in the marine carbon cycle. Moreover, the high preservation potential of their shells makes
70 them one of the most used groups for multi-proxy studies. Numerous paleoclimatic (e.g. Barker and
71 Elderfield, 2002; Lirer et al., 2014; Margaritelli et al., 2020; Sierro et al., 2005) and
72 paleoceanographic (Cisneros et al., 2016; Ducassou et al., 2018; Margaritelli et al., 2022; Toucanne
73 et al., 2007) reconstructions have used planktonic foraminifera as a proxy. In addition, their capacity
74 to reflect the water column's chemical properties has propelled studies that have focused on the
75 impact of recent climate and environmental variability on the water column in different parts of the
76 ocean (e.g. Azibeiro et al., 2023; Beer et al., 2010; Bijma et al., 2002; Chapman, 2010; Marshall et
77 al., 2013; Osborne et al., 2016). As marine calcifying organisms, they are considered particularly
78 vulnerable to the ongoing ocean warming and acidification (Bijma et al., 2002; Fox et al., 2020). Shell
79 calcification of several foraminifera species has been showed to decrease in response to ocean
80 acidification, and therefore, changes in the weight of their shells are considered an indicator of the
81 ocean acidification impact on different timescales (Béjard et al., 2023; de Moel et al., 2009; Fox et
82 al., 2020; Kroeker et al., 2013; Moy et al., 2009; Pallacks et al., 2023). In contrast, ocean warming
83 has been proposed to produce an opposite effect on foraminifera calcification, as some studies have

84 documented that an increase in water temperature results in larger shells and enhanced growth
85 rates (Lombard et al., 2011, 2009; Schmidt et al., 2006).

86 Despite the wide array of studies focused on planktonic foraminifera ecology and distribution,
87 several aspects of their ecology remain uncertain, such as their ecological tolerance limits (Mallo et
88 al., 2017), their geographical and temporal distributions and contribution to the marine
89 biogeochemical cycles (Jonkers and Kučera, 2015). As major contributors to the pelagic calcite
90 production (Schiebel, 2002), understanding their life cycle on different time scales is essential for
91 **constraining** the role they play in the marine carbon cycle and the impact of environmental change
92 on these organisms. In this regard, sediment traps represent a powerful tool to improve our
93 knowledge of planktonic foraminifera ecology and their impact on the biogeochemical cycles, as
94 they allow the monitoring of foraminifera shell fluxes for extended periods, thereby allowing to
95 document their seasonal and interannual variability and estimate their contribution to annual
96 budgets of carbonate export to the seafloor (Jonkers et al., 2019).

97 The Mediterranean Sea is a semi-enclosed sea often considered a “miniature ocean” (Bethoux et
98 al., 1999) from an oceanographic point of view or a “laboratory basin” (Bergamasco and Malanotte-
99 Rizzoli, 2010) for studying processes occurring on a global scale. In addition, it is supersaturated
100 regarding calcite (Álvarez et al., 2014), a key aspect in foraminifera studies, as this parameter favors
101 shell preservation and represents one of the main environmental controls on planktonic
102 foraminifera abundance and calcification (Aldridge et al., 2012; Marshall et al., 2013; Osborne et al.,
103 2016). These features make it an interesting zone of the global ocean to study the life cycle and
104 seasonal response to changing environmental conditions of calcifying plankton. The Sicily Channel,
105 in the central Mediterranean, is the sill that divides the Mediterranean into its western and eastern
106 basins. It is a choke point for the regional surface and deep-water circulation (Malanotte-Rizzoli et
107 al., 2014; Pinardi et al., 2015) and a transition region regarding the well-known west-to-east
108 oligotrophy gradient, functioning as a “biological corridor” (Siokou-Frangou et al., 2010) known in
109 the Mediterranean (Navarro et al., 2017).

110 Despite these characteristics, time series that focused on planktonic foraminifera in the
111 Mediterranean Sea are scarce. So far, the best monitored regions are the Alboran Sea (Bárcena et
112 al., 2004; Hernández-Almeida et al., 2011), the Gulf of Lions (Rigual-Hernández et al., 2012), and
113 more recently, the Levantine Basin (Avnaim-Katav et al., 2020). The latter studies showed that
114 planktonic foraminifera followed a unimodal distribution with maximum shell export occurring
115 during the months of April-May, February-March and February respectively, which agreed with the
116 local hydrographic conditions. However, the central Mediterranean remains understudied and
117 poorly documented regarding both continuous time series and planktonic foraminifera dynamics.

118 Therefore, this work aims to provide new planktonic foraminifera data from a sediment trap
119 mooring line located in the Channel of Sicily to improve the current knowledge about their
120 community composition and seasonal patterns in the central Mediterranean. For that purpose, here
121 we document the magnitude and composition of planktonic foraminifera fluxes identified in the
122 >150 μm fraction (i.e. the most commonly used size fraction for studying planktonic foraminifera
123 distribution) from November 2013 to October 2014. We compare our planktonic foraminifera data
124 with a suite of environmental parameters to assess the main environmental drivers that control the
125 seasonal variations in the composition and abundance of the sinking planktonic foraminifera

126 assemblages. To provide further insight on a regional and global scale of the planktonic foraminifera
127 association and fluxes identified here, we compare our data with other time series from the
128 Mediterranean, Atlantic Ocean and other regions of the world's oceans. Lastly, we compared the
129 assemblages collected by the sediment with seabed sediment located in the vicinity of the Sicily
130 Channel to document the potential shift in recent planktonic foraminifera populations.

131 2. Study area

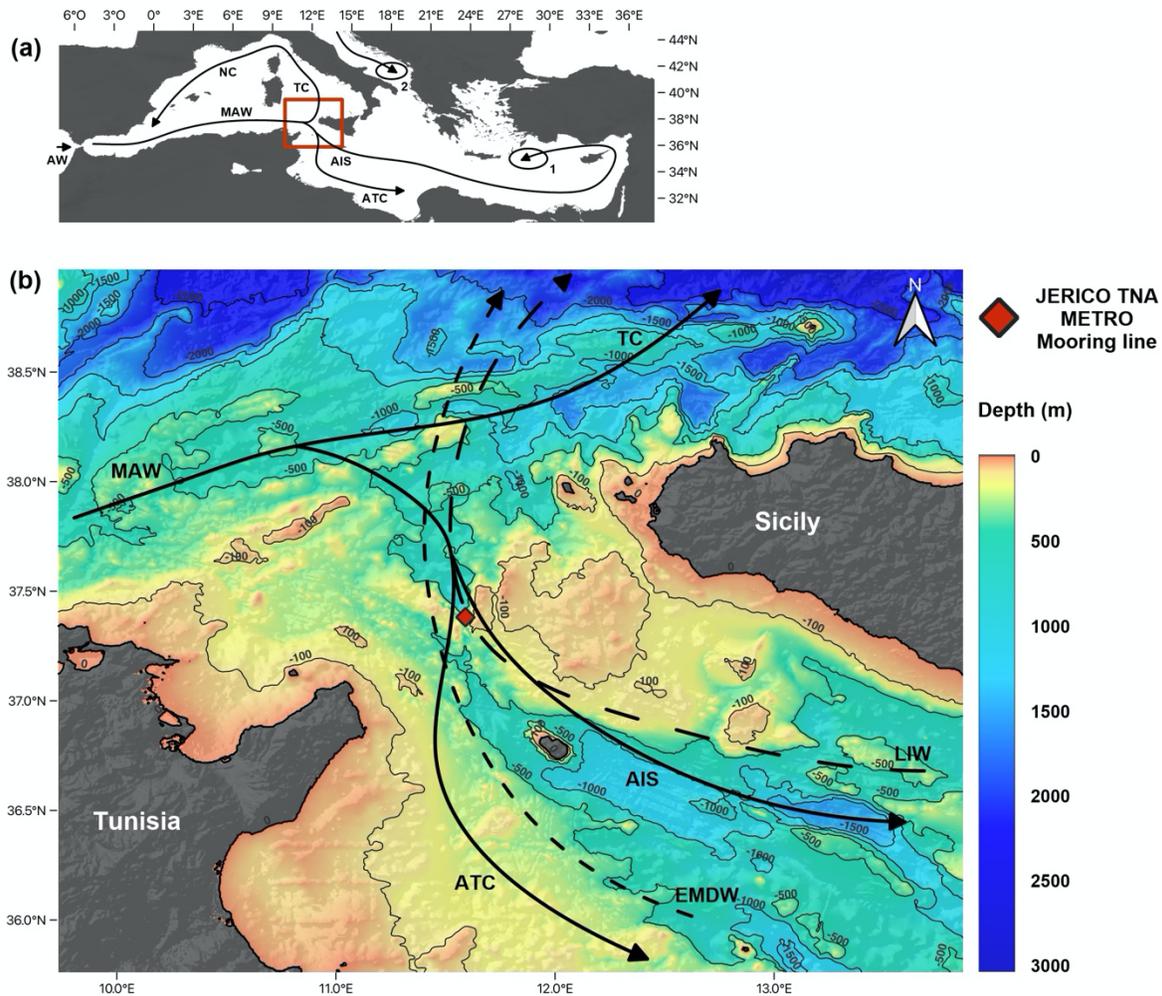

132

133 The Mediterranean is an elongated, semi-enclosed sea with an anti-estuarine circulation. It is
134 considered to be a concentration basin (Bethoux et al., 1999) in which the evaporation exceeds the
135 freshwater inputs, forcing a negative hydrological balance (Robinson and Golnaraghi, 1994). This
136 negative balance is compensated by the entrance of surface oceanic water from the Atlantic Ocean
137 through the Channel of Gibraltar. The colder and nutrient richer Atlantic Waters (AW) spread
138 eastward into the Mediterranean basin (Millot, 1991; Pinardi et al., 2015), where they progressively
139 become warmer, saltier and more oligotrophic as they mix with resident waters (Modified Atlantic
140 Waters – MAW. Also known as Atlantic Waters – AW). MAW circulate following a cyclonic circuit
141 along the Algerian coast (Algerian Current – AC) (Malanotte-Rizzoli et al., 2014; Millot, 1999) and
142 divide into two main branches at the entrance of the Sicily Channel (Figure 1a). One of these
143 branches spreads into the northwestern part of the basin, into the Tyrrhenian Sea, where it
144 continues its path cyclonically. The second branch flows south of Sicily into the Ionian Sea
145 (Lermusiaux and Robinson, 2001). In the Sicily channel itself, the water masses are split again in two
146 different streams (Béranger et al., 2004): (i) the Atlantic Tunisian Current (ATC) that flows to the
147 southeast following the African coast; and (ii) the Atlantic Ionian Stream (AIS) that flows into the
148 deep eastern part of the basin (Figure 1b) and contributes to the MAW transport in the eastern
149 Mediterranean (Jouini et al., 2016; Lermusiaux and Robinson, 2001).

150 The Sicily Channel is located in the central Mediterranean (Figure 1a) and acts as a sill that
151 topographically separates the western and eastern Mediterranean basins. The circulation through
152 the Sicily Channel is characterized by water masses that flow in opposite directions at different
153 depths of the water column (Béranger et al., 2004; Garcia-Solsona et al., 2020; Pinardi et al., 2015;
154 Schroeder et al., 2017). The Levantine Intermediate Water (LIW), which enters the Channel from
155 the Ionian Sea, occupies the deeper part of the water column along with occasional thin Eastern
156 Mediterranean Deep Water layers (Gasparini et al., 2005; Lermusiaux and Robinson, 2001). The
157 Ionian Water (IW) can be present at intermediate depths (Figure 1), while the MAW cover the
158 surface to subsurface part of the water column (Garcia-Solsona et al., 2020; Warn-Varnas et al.,
159 1999). Temperature and salinity range from 15-17 °C and 37.2-37.8 psu for the MAW, 15-16.5 °C
160 and 37.8-38.4 psu for the IW and 13.7-13.9°C and 38.7-38.8 psu for the LIW (Astraldi et al., 2002;
161 Bouzinac et al., 1999; Robinson et al., 1999). Lastly, it is important to note, that the surface
162 circulation in the Sicily Channel presents a large seasonal variability concerning the water masses
163 distribution (Béranger et al., 2004; Lermusiaux and Robinson, 2001). Surface circulation experiences
164 a substantial seasonality in the Sicily Channel: during late autumn to late spring, the MAW dominate
165 the surface circulation, allowing nutrient and chlorophyll-enriched waters to enter the Channel
166 (Astraldi et al., 2002; D’Ortenzio, 2009). In turn, summer and autumn are dominated by LIW waters.
167 Deep-water circulation remains relatively stable on a seasonal scale (Béranger et al., 2004) with a
168 continuous LIW presence over the year. Finally, during summer, an upwelling settles in the Sicily
169 Channel, allowing the impoverished LIW to reach the surface (Lermusiaux and Robinson, 2001).

170 Regarding its nutrient distributions, the Mediterranean Sea is generally considered an oligotrophic
171 to ultraoligotrophic sea (Krom et al., 1991). However, this oligotrophy is not homogenous and
172 displays a clear west-to-east gradient which is reflected in the nutrient concentration and algal

173 biomass accumulation derived from colour remote sensing (Navarro et al., 2017; Siokou-Frangou et
 174 al., 2010). The eastern part of the Mediterranean is considered to be more nutrient depleted than
 175 the western part of the basin (Krom et al., 2005; Raimbault et al., 1999), with N:P ratios around 50:1
 176 (Krom et al., 2005). At times of maximum annual algal concentration, primary productivity (PP) in
 177 the Levantine Basin reaches values of ca. $0.1 \text{ g C m}^{-2} \text{ d}^{-1}$ (Hazan et al., 2018). This value is substantially
 178 lower than those recorded in the high productivity regions of the western basin such as the Gulf of
 179 Lions, ca. $0.4\text{-}0.65 \text{ g C m}^{-2} \text{ d}^{-1}$ (Gaudy et al., 2003; Rigual-Hernández et al., 2012), or the Alboran Sea,
 180 ca. $0.3\text{-}1.3 \text{ g C m}^{-2} \text{ d}^{-1}$ (Bárcena et al., 2004; Morán and Estrada, 2001) during the corresponding
 181 period.

