Abstract. A unique chain connects the flow over the North Atlantic and the development of cyclones within the Mediterranean basin. One typical mechanism includes several successive processes: upper-level flow perturbations upstream cause Rossby wave breaking (RWB) events along the jet stream, which in turn develop into potential vorticity streamers. These streamers reach the Mediterranean, and through increased baroclinicity they enhance cyclonic activity in the region. Using ERA5 reanalysis data and rain gauge measurements, we provide a systematic analysis connecting wintertime North Atlantic storm track regimes and Eastern Mediterranean cyclones and rainfall. To do so, we use different detection algorithms for each element in the chain (RWBs, streamers and cyclones). A cluster analysis of upper tropospheric eddy kinetic energy reveals a favorable configuration of the storm track where North Atlantic storms are able to propagate farther northeast. This results in upper-level potential vorticity streamers forming more eastward alongside above-average precipitation over the Levant. Meanwhile, other latitudinal positions of the storm track (southward or northward) were found to hinder cyclonic activity in the region and reduce rainfall there. The intense rainy winter of 1991-1992 is brought as a test case to exemplify this mechanism in its extreme. We show that the rain-enhancing storm track regime was prominent throughout most of this season, alongside frequent streamers in the Eastern Mediterranean.

1 Introduction

The Mediterranean basin is considered to be one of the most cyclogenetic regions on the globe. Cyclones have significant societal and environmental impacts on the basin, as they are responsible for the majority of wintertime precipitation (Saaroni et al., 2010; Flaounas et al., 2022) and can be associated with extreme weather phenomena (e.g., floods, strong winds). A combination of geographical and dynamical features of the region are favorable to the formation and development of lows: the temperature contrast between the warmer sea and adjacent land, strong baroclinicity in the presence of the jet stream, and the surrounding mountain ranges serving as orographic drivers of convergence and vertical air motion.

1

Aside from the inherent cyclogenetic drivers in the basin, the activity of lows is also modulated by large scale flow surrounding the region. These supply the Mediterranean with moisture, heat and energy, which affect cyclone formation and development (Seager et al., 2020). This occurs mostly via changes to upper level flows, which are known to play a major role
25 throughout the life cycle of cyclones.

When northerly flowing cold upper tropospheric air reaches the Mediterranean, it increases atmospheric instability, and downstream upper level divergence, thus creating overall favorable conditions for baroclinic growth (Flaounas et al., 2015, 2021). In terms of potential vorticity (PV), these flows adiabatically advect strong positive PV anomalies (from either tropospheric or stratospheric origins) that induce cyclonic motion. In fact, Flaounas et al. (2015) describe Mediterranean cyclones as "PV tow-
30 ers", a tilted positive anomaly spanning vertically from the surface to the Tropopause. Dynamically, these upper level structures are classified as troughs (synoptic scale jet undulations) or PV streamers which are narrower and more intense. In the case of Israel, for example, trough orientation and location were shown to be crucial to rainfall distribution (Zangvil and Druian, 1990; Ziv et al., 2006).

While extratropical cyclones have additional sources of PV (Čampa and Wernli, 2012), they are usually smaller by an
35 order of magnitude (Flaounas et al., 2021). The authors examined the vertical PV profiles of a hundred intense Mediterranean cyclones, and noted that while upper level adiabatic advection was the most dominant process, most profiles also included low level diabatic heating. The ratio between the two led the authors to classify cyclones as adiabatically driven, diabatically driven or mixed.

The upper level flow over the Mediterranean connects Mediterranean cyclones to the large scale circulation around the
40 basin. Four major elements of extratropical circulation have been linked to either precipitation or cyclonic activity in the Mediterranean: undulations of the polar jet stream, the North Atlantic storm track, subseasonal Rossby wave packets and the subtropical jet entrance. While all four are interconnected (Watanabe, 2004; Novak et al., 2015; Raveh-Rubin and Wernli, 2015; Raveh-Rubin and Flaounas, 2017), their interactions with cyclones differ in terms of mechanism and scale.

The Atlantic jet stream is the main propagator of PV anomalies into the region, and its undulations form as cyclone-
45 enhancing upper level troughs. Shifts in jet latitude and the zonal extent of the jet exit region have been linked to differences in cyclone track density and Mediterranean precipitation variability on different time scales. The latitudinal displacement of the jet is correlated to east-west seasonal precipitation anomalies in the basin (Gaetani et al., 2011; Beghin et al., 2016), sometimes known as the Mediterranean seesaw. A more zonal and southern jet results in increased precipitation over the western Mediterranean, while a northeasterly tilted configuration corresponds to wetter conditions over the eastern Mediterranean. Ad-
50 ditionally, during anticyclonic Rossby wave breaking events (RWBs), the meridional PV gradient on the jet is reversed, and the resulting streamers create favourable conditions for intense cyclones near the jet exit region (Raveh-Rubin and Flaounas, 2017; Priestley et al., 2020; Tamarin-Brodsky and Harnik, 2024).

While generally less explored in this context, the subtropical jet has been linked to Mediterranean cyclones. Brayshaw et al. (2010) defined the intensity and location of the jet entrance as a "key meteorological forcing" of the Mediterranean storm track.
55 Wiegand and Knippertz (2014) stress the role of subtropical wave trains in predicting intense PV streamers and RWB events over the region.

North Atlantic storms (and their Eulerian representation, the North Atlantic storm track) can affect Mediterranean cyclonic activity from a distance through dynamical proxies. One such dynamical pathway for the formation of intense Mediterranean cyclones is described in Raveh-Rubin and Flaounas (2017), hereafter RRF17. This mechanism includes four steps: one or

60 several North Atlantic cyclones produce a warm conveyor belt (WBC