182
 183 **Figure 1. (a)** Mediterranean Sea general surface circulation (Astraldi et al., 2002; Béranger et al., 2004;
 184 Incarbona et al., 2011; Macias et al., 2019) and location of the study zone. The ellipses show the deep-
 185 water formation zones for the LIW (1) and the EMDW (2). **(b)** Regional oceanographic and geographic
 186 setting of the Sicily Channel. The red diamond represents the location of the JERICO TNA METRO C01
 187 mooring line. Black continuous lines represent the surface circulation dominated by the Atlantic Ionian
 188 Stream (AIS) and the Atlantic Tunisian Current (ATC); while dashed lines show deep-water circulation
 189 influences by the Levantine Intermediate Water (LIW) and the Eastern Mediterranean Deep Water
 190 (EMDW). The difference in the dashed lines period stands for the occasional aspect of the EMDW. The
 191 topographic model was downloaded from the GEBCO database.

192

193 **3. Material and methods**

194

195 **3.1. Field experiments**

196 The sediment trap (Figure 1) was deployed in the C01 mooring line maintained by ISMAR-CNR in the
197 Sicily Channel (37.38°N, 11.59°E) thanks to a TransNational Access (TNA) call in the FP7 JERICO
198 project (Mediterranean sediment Trap Observatory). The mooring line was equipped with a
199 sequential sampling sediment trap located 413 m below the sea surface in a water column of around
200 450 m deep. The sediment trap was a PPS3/3 model, conical in shape with a 2.5 height/diameter
201 ratio and equipped with 12 sampling cups. Further information about this sediment trap
202 configuration and model can be found in Heussner et al., (2006, 1990).

203 Here we present data from November 2013 to mid-October 2014. The sampling period was 15 to
204 16 days from November 2013 to July 2014 and from September 2014 to October 2014. Between
205 July 2014 and September 2014, the sampling was set to 31 days. Before deployment and to limit the
206 degradation of the material caught, sediment trap sampling cups from both mooring lines were
207 filled with a 5% formalin solution prepared with 40% formaldehyde mixed with 0.45 µm filtered
208 seawater. The solution was then buffered with sodium borate to keep the pH stable and prevent
209 the dissolution of carbonate.

210

211 **3.2 Processing of sediment trap samples**

212 After the recovery, the cups were stored at 2-4°C until their processing according to the procedure
213 of Heussner et al., (1990). In the laboratory, the largest swimmers that entered the trap were
214 removed by wet sieving through a 1 mm nylon and samples were subsequently split into 6 aliquots
215 using a peristaltic pump. One sub-sample was used for total mass flux measurements, after having
216 <1mm swimmers and formaldehyde removed.

217 Another subsample of a total of 19 samples from the sediment trap were processed for
218 micropaleontological analyses in the micropaleontology laboratory of the Geology department at
219 the University of Salamanca. The samples consisted of aliquots of 1/6 of the original mooring line
220 cups and were preserved in seawater, with a pH between 7.6 and 7.8. All samples were first wet
221 sieved to separate the <63µm fraction and then dry sieved to separate the 63-150 and >150 µm
222 fractions. The washing was carried out with a potassium phosphate-buffered solution (pH= 7.5) to
223 prevent carbonate dissolution.

224

225 **3.3 Planktonic foraminifera identification, flux calculations and imaging**

226 The planktonic foraminifera identification (Plate 1) and counting to the species level were carried
227 out in the >150 µm fraction using a microscope (Leica Wild M3B). To have a representative picture
228 of the planktonic foraminifera population, the complete samples were analyzed (i.e. no splits were
229 applied). Identification was carried out according to Schiebel and Hemleben, (2017). A total of 15
230 species were identified (Plate 1): *Globigerinella siphonifera*, *G. calida*, *Globigerinoides sacculifer*, *G.*
231 *ruber*, *G. ruber* (pink), *Globoturborotalita tenella*, *G. rubescens*, *Orbulina universa*, *Globorotalia*
232 *truncatulinoidea*, *G. inflata*, *G. scitula*, *Globigerina bulloides*, *G. falconensis*, *Neogloboquadrina*

233 *incompta* and *Turborotalita quinqueloba* (Plate 1). In addition, benthic foraminifera shells were
234 identified to the lowest taxonomic level possible and counted. The 150 µm size limit was used to
235 compare our results with other time series and seabed sediment populations as it is widely used in
236 planktonic foraminifera studies, however, we acknowledge that some “small-sized” species such as
237 *N. incompta* and *G. tenella* may be undersampled as their adult size tends to be smaller
238 (Chernihovsky et al., 2023).

239 The foraminifera fluxes were calculated according to the following formula:

$$240 \quad PF \text{ (shells } m^{-2} d^{-1}) = \frac{(N \times \text{aliq.}) \times SD^{-1}}{0.1256}$$

241
242 “PF” stands for planktonic foraminifera, “N” accounts for the number of individuals identified, “aliq.”
243 refers to the aliquot (1/6 for all samples) and “SD” represents the sampling interval that the
244 sediment trap cup stayed open. Relative abundance for each species was also calculated for all
245 samples.

246 Here we refer to the planktonic foraminifera collected by the sediment trap as the settling
247 assemblage.

248 Lastly, to describe the seasonal flux variations and to put our results into a regional context and be
249 coherent with previous studies, each season was defined as spring (March–May), summer (June–
250 August), autumn (September–November) and winter (December–February).

251 To showcase the species collected by the traps (Plate 1), foraminifera imaging was carried out using
252 a Nikon SMZ18 stereomicroscope equipped with a Nikon DS-Fi3 camera and the image processing
253 software NISElements (version 5.11.03).

254

255 **3.4. Satellite-derived environmental parameters**

256 To assess the possible relationship of planktonic foraminifera fluxes with environmental variability,
257 ~~key environmental parameters, namely~~ satellite-derived chlorophyll-*a* and Sea Surface
258 Temperatures (SSTs) were retrieved from global data sets. Satellite-derived chlorophyll-*a*
259 concentration (mg m⁻³) was obtained from MODIS L3m satellite through NASA’s Giovanni web
260 interface with an 8-day and 4 km resolution for a 0.2 x 0.2° area around the mooring location
261 between 01/10/2013 to 01/11/2014. Additionally, sea surface temperature SST (°C) were also
262 obtained from the same site with the same resolution to use as a proxy for water temperature and
263 water column stratification.

264

265 **3.5 Planktonic foraminifera flux and surface sediment data from other Mediterranean settings**

266 In order to put into context our observations with the regional variability of planktonic foraminifera
267 communities in the Mediterranean Sea, modern planktonic foraminifera flux datasets were
268 retrieved from different sites. Foraminifera fluxes of: (i) the Levantine basin (LevBas) were obtained
269 from Avnaim-Katav et al., (2020); (ii) the Gulf of Lions (stations Planier - PLA, and Lacaze Duthiers -
270 LCD) from Rigual-Hernández et al., (2012); (iii) and the Alboran Sea (stations ALB 1F and ALB 5F)
271 from both Bárcena et al., (2004) and Hernández-Almeida et al., (2011). The foraminifera fluxes of
272 the Gulf of Lions and Alboran Sea concerned the >150 µm fraction, while the ones from the
273 Levantine basin represented the >125 µm fraction (Figure 7).

274 Core-top data from the ForCenS database (Siccha and Kucera, 2017) was used to compare the
275 planktonic foraminifera abundance patterns from the C01 mooring line with the seabed sediment.
276 Only seabed sediment located on a 2.5 degree difference in both latitude and longitude was selected
277 to compare our data with sites in the vicinity of the Sicily Channel. This corresponded to a total of
278 16 core-tops part of the MARGO database. The complete details of the latter can be found in the
279 Supplementary data.

280 Additionally, the planktonic foraminifera population data from two box-cores analyzed by Incarbona
281 et al., (2019) were also included: sites 342 (36.42°N, 13.55°E) and 407 (36.23°N, 14.27°E). These two
282 sites are located in the Sicily Channel and they provide a robust chronology (²¹⁰Pb) that allowed to
283 document abundance changes across the recent Holocene. The dating covered the years 1558 to
284 1994 CE. Here we compared the sediment trap from the C01 mooring line samples with the mean
285 relative abundance from the 23 (site 342) and 24 (site 407) samples available.

286 Finally, to have a more complete picture of the modern planktonic foraminifera communities
287 currently living the surface ocean, the annual integrated data of our sediment trap was compared
288 with the BONGO nets data from Mallo et al., (2017), specifically, with the sample retrieved in the
289 axis of the Sicily Channel (37.08°N, 13.18°E) in Spring 2013.

290

291 **3.6 Statistical analysis**

292 To have uninterrupted monthly and daily values from NASA's Giovanni environmental parameters
293 that coincide with the mean sampling date from the sediment trap, a daily resampling has been
294 carried out using QAnalySeries software.

295 Pearson correlation and *p*-value tests between the foraminifera abundances and the environmental
296 parameters (SST and chlorophyll-*a*) were carried out with the Past4 program. A *p* < 0.05 was used
297 to denote statistical significance.

298 In addition, a canonical correspondence analysis (CCA) was also used to evaluate the influence of
299 both SST and chlorophyll-*a* on foraminifera species fluxes. A CCA is a correspondence analysis of a
300 species matrix where each site has given values for one or more environmental variables (SST and
301 chlorophyll-*a* concentration in this case). The ordination axes are linear combinations of the
302 environmental variables. A CCA is considered an example of direct gradient analysis, where the
303 gradient in environmental variables is known and the species abundances/fluxes are considered to
304 be a response or to be affected by this gradient (Nielsen, 2000).

305 Additionally, to evaluate the magnitude of the foraminifera fluxes across major regions of the
306 Mediterranean, an estimation of the annual planktonic foraminifera flux (shells m⁻² y⁻¹) was
307 calculated using the sediment trap data from the literature review and our study. To that purpose,
308 the data was annualized according to the following formula:

$$309 \text{ Annual PFF} = \sum(PF \times SD + cPF \times mSD)$$

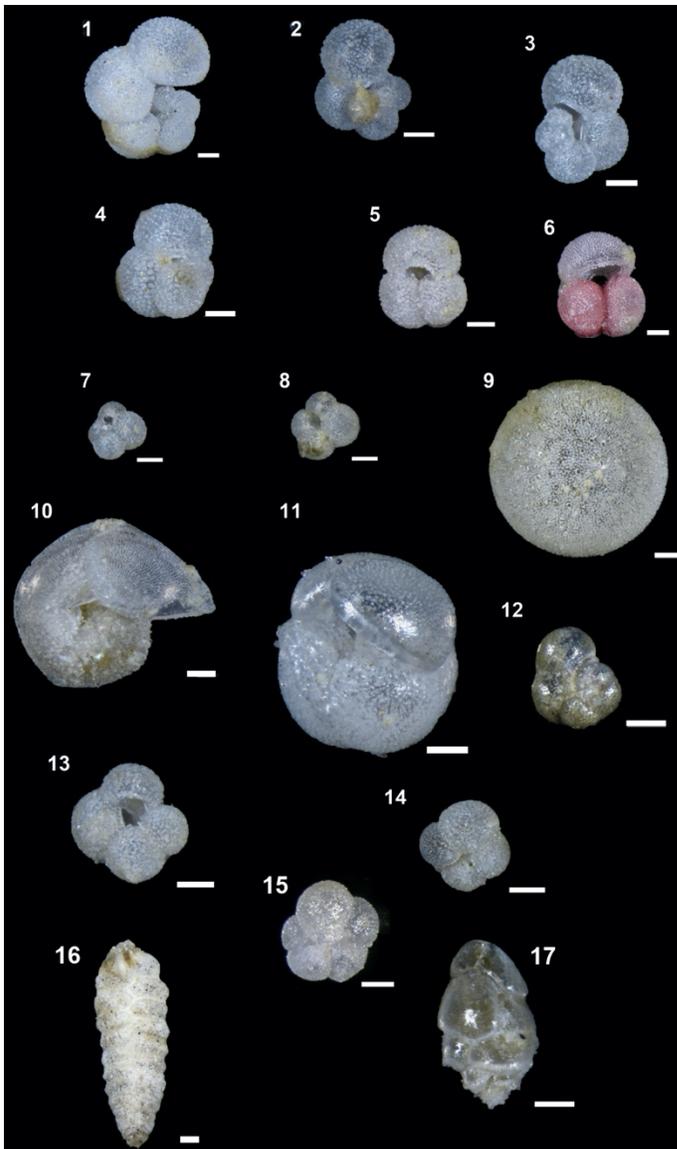

310 Where "PFF" stands for planktonic foraminifera flux (shells m⁻² d⁻¹), "SD" accounts for sampling days,
311 "cPF" represents calculated planktonic foraminifera flux (shells m⁻² d⁻¹) and "mSD" stands for missing
312 sampling days. "cPF" calculation depended on the site. For the datasets retrieved from the Sicily
313 Channel and the Levantine basin, less than 20 sampling days were missing, so the corresponding
314 planktonic foraminifera fluxes were replaced by the mean of the first and last flux values recorded.
315 The two datasets from the Alboran Sea displayed more than 70 missing days, so the corresponding

316 flux values used were a mean of the two closest months to the missing data. Concerning the two
317 time series from the Gulf of Lions, they covered more than one year. Therefore, a mean year was
318 estimated: a mean monthly flux value was calculated for all 12 months based on all the available
319 measurements and then multiplied by the corresponding mean duration of each month, and then,
320 all monthly fluxes were added together.

321 To compare the species richness and diversity across the previously described sites, Simpson (D) and
322 Shannon/Weiner (H/W) indexes were calculated. Here, we reported the inverse Simpson index (1-
323 D). None of these indexes were calculated for the Alboran Sea sites (ALB 1F and ALB 5F) because
324 only information about the four main species was documented (Bárcena et al., 2004; Hernández-
325 Almeida et al., 2011).

326 Finally, the squared chord distance (SCD) between the C01 sediment trap and every core top sample
327 downloaded from the ForCenS database (Siccha and Kucera, 2017) planktonic foraminifera relative
328 abundance was calculated. It is a widely used metric in palaeoecological and paleontological studies
329 as it is the most effective index for identifying the closest analogues in planktonic foraminifera
330 datasets (Prell, 1985). This is mainly because it shows the best balance in weighing the contribution
331 of abundant and rare species in a given association (Jonkers et al., 2019). In this study, SCD values
332 lower than 0.25 have been considered as reliable analogues (Ortiz and Mix, 1997).

353
 354 A total of 3723 **planktonic** foraminifera shells and 141 benthic foraminifera were counted.
 355 Planktonic foraminifera were identified at the species level, resulting in a total of 15 different species
 356 identified (Plate 1). A mean of 196 planktonic foraminifera specimens per sample were identified,
 357 with a minimum of 14 individuals in November 2013 and a maximum of 633 individuals in mid-
 358 March 2014 (Table 1).

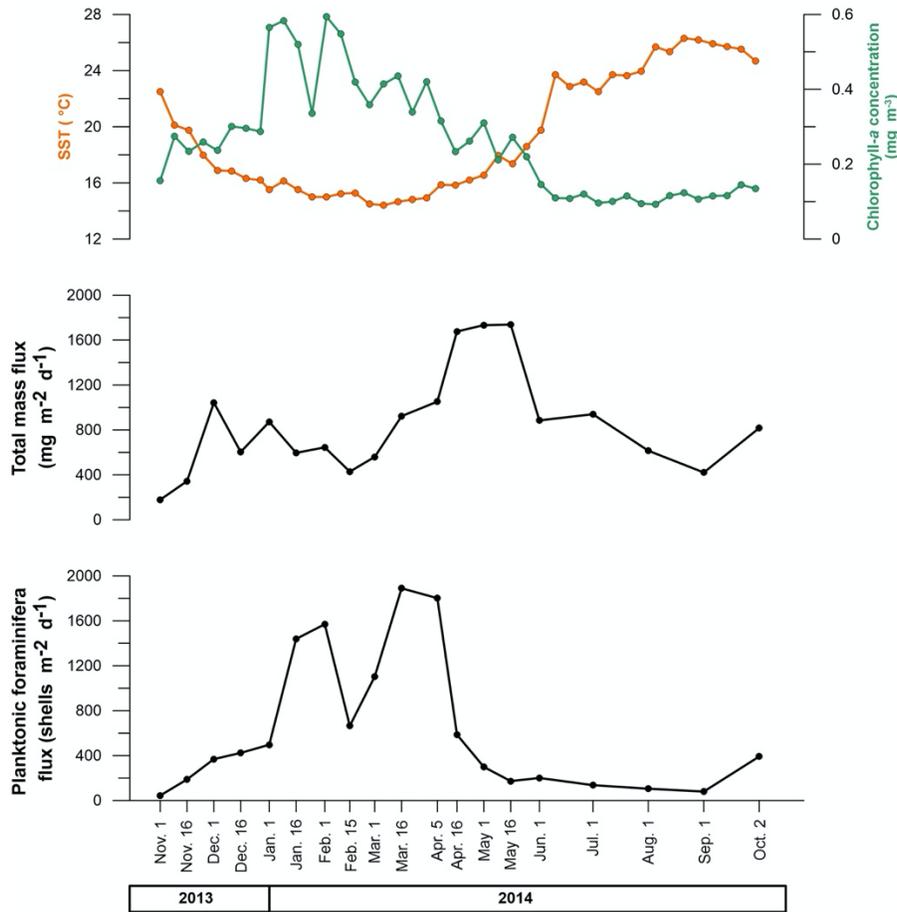

359 According to the raw counts results, the most abundant species was *G. inflata*, which represented
 360 55.7% of the total **planktonic** foraminifera individuals. The second most represented species was *G.*
 361 *truncatulinoides*, with 18.9%, followed by *G. bulloides* with 8.2%. These three species alone
 362 accounted for more than 80% of the planktonic foraminifera identified. The remaining species
 363 abundances were below 5%. *G. ruber*, *G. ruber* (pink), *O. universa*, *G. rubescens* and *G. sacculifer*
 364 represented between 2 and 3.3 % of the total individuals. Species like *G. tenella*, *G. scitula*, *N.*
 365 *incompta* and *T. quinqueloba* were very scarce and accounted individually for less than 1% of the
 366 total planktonic individuals (Table 1). *Finally, only one individual of G. falconensis has been*
 367 *identified.* Note that *G. inflata*, *G. truncatulinoides* and *G. ruber* were the only species present in all
 368 samples. *Concerning the differentiation between lobulated and sac-type Globigerinoides, we mainly*
 369 *found individuals belonging to the first group, the sac-type individuals were scarce. The latter were*
 370 *identified mainly during summer and autumn.*

371 Finally, the benthic foraminifera only represented 3.3% of the total foraminifera identified and 80%
 372 of the individuals were identified in the two samples retrieved during April 2014 (see Supplementary
 373 data).

374

375 **4.2 Total mass and planktonic foraminifera fluxes**

376

377

378 **Figure 2.** Total mass flux (TMF) (mg m⁻² day⁻¹), total planktonic foraminifera flux (PFF) (shells m⁻² day⁻¹),
 379 SST (°C) and chlorophyll-a concentration (mg m⁻³) changes between November 2013 and October 2014.

380

381 The mean total mass flux for the whole period of the study was 772.5 mg m⁻² d⁻¹, with a maximum
 382 value of 1737.7 mg m⁻² d⁻¹ and a minimum value of 179.5 mg m⁻² d⁻¹ reached in mid-May 2014 and
 383 November 2013 respectively (Figure 2). Higher total mass flux values were reached during spring
 384 2014, while lower values appeared during both autumn 2013 and 2014.

385 Planktonic foraminifera mean flux across the interval studied was 629.8 shells m⁻² d⁻¹ with a
 386 maximum value of 1889.9 shells m⁻² d⁻¹ and a minimum of 44.6 shells m⁻² d⁻¹ reached in mid-March
 387 2014 and in November 2013 respectively. Higher values occurred during two periods, early spring
 388 and winter 2014, while the lower ones occurred from late spring to fall 2014. Overall, the seasonal
 389 mean values were 1194.3 shells m⁻² d⁻¹ for the winter period, 612.3 shells m⁻² d⁻¹ for spring, 283.5
 390 shells m⁻² d⁻¹ for autumn and finally 107.2 shells m⁻² d⁻¹ for summer.

391 SST mean value was 19.2 °C and values ranged between a maximum of 26.1 and a minimum of 14.5
392 °C. The mean chlorophyll-*a* value was 0.27 mg m⁻³, the maximum value displayed was 0.56 mg m⁻³
393 while the minimum one was 0.09 mg m⁻³ (Figure 2).

394

395 **4.3 Foraminifera species fluxes**

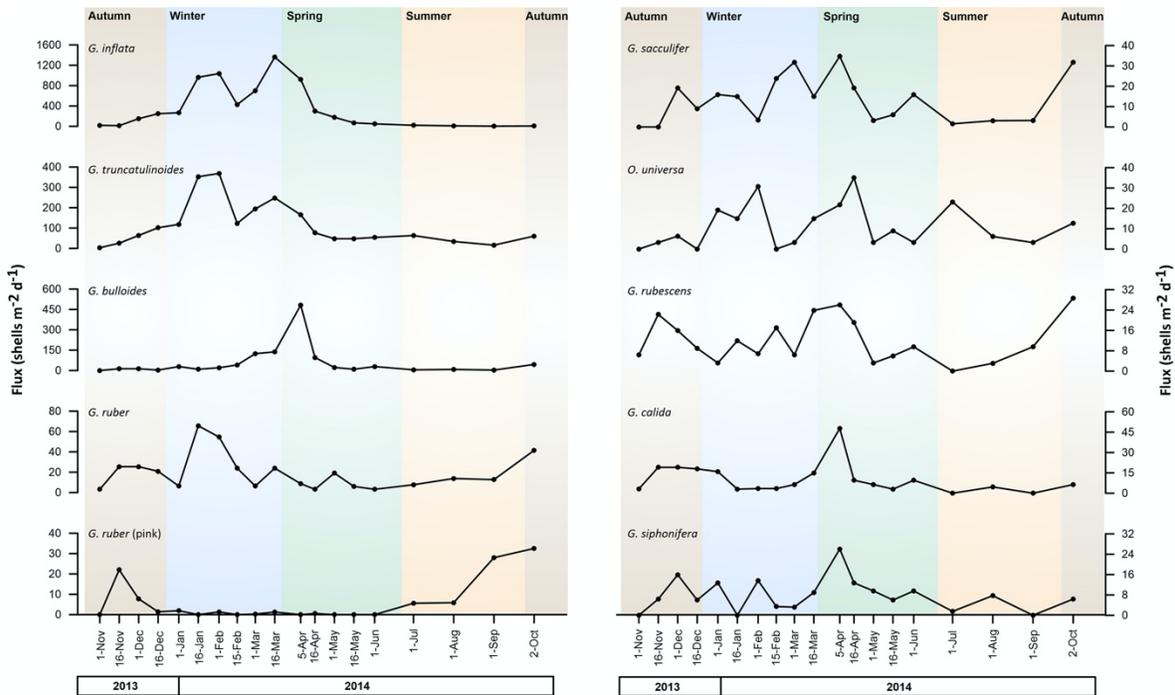

396 Overall, most of the planktonic foraminifera species collected by the trap exhibited either a uni-
397 modal or bi-modal flux distribution with a few exceptions (Figure 3).

398 *Globorotalia inflata* exhibited the highest fluxes of all species, with a mean flux of 368 shells m⁻² d⁻¹
399 throughout the record, with peak values in mid-March 2014 (1361 shells m⁻² d⁻¹) and minimum in
400 November 2013 (3 shells m⁻² d⁻¹). *G. truncatulinoides* was the second most important contributor
401 (mean of 114 shells m⁻² d⁻¹), with a maximum in mid-February and a minimum in November 2013
402 (368 and 3 shells m⁻² d⁻¹, respectively). *G. bulloides* was the third most important contributor to the
403 total planktonic foraminifera fluxes with a mean flux of 57.2 shells m⁻² d⁻¹ and maximum values
404 registered in April 2014 and minima in November 2013 (482 and 0 shells m⁻² d⁻¹, respectively).

405 The remaining species displayed mean fluxes lower than 50 shells m⁻² d⁻¹. *G. calida*, *G. ruber*, *G. ruber*
406 (pink), *G. rubescens* and *O. universa* mean fluxes were comprised between 10 and 20. Among these
407 species, *G. ruber* and *G. ruber* (pink) stood out and showed maximum fluxes of 66 shells m⁻² d⁻¹ in
408 February 2014 and 127 shells m⁻² d⁻¹ in October 2014, respectively. The remaining species, *G.*
409 *siphonifera*, *G. scitula*, *G. falconensis*, *N. incompta* and *T. quinqueloba* mean and maximum fluxes
410 were lower than 10 and 35 shells m⁻² d⁻¹, respectively, thereby representing a low contribution to
411 the total foraminifera fluxes.

412 Finally, it is worth noting that benthic foraminifera were also collected by the trap, displaying a mean
413 flux of 25 shells m⁻² d⁻¹. The peak contribution of these taxa was recorded in April 2014 (182 shells
414 m⁻² d⁻¹), and a minimum value in January 2014 (3 shells m⁻² d⁻¹). In terms of annualized foraminifera
415 flux, their contribution was only a 1.1% of the total foraminifera identified of which 75% was
416 recorded during April 2014 (Figure 6).

417

418
 419 **Figure 3.** Planktonic foraminifera fluxes (shells $\text{m}^{-2} \text{d}^{-1}$) and relative abundances (%; grey lines) from
 420 November 2013 to October 2014 of the 10 most abundant species identified. Note that the scale of the
 421 fluxes and abundances depend on the species. Background colour filling represents the different
 422 seasons: brown for autumn, blue for winter, green for spring and orange for summer.

423
 424 The variations in relative abundance differed according to the species. Most of the species displayed
 425 a unimodal distribution across the studied interval (Supplementary Figure 3), with some exceptions
 426 such as *G. siphonifera*, *G. calida* or *G. ruber*. Overall, *G. inflata* dominated the association from late
 427 autumn until mid-spring. Its relative abundance was comprised between 72% reached in mid-March
 428 2014 and around 2% in mid-November 2013 (Figure 3). *G. truncatulinoides* relative abundance
 429 pattern was similar to that of *G. inflata*, with maximum values in autumn and late summer. The
 430 lowest relative abundance was reached in November 2013: around 7%, while the highest abundance
 431 was 46% in July 2014. Note that despite the seasonality of its abundance, the amplitude of its
 432 relative abundance change was low compared to other species (Figure 3). In turn, the third most
 433 abundant foraminifera species, *G. bulloides*, displayed a pronounced seasonal change in its relative
 434 abundance reaching values up to 27% in early spring (April 2014) and dropping to about 5-8% in
 435 November 2014.

436 Secondary contributors, such as *G. siphonifera* and *G. sacculifer* reached their maximum
 437 contributions (~8%) in August and June 2014, respectively, *G. calida* in mid-November 2013 (10%),
 438 *G. ruber* in November 2013 (16%), *G. ruber* pink in October 2014 (32.5%) and both *G. rubescens* and
 439 *O. universa* exhibited their maximum contributions (with 14-15% for both species) in November
 440 2013 and in July 2014, respectively.

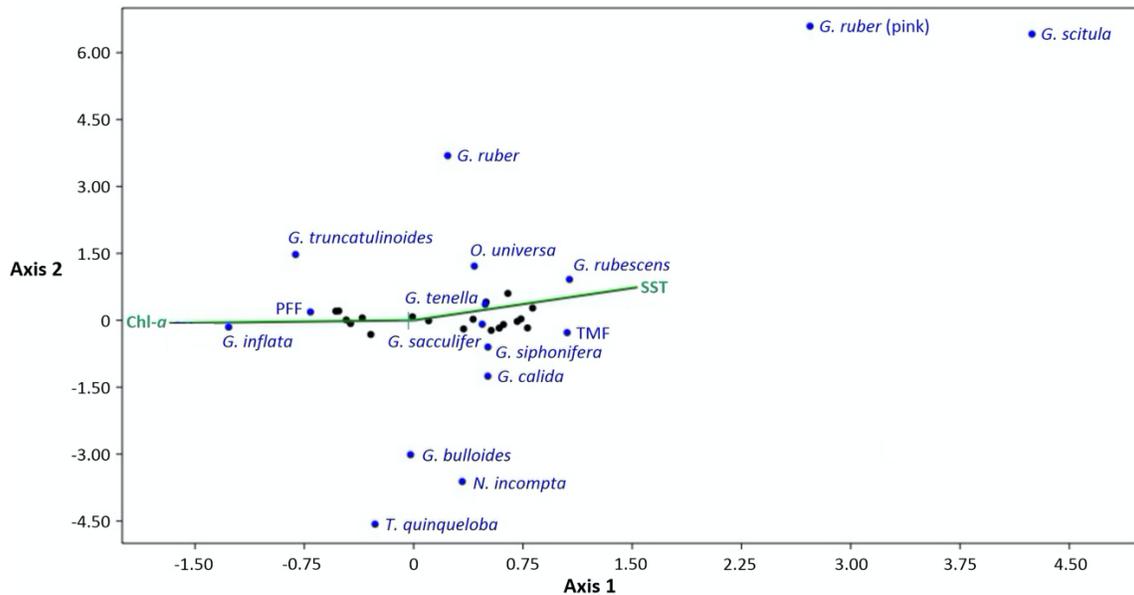

441 Overall, *G. inflata* is the only species that displayed its maximum mean relative abundance during
 442 winter: 64%. *G. siphonifera*, *G. sacculifer*, and *G. bulloides*, maximum mean relative abundances
 443 were reached during spring: 3%, 3.5%, 14% respectively. *G. calida*, *G. tenella*, *G. rubescens* and *N.*

444 *incompta* maximum mean abundances appeared to be in autumn: 5.7%, 2.2%, 8% and 4.8%
 445 respectively. Finally, *G. ruber*, *G. ruber* (pink), *O. universa*, *G. truncatulinoides* and *G. scitula*
 446 maximum mean relative abundances were displayed in summer: 11.6%, 13.2%, 8.9%, 32.8% and
 447 6.4% respectively (Supplementary Figure 3).

448

449 4.4 Chlorophyll-*a* and SST impact on foraminifera fluxes

450

451

452 **Figure 4.** CCA analysis of all the planktonic foraminifera species flux with the SST (°C) and the chlorophyll-
 453 *a* (“chl-*a*” in the CCA, in mg m⁻³) as the explanatory variables. The total mass flux (“TMF”) and planktonic
 454 foraminifera flux (“PFF”) are also included. Black dots represent the 19 sediment trap samples.

455

456 A CCA (see section 3.4) was carried out to characterize the impact of both the SST and the
 457 chlorophyll-*a* on the planktonic foraminifera fluxes (Figure 4).

458 Axis 1 shows, overall, the differences between deep and surface dwellers. Total planktonic
 459 foraminifera flux (PFF) and the fluxes of *G. inflata* and *G. truncatulinoides* are positively affected by
 460 the chlorophyll-*a* concentration and negatively affected by the SST. On the other hand, *G. ruber*, *G.*
 461 *ruber* (pink) and *G. scitula* fluxes showed an opposite pattern, being positively related with the SST
 462 and negatively with the chlorophyll-*a* concentration. *O. universa*, *G. rubescens*, *G. tenella*, *G.*
 463 *sacculifer*, *G. siphonifera* and *G. calida* fluxes are positively correlated with the SST and negatively
 464 with chlorophyll-*a* concentration, nonetheless, the impact of these parameters is weaker compared
 465 with the previous species. Finally, *G. bulloides*, *N. incompta* and *T. quinqueloba* fluxes are slightly
 466 positively influenced by the chlorophyll-*a* concentration, however. Axis 2 tends to separate the
 467 species between the different trophic regimes. Overall, it confirms that, in the one hand, *G. ruber*,
 468 *G. ruber* (pink) and *G. scitula* display a strong negative correlation with chlorophyll-*a* and therefore
 469 an affinity for oligotrophic and warm conditions; and on the other hand, shows that *G. bulloides*, *N.*
 470 *incompta* and *T. quinqueloba* display a positive correlation with chlorophyll-*a* and eutrophic

471 conditions. Furthermore, *G. bulloides* flux shows a strong correlation with the latter two species:
472 0.89 and 0.83 ($p < 0.05$).
473

474 5. Discussion

475

476 5.1 Seasonal variations in the magnitude of planktonic foraminifera fluxes in the Sicily Channel

477

478 The strong seasonality in the planktonic foraminifera fluxes registered by the trap is generally similar
479 in amplitude to previous studies in the Mediterranean (Bárcena et al., 2004; Rigual-Hernández et
480 al., 2012) and other temperate settings (Kuroyanagi and Kawahata, 2004; Wilke et al., 2009),
481 thereby suggesting the C01 record mainly reflects the temporal variations in planktonic foraminifera
482 abundance in the upper water column. Therefore, next, we discuss the influence of oceanographic
483 controls on the planktonic foraminifera fluxes.

484 Our data shows that, despite differences in the magnitude of their fluxes, most of the species
485 identified display their maximum flux during winter, winter/spring transition or spring (Figure 3)
486 thereby coinciding with the period of maximum algal biomass accumulation and coldest SSTs (Figure
487 2). The enhanced primary productivity during winter and spring is mostly related to an
488 intensification of the chlorophyll-*a* and nutrient richer MAW flow into the Eastern Mediterranean
489 basin (D'Ortenzio, 2009; Pinardi et al., 2015; Siokou-Frangou et al., 2010). Our CCA results (Figure 4)
490 show that, although the flux patterns increase during winter and spring, only the planktonic
491 foraminifera flux, *G. inflata*, *G. truncatulinoides* and arguably *G. bulloides* (further discussed below)
492 fluxes are negatively related to SSTs and positively with the chlorophyll-*a* concentration. The
493 dominance of the planktonic foraminifera fluxes by these three species and their affinity for
494 mesotrophic waters is not surprising as *G. inflata* and *G. truncatulinoides* are typically associated
495 with the MAW, winter water mixing events and hydrologic fronts in the western Mediterranean,
496 while *G. bulloides* is generally associated with eutrophic environments linked to upwelling
497 conditions (Azibeiro et al., 2023). Overall, these three taxa have been described to be dominant
498 during winter in various western regions of the Mediterranean, such as the Alboran Sea (Bárcena et
499 al., 2004; Hernández-Almeida et al., 2011), the Provençal basin and in the Gulf of Lions (Pujol and
500 Grazzini, 1995; Rigual-Hernández et al., 2012). Interestingly *G. inflata*, *G. truncatulinoides* and *G.*
501 *bulloides* are almost absent in the eastern part of the basin, most likely due to the low algal biomass
502 accumulation (Avnaim-Katav et al., 2020; Thunell, 1978).

503 Conversely, species such as *G. ruber*, *G. ruber* (pink), *G. scitula*, *G. rubescens* and *G. sacculifer* display
504 their maximum fluxes in summer or autumn (Figure 3). During the warm periods, summer and
505 autumn, the eastward advection of Atlantic waters in the Sicily Channel is weakened due to an
506 increased meandering of the ATC (Figure 1) and the local hydrography patterns (Béranger et al.,
507 2004), leading to a local water column stratification period which is also well documented in the
508 whole Mediterranean basin during summer (Siokou-Frangou et al., 2010). This translates into a
509 reduced MAW influence, and a larger influence of the LIW at intermediate depths (Astraldi et al.,
510 2002, 2001; Jouini et al., 2016). Therefore, the water column becomes warmer, saltier and more
511 nutrient depleted than the general conditions of the western basin (Gasparini et al., 2005; Navarro
512 et al., 2017; Siokou-Frangou et al., 2010) and provides the necessary environmental and

513 oceanographical configuration for eastern basins taxa to develop or being transported from the
514 easternmost part of the Mediterranean. Indeed, our CCA results (Figure 4) support these
515 observations (Figure 3). The latter species have been described to reach their maximum abundances
516 in the eastern part of the Mediterranean, specifically in the Ionian and Levantine basins during both
517 summer and autumn (Avnaim-Katav et al., 2020; Pujol and Grazzini, 1995).

518 Some species, such as *O. universa* or *G. calida*, do not display a clear flux pattern over the period
519 studied. CCA results suggest that these species have an affinity for warm and less productive
520 conditions. These taxa are considered widespread in the Mediterranean basin, although their
521 relative contributions are generally higher in the eastern part of the basin (Avnaim-Katav et al.,
522 2020; Pujol and Grazzini, 1995; Thunell, 1978). Lastly, it is important to note that the low number of
523 specimens of *G. falconensis*, *N. incompta*, *T. quinqueloba* and *G. tenella* found in our samples, makes
524 the estimation of shell fluxes for these species unreliable. These results are not surprising, since *N.*
525 *incompta* is mainly found in the northwestern part of the basin owing to cold and eutrophic
526 conditions (Azibeiro et al., 2023; Millot and Taupier-Letage, 2005) while *T. quinqueloba* has generally
527 been associated to cool Atlantic waters or cool marginal seas (Azibeiro et al., 2023).

528 In summary, planktonic foraminifera flux was maximum during winter and spring, coinciding with
529 the maximum seasonal eastward advection that brings MAW further east into the Sicily Channel.
530 These waters are less saline and nutrient enriched compared to the easternmost waters from the
531 Levantine basin. *G. inflata*, *G. truncatulinoides* and *G. bulloides* (the three most abundant species
532 that dominate the PFF), which are species described to come from the western basins, are probably
533 brought by the MAW and then dominate the planktonic foraminifera population. On the other hand,
534 during summer and autumn, the eastward advection weakens, allowing the LIW and AIS to
535 dominate the surface circulation due to the water column stratification and set favourable
536 conditions for eastern basin dominant taxa such as both morphotypes of *G. ruber*, *G. rubescens*, *G.*
537 *sacculifer*. This results in a significantly decreased planktonic foraminifera flux due to the absence
538 of western basin dominant species.

539

540 **5.2 Species succession, ecology and impact of the SST and chlorophyll-*a***

541 **The time series of settling planktonic foraminifera reflects a diverse assemblage** with species with
542 contrastingly different ecological preferences, encompassing a wide range of depth habitats and
543 diverse feeding strategies. Overall, the annual assemblage composition agrees well with previous
544 ship-board observations (Pujol and Grazzini, 1995) in the Channel of Sicily during VICOMED 1988
545 cruise, where *G. inflata*, *G. truncatulinoides* and *G. bulloides* were documented as the most
546 abundant taxa.

547 Next, we discuss the ecology of the most abundant species and the impact of chlorophyll-*a* and SST
548 on their distribution. We also discuss the foraminifera groups suggested by Jonkers and Kučera,
549 (2015), to explore their correlation with the previous parameters on an interannual scale. The latter
550 work proposed 3 groups: group 1 is formed by tropical and subtropical species, group 2 consists of
551 temperate to subpolar taxa, and group 3 represents the deep-dwelling species. These groups were
552 described as a result of the seasonal maximum fluxes timing of each species and their relationship
553 with both temperatures and nutrients (amongst other parameters) in different time-series across

554 the world ocean. Therefore, here we also used this grouping to compare and complete this
555 classification from a new time-series dataset.

556 *Globorotalia inflata* is the most abundant taxon in our samples. Our data shows that maximum
557 fluxes and relative abundances of this species are reached during winter and the winter-spring
558 transition (Figure 3). The relative abundances showed strong positive and negative significant (p
559 <0.05) correlations with the chlorophyll- a concentration and the SST: 0.808 and -0.896 respectively
560 (Figure 5). It is a non-spinose species and is considered a deep dweller (Hemleben et al., 1989;
561 Schiebel and Hemleben, 2017). Generally regarded as showing limited opportunistic behaviour and
562 it has been often associated with eddies and hydrological fronts (Chapman, 2010; Retailleau et al.,
563 2011). Concerning the Mediterranean, its maximum stocks and abundances have been recorded
564 along the southern margin of the western Mediterranean basin (Azibeiro et al., 2023), especially
565 during winter (Bárcena et al., 2004; Pujol and Grazzini, 1995; Rigual-Hernández et al., 2012); while
566 it is poorly represented in the eastern part, even absent in the Levantine basin (Avnaim-Katav et al.,
567 2020). As a consequence, *G. inflata* can be considered as a mesotrophic species, which is dominant
568 in regions with some degree of stratification of the water column and an intermediate amount of
569 nutrients and it has been used as a tracer of the Atlantic inflow in the Mediterranean basin (Azibeiro
570 et al., 2023), which agrees with the local hydrography in the Sicily Channel during winter and spring.
571 As *G. inflata* appeared in periods of cool and nutrient enriched waters (Figure 3), which coincide
572 with the periods of higher MAW influence in the Sicily Channel (Béranger et al., 2004), we consider
573 that our results further confirm *G. inflata* as tracer of the MAW in the Sicily Channel.

574 *Globorotalia truncatulinoides* is the second most abundant species in our record. However, our CCA
575 results suggest that the seasonal variations in *G. truncatulinoides* are not directly correlated with
576 either chlorophyll- a concentration or SSTs ($r = -0.162$ and 0.256 , respectively, $p >0.05$) (Figure 5).
577 This highlights the fact that environmental controls other than the ones considered here may be
578 affecting its distribution. This taxon is a cosmopolitan species found in all major oceans (Schiebel
579 and Hemleben, 2017) and is considered a deep dweller with an affinity for water-mixing conditions
580 (Margaritelli et al., 2020; Schiebel and Hemleben, 2005). It is a non-spinose species with a complex
581 life cycle. In the Mediterranean, peak abundances of this species are found in the northwestern part
582 of the basin, where it represents a major component of the assemblages (Pujol and Grazzini, 1995;
583 Rigual-Hernández et al., 2012), while it is absent in the easternmost part of the basin (Avnaim-Katav
584 et al., 2020). This species has been documented to have a complex life cycle and reproductive
585 strategy. *G. truncatulinoides* has been described to reproduce once a year in the upper layers of the
586 water column, generally when the water mixing allows the migration of juvenile individuals to the
587 surface (Lohmann and Schweitzer, 1990; Schiebel et al., 2002). Then, adult individuals migrate
588 downward the water column and spend the rest of their life cycle (Rebotim et al., 2017; Schiebel
589 and Hemleben, 2005). Hence, we speculate that these complex migratory patterns may be playing
590 a role here. As its reproduction cycle is mainly controlled by the gametogenesis process, and as
591 described previously, it reproduces once a year (a slower rate than the majority of the planktonic
592 foraminifera species) (Schiebel and Hemleben, 2017), then, although different stages of its life cycle
593 could be affected by SST and chlorophyll- a , this is not necessarily registered by the sediment traps
594 in every stage of its growth.

595 *Globigerina bulloides* was the third most abundant planktonic foraminifera species identified here.
596 It is a surface to subsurface dweller and one of the most common species across the world ocean
597 (Schiebel and Hemleben, 2017). Interestingly, our analysis showed no significant correlation
598 between changes in *G. bulloides* relative abundance and chlorophyll-*a* concentration or SST ($r = -$
599 0.145 and -0.111 respectively, $p > 0.05$). However, across the time span studied, this taxon showed
600 its maximum abundance and fluxes during relatively high chlorophyll-*a* and cool SST conditions
601 (Figure 3). This highlights that other environmental parameters than the ones considered here might
602 be playing a role in its distribution. It is a spinose species known for its opportunistic feeding strategy
603 (Schiebel et al., 2001) and affinity for upwelling and eutrophic environments (Azibeiro et al., 2023;
604 Bé et al., 1977). Within the Mediterranean Sea, it displays peak export fluxes to the deep sea in
605 areas of high productivity such as the Gulf of Lions and the Alboran Sea during the high productivity
606 period in late winter to spring (Azibeiro et al., 2023; Bárcena et al., 2004; Hernández-Almeida et al.,
607 2011; Rigual-Hernández et al., 2012), while few individuals are found in the eastern part of the
608 Mediterranean (Avnaim-Katav et al., 2020). We surmise that owing to its multiple trophic strategies
609 and its multi-diet characteristics, it could adapt and feed on varying chlorophyll-*a* concentrations.
610 Also, the lack of correlation with both parameters could be explained by the fact that this taxon is
611 associated with eutrophic conditions. In the Sicily Channel, the high productivity period ranges from
612 winter to spring, and the conditions allow deep mesotrophic dwellers (i.e. *G. inflata*) to dominate
613 the assemblage; while in summer and autumn, the upwelling setting brings oligotrophic conditions
614 that are not favourable for this species. ~~In addition, the maximum abundances of *G. bulloides* are
615 displayed coincidentally with the highest number of benthic foraminifera identified (see
616 Supplementary data), which in turn could mean that some of the *G. bulloides* specimens during their
617 maximum abundance have a resuspended origin.~~
618 Generally, both *G. bulloides* and *G. truncatulinoides* fluxes and abundances are positively linked to
619 favourable food conditions and high-productivity environments. The first species tends to exhibit a
620 “bloom” strategy on short time scales, while the second species tends to be related to nutrient
621 advection zones in the Mediterranean Sea (Margaritelli et al., 2022). Furthermore, in the
622 Northwestern Mediterranean a previous study showed that the fluxes of these two species are
623 almost in phase (Rigual-Hernández et al., 2012). Interestingly, in the Sicily Channel, this relation is
624 not straightforward. In the Gulf of Lions, *G. bulloides* is the main species and shows the classical
625 “bloom” behaviour, while *G. truncatulinoides* pattern is more constant and its variations are more
626 gradual (Rigual-Hernández et al., 2012). Although the timing of the two species is different in our
627 record, the response of *G. truncatulinoides* is similar across the record. Furthermore, from a
628 productivity standpoint, the Sicily Channel is less productive than the Gulf of Lions (Siokou-Frangou
629 et al., 2010), which, in turn, does not benefit *G. bulloides* abundances and, as the upwelling in our
630 study zone is less pronounced than in other parts of the Mediterranean, the timing between the
631 two species is different. Additionally, the intensity of the upwelling in the central Mediterranean is
632 controlled by variations in the intensity of the LIW flowing to the western part of the basin (Astraldi
633 et al., 2001; Lermusiaux and Robinson, 2001; Pinardi et al., 2015), with higher intensity leading to
634 reduced upwelling and therefore, productivity. This could explain the lack of high abundance of *G.*
635 *bulloides* in our study region as the upwelling in the Sicily Channel is reduced compared to other
636 places in the Mediterranean (D’Ortenzio, 2009; Siokou-Frangou et al., 2010) and therefore, the

637 increase in productivity is diminished compared to other regions in which the productivity and the
638 abundance of *G. bulloides* are higher, such as the Alboran Sea (Bárcena et al., 2004). Therefore, we
639 consider that a combination of ecological preferences and oceanographic processes could explain
640 the lack of synchronicity between these two species fluxes and abundances.

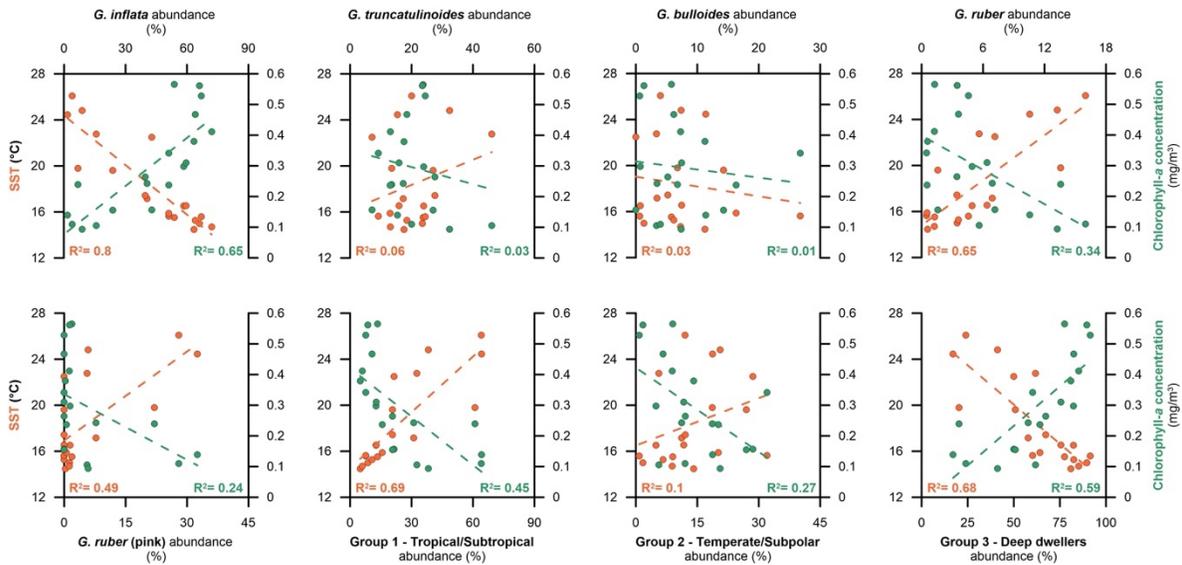

641 *Globigerinoides ruber* and *G. ruber* (pink) were the fourth and fifth most abundant species in our
642 samples (Table 1). Our correlation analyses showed a significant positive effect of SST ($r= 0.803$ and
643 0.678 , $p < 0.05$) and a significant negative effect of chlorophyll-*a* ($r= -0.567$ and -0.464 respectively,
644 $p < 0.05$) on both *G. ruber* and *G. ruber* (pink) respectively (Figure 5). These species have been
645 described as tropical to subtropical taxa, with an affinity for oligotrophic and stratified waters (Bé
646 et al., 1977). Both of these species are among the shallowest dwellers of the extant planktonic
647 foraminifera species and are considered one of the most adaptable to varying surface water
648 conditions (Kemle-von Mücke and Oberhänsli, 1999; Schiebel and Hemleben, 2017). Due to its
649 temperature and salinity limits for food acceptance, the white variety is one of the most studied
650 foraminifera species in culture experiments, which highlight their euryhaline and eurythermal life
651 cycle (Bijma et al., 1990; Lombard et al., 2009). In today's ocean, the white variety is substantially
652 more abundant than the pink one (Schiebel and Hemleben, 2017). In the case of the Mediterranean
653 basin, *G. ruber* is generally associated with warm and oligotrophic waters (Pujol and Grazzini, 1995)
654 and is abundant in the eastern oligotrophic basin, where it dominates the assemblages in the
655 Levantine basin during spring and fall (Avnaim-Katav et al., 2020). However, although present in the
656 western basin, its abundance is much lower in the Gulf of Lions (Rigual-Hernández et al., 2012) and
657 in the Alboran Sea (Bárcena et al., 2004). Overall, the correlation data agrees with the previous work
658 that linked *G. ruber* (both varieties) to warm and oligotrophic conditions generally displayed during
659 a higher stratification of the water column (Schiebel et al., 2004). As this species is mostly abundant
660 in the eastern part of the Mediterranean, it should be expected that the LIW, when it dominates
661 the circulation during summer and autumn, brings this species along with other oligotrophic taxa.
662 However, fluxes (Figure 3) and relative abundance data (supplementary Figure 3) showed that this
663 species maximum appearances were recorded during winter, coincidentally with *G. inflata* and *G.*
664 *truncatulinoides*. Therefore, the winter recorded in our dataset showed favorable conditions for
665 both deep mesotrophic dwellers and oligotrophic species such as *G. ruber*. We interpret this pattern
666 as a reduced influence of the MAW during winter in the Sicily Channel that could lead to slightly
667 warmer than usual surface conditions that favor the stratification and hence, the *G. ruber*
668 abundances. Concerning *G. ruber* (pink), as its fluxes and abundances were higher during summer,
669 and it is mainly identified in the eastern part of the Mediterranean as well, we consider that the LIW
670 influence bring this species in the Sicily Channel. ~~as they appear mainly during summer and autumn,~~
671 ~~coincidentally with the increased LIW and eastern basin waters influence in the Sicily Channel.~~

672 According to Jonkers and Kučera, (2015), the foraminifera fluxes can be predicted on a seasonal
673 scale for three different groups of planktonic foraminifera. Following this approach, we explore the
674 relative abundance of these three aggrupations to document if these correlate with both SST and
675 chlorophyll-*a* concentration (see Supplementary Table 1) on the period covered by the sediment
676 trap (Figure 5). The first group (group 1) consists of both *G. ruber* varieties, *G. sacculifer*, *O. universa*,
677 *G. siphonifera*, *G. rubescens* and *G. tenella*. The second group (group 2) is formed by *G. bulloides*, *T.*
678 *quinqueloba*, *N. incompta*, *G. scitula* and *G. calida*. In our record, however, either *G. bulloides* or *G.*

679 *calida* displayed a similar trend, and the remaining three species abundance was <1.5%, making any
680 significant assumption difficult (Table 1). The third (group 3) is composed by the deep dwellers *G.*
681 *inflata* and *G. truncatulinoides*. Group 1 showed a strong and significant positive correlation with
682 the SST (Figure 5) and a negative with the chlorophyll-*a* ($r= 0.828$ and -0.668 respectively, $p < 0.05$,
683 see Supplementary Table 1). This is not surprising as the majority of the group is formed by species
684 not only considered tropical but also well adapted to oligotrophic and nutrient impoverished
685 environments (Chapman, 2010; Hemleben et al., 1989; Schiebel and Hemleben, 2017). In addition,
686 most components of this group are symbiont bearing species (Takagi et al., 2019), which have been
687 described to be more adapted to nutrient depleted and oligotrophic conditions. Group 2 on the
688 other hand did not show any strong correlation to either SST and chlorophyll-*a* concentration,
689 although a significant negative correlation was displayed between the group abundances and the
690 latter parameter ($r= -0.525$, see Supplementary Table 1). This result is not surprising as the main
691 component of this group is *G. bulloides*, which previously showed a lack of correlation with both SST
692 and chlorophyll-*a*, while the remaining species of this group were taxa that tend to be outnumbered
693 by more opportunistic species (i.e. *N. incompta* and *T. quinqueloba*) (Kuroyanagi and Kawahata,
694 2004; Schiebel, 2002). Also, the overall abundance of these taxa was very low in our samples
695 compared to the other two groups, which in turn could affect the correlation results. Here we
696 propose that the mesotrophic conditions of the Sicily Channel developed during the relatively high
697 productivity period are not favourable enough for the development of the taxa comprised in group
698 2. Finally, group 3 displayed a strong and significant positive correlation with chlorophyll-*a*
699 concentration ($r= 0.771$, $p < 0.05$), which is an expected trend according to the affinity showed to
700 mesotrophic conditions by the two species that constitute this group, however, as compared to
701 Jonkers and Kučera, (2015), we showed a strong and significant negative correlation of these two
702 species abundances with the SST (Figure 5). The latter work stated that the cycles of these species
703 were independent of the temperature changes, however, these two species tend to be used as
704 tracers of cool and deep mesotrophic waters in the Mediterranean, generally associated with the
705 MAW (Azibeiro et al., 2023).

706 In summary, our data showed that in the Sicily Channel, the three major ecological groups proposed
707 by Jonkers and Kučera, (2015), exhibited a different response to environmental variability. Overall,
708 groups 1 and 3 showed significant correlation with the latter parameters and were in accordance
709 with their corresponding species ecologies. However, group 2 did not show any significant
710 correlation, which we interpreted as the result of very low abundances of the taxa comprised within
711 this group. This translates into the dominance of group 1 during summer and autumn when
712 oligotrophic and warm eastern waters dominate the water column, while the mesotrophic taxa from
713 group 3 dominate during winter and spring, coincidentally with higher primary productivity, yet not
714 eutrophic enough for the opportunistic taxa comprised in the group 2, which is less well represented
715 in the Sicily Channel.

A possible source of variability between the living foraminifera assemblages and those collected by the trap could be the preferential transport of certain species by the currents as well as differences in the sinking rates between species. Typically, deep dwelling species produce heavier shells than the surface dwelling ones (Zarkogiannis et al., 2022). Theoretically, lighter species are easier to remobilize than the heavier ones, however, if the current is strong enough, lighter species could travel far away while heavier species could be reworked in the vicinity of their deposition zone. *G. truncatulinoides* is among the heaviest planktonic foraminifera species (Beer et al., 2010; Béjard et al., 2023). Therefore, if the current is strong enough, it could be resuspended and be recorded by the sediment trap. The record in the seabed sediment (see section 5.5) showed that *G. truncatulinoides* was more abundant in the settling particles from the C01 mooring line (Figure 8), and according to the winnowing theory, *G. inflata* should follow a similar pattern as it also a heavy species (Zarkogiannis et al., 2022). However, surface data (Mallo et al., 2017) showed that the latter is also the dominant species in the BONGO nets (see section 5.5). Furthermore, Takahashi and Be, (1984) presented the data about the sinking speeds of different planktonic foraminifera species. As an example, *G. inflata* showed a sinking speed of 500 m per day, compared to 330 m per day for *G. bulloides*. These different sinking rates applied in a water column of around 450 m suggest that the likely origins of the planktonic foraminifera collected by the traps must be similar and are insufficient to generate discrepancies between the foraminifera assemblages living in the upper water column and those collected by the trap.

744 **Figure 6.** *G. bulloides* and benthic foraminifera fluxes (shells m⁻² d⁻¹) between November 2013 and
 745 October 2014.
 746

747
 748 The identification of benthic foraminifera individuals highlights suggest an impact of the
 749 hydrodynamic conditions on the settling particles populations. The main species identified were *T.*
 750 *saggitula* spp. and *B. marginata* (Plate 1) along with a small number of *Uvigerina mediterranea* and
 751 *Lagenina striata*. These taxa are considered infaunal species, i.e. they live buried in the sediment
 752 (Balestra et al., 2017; Milker and Schmiiedl, 2012) and are commonly found in continental shelves
 753 and slopes. Overall, benthic foraminifera accounted only for a mean of 3.4% of the total foraminifera
 754 identified in the C01 settling particles (Table 1) and the percentage of planktonic oscillated between
 755 89 and 99.4%. Most of the annual benthic fluxes occurred during April, when a total of 80% of the
 756 annual benthic foraminifera fluxes were recorded (Figure 6). As described previously, the Sicily
 757 Channel hydrography is complex from both a vertical and seasonal point of view (Astraldi et al.,
 758 2001; Garcia-Solsona et al., 2020; Incarbona et al., 2011; Pinardi et al., 2015; Schroeder et al., 2017).
 759 In the Sicily Channel, the tidal and subtidal current speed is known to reach maximum annual values
 760 during the spring period (Gasparini et al., 2004) which could be invoked as a possible source of
 761 sediment resuspension including benthic species. This has also been observed in different parts of
 762 the Mediterranean (Grifoll et al., 2019). Indeed, in our record, the highest benthic foraminifera
 763 fluxes were collected during spring (Figure 6), i.e. the period of peak current intensity in the Channel.
 764 Coincidentally, it also showed the highest fluxes of *G. bulloides* (Figure 3), which is the third most
 765 abundant species in our record (Table 1). Interestingly, this species annual flux distribution showed
 766 no correlation with either the SST nor the chlorophyll-*a* (Figure 5). These observations, coupled with
 767 the fact that the fluxes of *G. bulloides* and the benthic foraminifera were positively and significantly
 768 correlated ($r= 0.89, p<0.05$), suggest that benthic species were resuspended, being caught at 40 m
 769 of water depth by our sediment trap. Furthermore, a low number of detritic debris, such as mica
 770 flakes, were identified in the samples that contained the highest number of benthic foraminifera
 771 (April 2014), which again suggest a secondary influence of resuspended sediments in the sediment
 772 trap record in specific intervals of the annual cycle. However, no such relationship has been
 773 identified with the other species that did not show any correlation with the previous environmental
 774 parameters: *G. truncatulinooides*. Consequently, we hereby propose that *G. bulloides* distribution
 775 and abundances are blurred in specific intervals by the resuspension of sea floor sediments. Finally,

776 the increase of *G. bulloides* abundance and fluxes that has been identified coincidentally with a higher
777 number of benthic foraminifera during early April could lead to the interpretation that the benthic
778 foraminifera are the result of the intensification of the MAW. However, as the presence of the
779 benthic foraminifera is patchy and not constant, we do not consider their presence is ruled out as a
780 reliable proxy for the MAW/LIW intensity. Therefore, it can be concluded that the C01 sediment
781 trap mainly records a pelagic signal with a secondary influence of resuspended sediments.

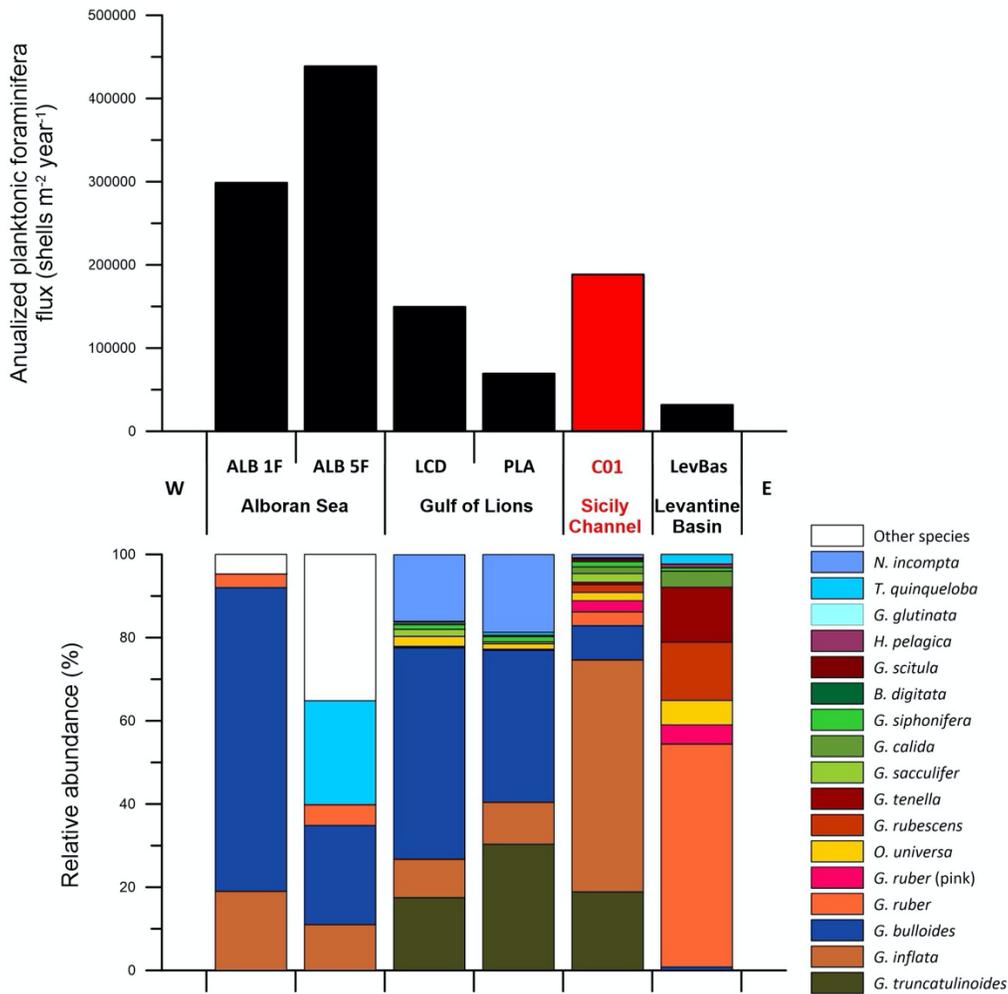

782

783 **5.4 Geographical variability in the magnitude and composition of planktonic foraminifera fluxes** 784 **across the Mediterranean**

785 The comparison of the settling planktonic foraminifera assemblage sediment trap from the Sicily
786 Channel with the ones retrieved from different parts of the Mediterranean offers a unique
787 opportunity to provide further insight into the central Mediterranean dynamics and ecology of this
788 group.

789 As stated previously, the planktonic foraminifera flux in the Sicily Channel was higher from mid-
790 January to mid-March, which coincided with the highest chlorophyll concentrations and the coolest
791 SST recorded (Figure 2). This seasonality is similar to the one observed in the Gulf of Lions, where
792 the planktonic foraminifera flux reached its highest values from mid-February to mid-March during
793 different years (Rigual-Hernández et al., 2012). Although slightly different, the planktonic
794 foraminifera fluxes patterns from both the Levantine basin and the Alboran Sea also displayed
795 maximum values between mid-February to mid-March and mid-January to mid-February
796 respectively (Avnaim-Katav et al., 2020; Hernández-Almeida et al., 2011). However, the magnitude
797 of the planktonic foraminifera flux values displayed some differences between the sites (see
798 Supplementary Figure 2). Overall, for the Sicily Channel, values ranged between 0-1889 shells $m^{-2} d^{-1}$
799 with a mean value of 629 shells $m^{-2} d^{-1}$. These values were comparable to the ones from the Gulf
800 of Lions: 0-2114 and 4268 shells $m^{-2} d^{-1}$ with a mean value of 225.4 in Planier sediment trap to 419
801 shells $m^{-2} d^{-1}$ in Lacaze-Duthiers sediment trap (Figure 7). On the other hand, the Levantine basin
802 values were lower: 0-429 shells $m^{-2} d^{-1}$, with a mean value of 93 shells $m^{-2} d^{-1}$. Finally, the highest
803 values belonged to the Alboran Sea: 0-6000 shells $m^{-2} d^{-1}$ with a mean value of 783 to 970 shells m^{-2}
804 d^{-1} depending on the gyres. Note that the planktonic foraminifera flux values from the Levantine
805 basin used here represent the foraminifera shells from the $>125 \mu m$ fraction, which highlights the
806 fact that compared to the $>150 \mu m$, the flux values should be even lower. The corresponding
807 chlorophyll-*a* values registered in the latter sites were 0.2-0.65 $mg m^{-3}$ for the Sicily Channel (Figure
808 5), 0.25-0.85 $mg m^{-3}$ for the Gulf of Lions (0-0.65 $mg m^{-3}$ in the Planier site, 0.25-0.85 $mg m^{-3}$ for
809 Lacaze-Duthiers) (Rigual-Hernández et al., 2012), 0.02-0.4 $mg m^{-3}$ for the Levantine basin (Avnaim-
810 Katav et al., 2020) and 0.1-1.2 $mg m^{-3}$ in the Alboran Sea (Hernández-Almeida et al., 2011), indicating
811 a similar productivity in terms of chlorophyll-*a* between the Gulf of Lions and the Sicily Channel. In
812 addition, here we calculated an annualized planktonic foraminifera flux (section 3.4) for each of the
813 6 sites compared here (Figure 7). Overall, the highest annualized fluxes were displayed in the
814 Alboran Sea (Figure 7): around 3×10^5 and 4.4×10^5 shells $m^{-2} y^{-1}$, while the lowest one was displayed
815 in the Levantine Basin: a little over 30000 shells $m^{-2} y^{-1}$ (Figure 7). The Gulf of Lions and the Sicily
816 Channel displayed comparable annualized fluxes although higher for the latter: around 1.5×10^5 and
817 1.85×10^5 shells $m^{-2} y^{-1}$ respectively. Note that PLA site values were significantly lower: around 7×10^4

818 shells $\text{m}^{-2} \text{y}^{-1}$ (Figure 7). Previous work showed that these planktonic foraminifera patterns were
819 mainly linked to specific regional oceanographic processes. First of all, the Levantine basin is well
820 known for being an ultra-oligotrophic region and being the warmest and saltiest of the
821 Mediterranean basins (Ozer et al., 2017), mainly due to the W-E anti-estuarine circulation. On the
822 other hand, the Gulf of Lions is considered an exception to the general oligotrophy of the
823 Mediterranean. Seasonal vertical mixing phenomenon occurs in winter, generated by cold winds.
824 This winter mixing recharges the surface waters with nutrients, allowing a winter/spring productivity
825 bloom (Durrieu de Madron et al., 2013; Houpert et al., 2016). Finally, the Alboran Sea is a transitional
826 region between the Atlantic Ocean and the Mediterranean Sea (Hernández-Almeida et al., 2011),
827 and unlike the latter, is not an oligotrophic region due to the two systems of high productivity
828 related to the gyres generated by an intense westerlies activity, which allow nutrients enriched
829 (compared to the resident waters) Atlantic waters to spread into the Mediterranean. This results in
830 an enhanced primary productivity period from November to March. According to the PFF patterns
831 displayed in this study, the Sicily Channel presents similar values and fluxes distributions to the Gulf
832 of Lions, however, its oceanographic circulation is significantly different from the latter. These
833 observations agree with the work of Mallo et al., (2017) carried out with plankton tows in the whole
834 Mediterranean basin. The latter work found that the Alboran Sea displayed the highest standing
835 stocks of planktonic foraminifera, while the easternmost part of the Mediterranean showed the
836 minimum values. Also, the Gulf of Lions and the Channel of Sicily displayed similar stocks, although
837 slightly superior for the Channel of Sicily.

838
 839 **Figure 7.** Comparison of the annualized (see section 3.4) planktonic foraminifera flux and the relative
 840 abundance of each species identified in different time-series across the Mediterranean Sea (see section
 841 3.5). The data from the Sicily Channel (C01) is depicted in red. Note that the Levantine Basin (LevBas)
 842 dataset covers the >125 μm fraction. Other species (white bar) in the Alboran Sea corresponds to any
 843 species different from the main 4 taxons identified in Bárcena et al., (2004) and Hernández-Almeida et
 844 al., (2011).

845

846 Concerning the species composition, we identified 15 planktonic foraminifera species in the Sicily
 847 Channel, which is a similar species number to the one from the Gulf of Lions (14 species) and higher
 848 than in the Levantine basin (10 different species). The Sicily Channel site displayed the highest
 849 planktonic foraminifera assemblage diversity among the three sites compared: a mean 1-D and S/W
 850 index of 0.68 and 1.57 respectively. (Table 2). Interestingly, despite showing a similar number of
 851 different species, the Gulf of Lions displayed the lowest diversity values, especially for the PLA site:
 852 mean 1-D of 0.55 and mean H/W of 1.08, while the LCD site 1-D and h/w were 0.58 and 1.15
 853 respectively. These observations highlight that, although the annualized planktonic foraminifera flux
 854 was similar between the Gulf of Lions (for the LCD site) and the Sicily Channel (Figure 7), the
 855 assemblage in the latter site was significantly more diverse regarding species composition. The

856 composition of the annual planktonic foraminifera population of the different species showed some
 857 differences between the sites compared here. In the Levantine basin, the majority of the planktonic
 858 foraminifera population consisted of surface symbiont bearing species such as *G. ruber*, *G. ruber*
 859 (pink), *G. rubescens*, *G. tenella*, *O. universa*, which are well adapted to the ultra-oligotrophic
 860 conditions (Lombard et al., 2011; Schiebel and Hemleben, 2017). The latter species represented 96%
 861 of the total planktonic foraminifera in the Levantine basin, while the same species in the Sicily
 862 Channel accounted for around 10% of the total individuals (Figure 7). Note that both *G. rubescens*
 863 and *G. tenella* are considered small-sized species (Chernihovsky et al., 2023) and their adult size is
 864 often smaller than 150 μm , so it is possible that some individuals of those species may not be
 865 recorded in our data. On the other hand, in the Gulf of Lions, the four main species were *G. bulloides*,
 866 *N. incompta*, *G. inflata* and *G. truncatulinoides*, which represented 88 to 95% of the total planktonic
 867 foraminifera (Rigual-Hernández et al., 2012). These species tend to be associated with eutrophic to
 868 mesotrophic environments which coincides with the Gulf of Lions locally enhanced primary
 869 productivity conditions. In the Sicily Channel, the same species accounted for 83% of the total
 870 individuals, and, except for *N. incompta*, the remaining three species were also the most abundant
 871 in our samples.

872

873 **Table 2.** Inverse Simpson (1-H) and Shannon-Weiner indexes mean, standard deviation (“Stan. Dev.”)
 874 and maximum values for the two Gulf of Lions sites (PLA and LCD), the Sicily Channel (C01, this study)
 875 and the Levantine Basin (LevBas).

	Gulf of Lions		Sicily Channel	Levantine Basin
	LCD	PLA	C01	LevBas
Simpson 1-H				
Mean	0.581	0.553	0.681	0.615
Stan. Dev.	0.168	0.180	0.132	0.144
Max	0.802	0.781	0.872	0.804
Shannon H/W				
Mean	1.151	1.078	1.572	1.230
Stan. Dev.	0.359	0.375	0.398	0.316
Max	1.789	1.630	2.188	1.759

876

877 Considering the planktonic foraminifera fluxes patterns, the species diversity and the planktonic
 878 foraminifera most abundant species from each of the three Mediterranean time-series with which
 879 we compared our data, we interpret that, from a planktonic foraminifera population point of view,
 880 the Sicily Channel could be considered as a transition zone and a biological corridor between the
 881 western and eastern basins.

882

883 Finally, to put our data into a global context, here we compare our dataset with planktonic
 884 foraminifera data from the same size fraction retrieved in the Gulf of Mexico, high latitudes North
 885 Atlantic and gyres region of the North Atlantic Ocean. In the northern Gulf of Mexico, from 2008 to
 886 2010, the $>150 \mu\text{m}$ PFF was comprised between 0 and slightly over 800 shells $\text{m}^{-2} \text{d}^{-1}$, with a mean

887 value of around 250 shells $\text{m}^{-2} \text{d}^{-1}$ (Poore et al., 2013). A total of 12 species were identified, with *G.*
888 *truncatulinooides*, *G. ruber* (pink) and *N. dutertrei* as the most abundant species recorded. On the
889 other hand, in the North and high-latitudes Atlantic Ocean, Wolfteich (1994), showed that the PFF
890 oscillated between 0 and around 5000 shells $\text{m}^{-2} \text{d}^{-1}$ for a mean value of 800 shells $\text{m}^{-2} \text{d}^{-1}$, while *G.*
891 *bulloides* and *N. incompta* were the most abundant species. Although the latter work only focused
892 on the most abundant species, additional work has documented more than 20 species in the vicinity
893 of the North-Atlantic gyres (Salmon et al., 2015), but around only three to four in the high latitudes.
894 This highlights that, from a planktonic foraminifera population point of view on a wider scale, the
895 Sicily Channel displayed a higher planktonic foraminifera flux and species richness compared to the
896 tropical to subtropical Gulf of Mexico and to the high latitudes of the North Atlantic, but lower values
897 compared to the North Atlantic gyres region.

898

899 **5.5 Recent planktonic foraminifera assemblage comparison with seabed sediment**

900

901 The Mediterranean Sea is often referred to as a climate change hotspot and a “laboratory basin” where
902 many global environmental trends are amplified (Bethoux et al., 1999). In particular, ocean warming is
903 expected to exceed the global average (Hassoun et al., 2022, 2015; Lazzari et al., 2014) while it is
904 considered a specially sensitive zone of the ocean to acidification due to the fast turnover of its waters
905 and penetration of anthropogenic CO_2 (Bethoux et al., 1999; Schneider et al., 2007). One of the main
906 questions about planktonic foraminifera concerns the way they are going to react to the ongoing climate
907 change in the global ocean (Jonkers and Kučera, 2015; Schiebel and Hemleben, 2017). Previous work
908 suggests that global communities of planktonic foraminifera have already been affected by
909 environmental change since the onset of industrialization (Jonkers et al., 2019). Moreover, recent work
910 has shown that the calcification of several planktonic foraminifera species has decreased during the
911 industrial era in the northwestern Mediterranean (Béjard et al., 2023). Therefore, here we aim to assess
912 if modern planktonic foraminifera communities dwelling in the Sicily Channel differ from their pre-
913 industrial counterparts. [To do so, next, we compare the annual integrated assemblages collected by the](#)
914 [sediment trap in the C01 mooring line with the ones from a set of core-tops, two box-cores and BONGO](#)
915 [nets retrieved in the vicinity of the studied zone \(see Section 3.5\).](#)

916 As planktonic foraminifera are a group of calcifying plankton, when comparing sediment trap and
917 seabed sediment data, the possible role of calcite dissolution must be discussed. Firstly, the
918 Mediterranean Sea is supersaturated with respect to calcite (Álvarez et al., 2014; Millero et al., 1979)
919 and the depth of the studied material is substantially shallower than the calcite saturation horizon
920 (Álvarez et al., 2014). Secondly, recent work suggests that calcite experiences little to negligible
921 changes in the water column and burial in recent sediments (Béjard et al., 2023; Pallacks et al.,
922 2023). All this evidence suggests that dissolution played a negligible role in the preservation of
923 planktonic foraminifera preserved in the sediment record in the study region.

924 The core-tops [used for comparison were part with which the C01 sediment trap data is compared](#)
925 [were part of the](#) MARGO database (see Section 3.5 for more details). Note that the MARGO sites
926 3735 to 3739 seabed sediment was taken using a trigger-weight corer (Thunell, 1978). However,
927 samples 3658, 3672 and 3673 were retrieved using a piston corer (Hayes et al., 2005). Generally,
928 sampling with the trigger-weight method is considered to retrieve less mixed and disturbed

929 sediment than the piston or box corer sampling methods (Skinner and McCave, 2003; Wu et al.,
930 2020). Therefore, the foraminifera assemblages from the core-tops may likely represent a mix of
931 Holocene populations rather than exclusively modern assemblages. Although the lack of dating
932 control makes it impossible to determine the exact date of the core top assemblages. ~~our data~~
933 ~~suggest that the composition of modern foraminifera assemblages in the Sicily Channel has changed~~
934 ~~between the late Holocene and the present day.~~

935 The sites 342 and 407, studied by Incarbona et al., (2019), were retrieved with a box-corer. A total
936 of 23 and 24 samples were analyzed in the latter work, respectively. The advantage of comparing
937 the C01 assemblages with those of Incarbona et al., (2019) is the availability of high resolution ²¹⁰Pb
938 chronology. The ages ranged from 1718 to 1962 CE for site 342 and from 1558 to 1994 CE for site
939 407. Therefore, here we present a comparison with the mean relative abundance of the main
940 planktonic foraminifera species from all the samples available (Figure 8).

941 Finally, to provide a more complete snapshot of the surface assemblages, we also include the
942 abundances from Mallo et al., (2017) that were collected with a BONGO net during spring 2013 in
943 the axis of the Sicily Channel (Figure 8).

944 ~~The reasons of this change are uncertain, although we speculate that ongoing warming (Lazzari et~~
945 ~~al., 2014), the consequent increasing stratification of the water column in the Mediterranean~~
946 ~~(Siokou-Frangou et al., 2010) and a shift in the oceanographical configuration could have already~~
947 ~~reduced primary production in the Sicily Channel.~~

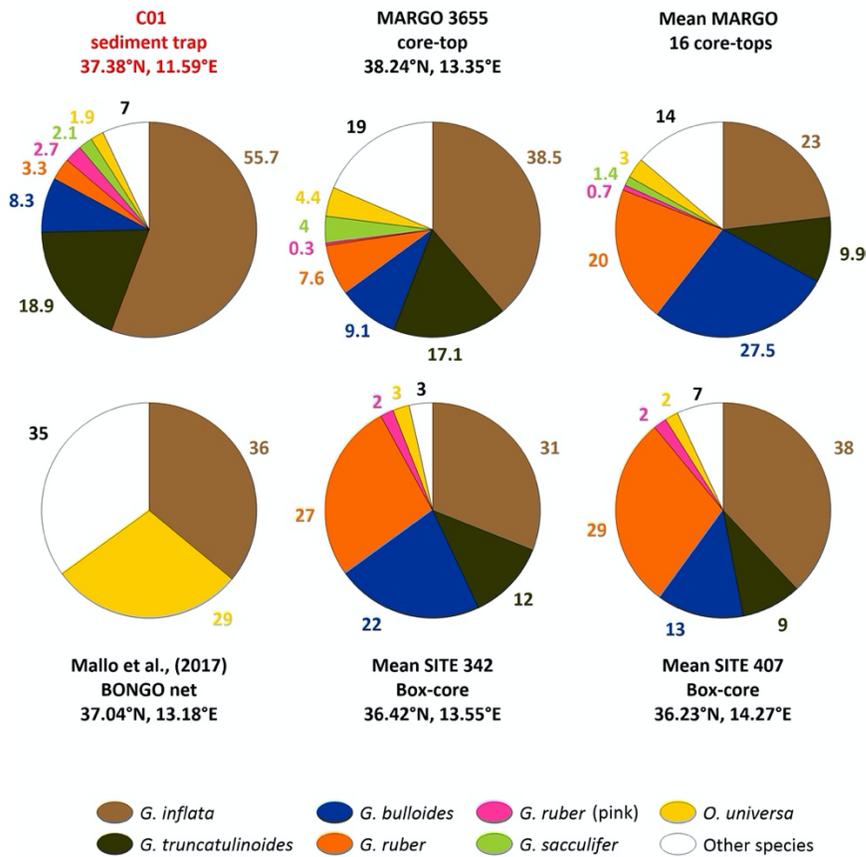

948 In terms of planktonic foraminifera assemblage composition, major differences were observed
949 between the different seabed sediments datasets (Figure 8). Overall, the **settling population from**
950 **the C01 mooring line** appeared to be closer to the assemblages from sites 342 and 407 (Figure 8)
951 than to the mean from the MARGO database (see Supplementary data). The most evident
952 observation relies on the shift of the dominant species when comparing the **settling population** with
953 the sites 342, 407, the BONGO net and the core-top assemblages (Figure 8). As described previously,
954 *G. inflata* dominated the assemblages collected by the **sediment trap** (Table 1). This is also the case
955 for the sites 342 and 407 and the BONGO net (Figure 8). However, *G. bulloides* was the best-
956 represented species in the core-tops from the MARGO database. Also, the second most abundant
957 species varied across the datasets: *G. ruber* in the sites 342 and 407, *O. universa* in the BONGO nets
958 and *G. inflata* in the MARGO core-tops, with abundances around 27-29, 29 and 27.5%, respectively.
959 ~~ollowed by *G. inflata* and *G. ruber* (Figure 8). The latter species showed mean relative abundances~~
960 ~~of 27.5%, 23% and 20% across all core-tops, respectively.~~ Interestingly, *G. truncatulinoides*
961 abundance was significantly lower in the seabed datasets and absent in the BONGO nets,
962 highlighting the deep aspect of its ecology (Figure 8). On the other hand, the “other species”
963 category, which consists of minor taxa such as *G. rubescens*, *G. siphonifera* and *G. calida* (amongst
964 others) played a more significant role in the MARGO core-tops and BONGO nets assemblages,
965 reaching abundances up to 26% (Figure 8), while in the sites 342 and 407, these species abundances
966 are similar to those of the sediment trap.

967 These results lead to several observations. Firstly, ~~*G. bulloides*, considered more susceptible to~~
968 ~~dissolution than the average planktonic foraminifera species (Dittert et al., 1999), dominates the~~
969 ~~seabed sediment assemblages; and *G. inflata*, considered a less dissolution susceptible species~~
970 ~~(Schiebel and Hemleben, 2017) dominates the sediment trap population. This information~~

971 ~~reinforces the idea that calcite dissolution in the water column or sediments is negligible. In other~~
972 ~~words, if dissolution was to take place here, *G. inflata* would be overrepresented in the seabed~~
973 ~~sediment, which is not the case.~~, concerning the seabed sediment comparison, the sediment trap
974 assemblage is closer to the sites 342 and 407 than to the MARGO database core-tops. The
975 comparison with the surface BONGO nets shows that, although the dominant species are the same
976 (i.e. *G. inflata*), the influence of *O. universa* and the overall diversity is less important in surface
977 waters. This highlights the complexity of the Sicily Channel configuration and the differences
978 between the surface (BONGO nets), the water column (sediment trap) and the seabed sediment
979 (MARGO database and sites 342 and 407) regarding the planktonic foraminifera populations.
980 Secondly, the seabed sediment planktonic foraminifera populations showed a reduced influence of
981 deep-dwelling species (excepting for *G. inflata* in sites 342 and 407) and a more pronounced
982 influence of both eutrophic and oligotrophic species. These eutrophic species (such as *G. bulloides*
983 but also *N. incompta*) are associated with MAW and western basins in the modern Mediterranean
984 Sea, while the more oligotrophic taxa (*G. ruber*, *G. rubescens*, *G. calida*...) are considered to be
985 abundant in the easternmost part of the basin (Azibeiro et al., 2023). As noted previously, although
986 the settling assemblage differs to the ones from the seabed sediment, it is more similar to the sites
987 342 and 407 than to the MARGO database core-tops. Also, the ²¹⁰Pb chronology available for sites
988 342 and 407 covers the years 1558 to 1994 CE (Incarbona et al., 2019). A possible interpretation of
989 these results is that the MAW influence into the basin may have shifted. Instead of bringing rich and
990 eutrophic waters that would allow the development of opportunistic species, it nowadays brings
991 more mesotrophic water masses that favour the development of deep dwellers in the Sicily Channel.
992 On the other hand, this could also lead to the assumption of a reduced eastward and LIW influence
993 in the present day as seen by the significantly lower abundance of oligotrophic species in the settling
994 assemblages. Also, a change in the environmental conditions could lead to the increase of deep
995 dwellers in substitution of eutrophic species such as *G. bulloides*. As described previously, the
996 Mediterranean Sea has already been described as a climate change “hotspot”, therefore the already
997 documented ocean warming and the consequent stratification (Malanotte-Rizzoli et al., 2014;
998 Siokou-Frangou et al., 2010) could have led to unfavorable conditions for several taxa. A decrease
999 in the primary production might have caused a shift in the dominance of the opportunistic *G.*
1000 *bulloides* by *G. inflata*. As described previously, *G. bulloides* shows a high affinity for high
1001 productivity environments, while deep dwellers such as *G. inflata* and *G. truncatulinoides* tend to
1002 prefer mesotrophic and stratified waters. Finally, note that the high abundance of *G. bulloides* in
1003 the seabed sediment could also be the result of a punctual high productivity events. In the Alboran
1004 Sea, during upwelling events, big amounts of *G. bulloides* are deposited in the seabed and dominate
1005 the assemblages, which reduces the relative abundance of other mesotrophic taxa (Bárcena et al.,
1006 2004; Hernández-Almeida et al., 2011). Then, multiple recurring high productivity events occurring
1007 over time in the Sicily Channel could explain the amount of *G. bulloides* in both the MARGO core-
1008 tops and the sites 342 and 407. In that sense, the recent warming and stratification of the
1009 Mediterranean could explain the recent trend in the planktonic foraminifera population registered
1010 by the C91 sediment trap. However, in that case, species such as *G. ruber* and other oligotrophic
1011 species should be at least as much represented as in the seabed sediment. Alternatively, this could

1012 imply a change in the intensity of the water masses flowing, such as an increased mesotrophic MAW
 1013 influence and a reduced oligotrophic LIW influence.

1014 Additionally, from a chronological point of view, we propose that the main assemblage change
 1015 between the settling and the seabed sediment assemblages (i.e. the dominance of *G. inflata*) took
 1016 place during the late Holocene but preceded the industrial period. The Incarbona et al., (2019) dates
 1017 showed that, overall, since 1558 CE, *G. inflata* already dominated the samples. Also, the chronology
 1018 in the work from Margaritelli, (2020) coupled with the abundances presented in allowed to show
 1019 that, since the Little Ice Age, the three dominant species in the western Sicily Channel are *G. inflata*
 1020 followed by *G. ruber* and *G. bulloides*. This brings further confirmation that *G. inflata* dominated the
 1021 seabed sediment in the late Holocene, but also to the fact that the shift in the secondary species
 1022 (i.e. *G. truncatulinoides* instead of *G. ruber* and *G. bulloides*) is rather recent. Also, we assume that
 1023 the discrepancy with the MARGO core-tops sample is the result of the low temporal resolution.
 1024

1025

1026

1027 **Figure 8.** Comparison of the relative abundance of the planktonic foraminifera from the sediment trap and seabed sediment. From top left to bottom right: the settling assemblage from the sediment is depicted in red; MARGO site 3655 corresponds to the lowest squared chord distance; the mean relative abundance of all MARGO sites included in this study (see Supplementary data); the results from the BONGO net retrieved in the Sicily Channel from Mallo et al., (2017); finally, the mean abundances (see section 3.5) from the two sites presented in Incarbona et al., (2019): sites 342 and 407.

1068

To document the differences between the assemblage in the C01 mooring line and the MARGO database core-tops, we hereby analyze the SCD between the annual integrated settling foraminifera assemblage of the C01 mooring line and all the core-tops located in the Sicily Channel (see Supplementary Figure 2). Overall, the SCD ranged between 0.27 and 1.1 (Table 3). By using a dissimilarity coefficient value of <0.25 as cutoff criteria (see section 3.6 for more details), it can be concluded that none of the core-tops assemblages can be considered close analogues to the C01 mooring line. The only exception might be MARGO site 3655, located around 180 km northeast of the mooring line, which displayed an SCD value of 0.27, very close to our cutoff threshold. ~~The mean SCD between all core tops and the sediment trap is 0.8, which contrasts with the SCD between the core tops, which exhibited an average value between them of 0.47 (see Supplementary data), indicating a higher similarity between them than with the sediment trap.~~ Interestingly, from a geographical point of view, the geographical closest site analyzed (MARGO 3680) displayed a high SCD (0.89) despite being retrieved virtually in the underlying sediments beneath the C01 mooring line (Table 3). Overall, the 4 most similar sites (SCD <0.6) to the settling assemblage are all located eastward, while the 4 most different sites (SCD >1) are all located northward to the location of the mooring line. This highlights the geographical variability of the Sicily Channel regarding the planktonic foraminifera population and the complex oceanographic conditions. Note that, as mentioned previously, the lack of dating in these samples do not allow to bring further interpretations about the timing of planktonic foraminifera populations shifts. In addition to the lack of chronology control in these samples, no data is available for the sedimentation rate, which makes any assumption around the intensity of the hydrodynamics impossible. Finally, and as mentioned earlier, the retrieval method applied for the different core-tops could also be cited as source of the differences between the MARGO core-tops and with the sediment trap in the C01 mooring line. While a box-corer was used for sampling in sites 342 and 407 (Incarbona et al., 2019), various devices were used for the MARGO core-tops, that includes piston and gravity cores that are known to often experience stretching or loss of material during the recovery of the sediments. Therefore it is likely that the different MARGO surface sediment data set represent different time intervals. ~~We speculate that the C01 sediment trap, in addition to registering species from both the western and eastern Mediterranean basins, could also be considered a key point in an east to west planktonic foraminifera population gradient. Interestingly, the most different core tops are located in the vicinity of the Tyrrhennian Sea and the most similar ones can be found in the easternmost part of~~

1069 ~~the Sicily Channel. In combination with the dominant taxa registered, we propose that the MAW~~
1070 ~~and western basin waters influence could have spread further east into the Sicily Channel. This, in~~
1071 ~~combination with the resident eastern basin waters, could reconcile the planktonic foraminifera~~
1072 ~~assemblage described from the C01 sediment trap and the fact that it is more similar to core tops~~
1073 ~~located eastward.~~

1074 Taken into consideration all the uncertainties presented above, our data suggest that a change in
1075 the composition of the planktonic foraminifera assemblages took place at some stage of the late
1076 Holocene but before the onset of the industrial period. However, the available data precludes the
1077 determination of the main environmental drivers causing this change. ~~Overall, these results call for~~
1078 ~~increasing the monitoring of planktonic foraminifera populations and accentuating the comparisons~~
1079 ~~between recent and seabed sediment assemblages in the Mediterranean to determine if the trends~~
1080 ~~suggested by our data are the result of the recent environmental change.~~

1081

1082 **Conclusions**

1083

1084 The C01 mooring line, located on the axis of the Sicily Channel, provided the opportunity to
1085 document the planktonic foraminifera population on an interannual scale. We analyzed 19 samples
1086 that covered the timespan between November 2013 and October 2014. A total of 3723 individuals
1087 and 15 different species were identified. *G. inflata*, *G. truncatulinoidea*, *G. bulloides*, *G. ruber* and *G.*
1088 *ruber* (pink) were the five most abundant species, representing 56, 19, 8, 3.5 and 3% of the total
1089 foraminifera. The remaining species represented less than 5% of the total individuals. Total
1090 planktonic foraminifera flux ranged between 44 and 1890 shells $m^{-2} d^{-1}$, higher values were reached
1091 during spring while values were lower during summer. Our data indicates that the planktonic
1092 foraminifera fluxes mainly reflect the oceanographic configuration of the Sicily Channel and its
1093 seasonal surface circulation variability. During winter and spring, a stronger eastward advection
1094 favours the MAW entrance in the Sicily Channel, allowing cool and nutrient enriched waters to enter
1095 the Channel. This resulted in an increased planktonic foraminifera flux and a higher presence of *G.*
1096 *inflata*, *G. truncatulinoidea* or *G. bulloides*, which are taxa associated with the western basin. On the
1097 other hand, during summer, the eastward advection is reduced and the LIW dominates the water
1098 column, favorizing the increase of species associated with the eastern basin, such as *G. ruber*, and
1099 *G. ruber* (pink). Our correlation data with both SST and chlorophyll-*a* showed that *G. inflata* was
1100 associated with cool and nutrient rich waters. In contrast, both *G. ruber* species were associated
1101 with warm and oligotrophic waters, which agrees with their ecology. Surprisingly, no significant
1102 trends were identified for either *G. truncatulinoidea* or *G. bulloides*. ~~As *G. bulloides* flux increased~~
1103 ~~coincidentally with the benthic foraminifera one, we considered that this species might have a~~
1104 ~~resuspended origin.~~ The comparison with integrated annual data from other sediment trap
1105 experiments conducted in in different regions of the Mediterranean basin, our fluxes and diversity
1106 data indicated that the Sicily Channel can be considered a transitional zone in regard to planktonic
1107 foraminifera populations: annualized fluxes were lower compared to the westernmost Alboran Sea,
1108 but higher than in the easternmost Levantine basin. However, the Sicily Channel exhibited the
1109 highest diversity values across all the sites analyzed, highlighting the influence of both the western
1110 and eastern basins. ~~Finally, the planktonic foraminifera assemblages from the sediment trap were~~

1111 also compared with seabed sediment assemblages. Overall, both eutrophic and oligotrophic taxa
1112 were more abundant in the seabed sediment, however, *G. inflata* dominated the assemblages in
1113 the closest samples to the sediment trap location. Our dataset was similar to the assemblages from
1114 sites 342 and 407 (Incarbona et al., 2019) but different than the ones from the MARGO core-tops.
1115 This is likely due to the fact that they represented different time periods. Finally, the high-resolution
1116 chronology from sites 342 and 407 allowed to show that the planktonic foraminifera population
1117 shift likely developed during the late Holocene prior to the industrial period. However, the causes
1118 of this shift remain uncertain, and our results call for increasing the monitoring of planktonic
1119 foraminifera populations and accentuating the comparisons between recent and seabed sediment
1120 assemblages in the Mediterranean to determine if the trends suggested by our data are the result
1121 of the recent environmental change.

1122

1123 *Data availability.* All data used in this study are presented in the Supplement and are available online
1124 at doi: 10.17632/tp4v6hm7dc.1 (Béjard et al., 2023).

1125

1126 *Supplement.* The supplement related to this article is available online at:

1127

1128 *Author contributions.* ASRH, FJS and TMB designed the study. JPT designed Fig. 1 and contributed to
1129 planktonic foraminifera identification and imaging. ASV and ILC provided the JERICO C01 sediment
1130 trap samples and led the sample processing. TMB led the microscopy and image analysis, the
1131 foraminifera study, statistical analysis and wrote the manuscript with feedback from all authors.

1132

1133 *Competing interests.* The contact author has declared that none of the authors has any competing
1134 interests.

1135

1136 *Acknowledgements.* The authors would like to thank Aidan Hunter from the BAS (Cambridge) for
1137 the statistical analysis inputs and Francesca Bulian (University of Groningen) for benthic
1138 foraminifera identification support.

1139

1140 *Financial support.* This research has been supported by the Ministerio de Ciencia e Innovación (grant
1141 nos. RTI2018-099489-B-100, PID2021-128322NB-100, and PRE2019-089091). This research has also
1142 received funding from the JERICO project under the FP7 contract agreement nº 262584 and
1143 supported by ISMAR, CNR. ASV acknowledges the financial support by the Catalan Government
1144 Grups de Recerca Consolidats grant (2021 SGR 01195). This project has received funding from the
1145 project BASELINE (grant no. PID2021- 126495NB-741 C33) granted by the Spanish Ministry of
1146 Science and Innovation and Universities (Andrés S. Rigual-Hernández).
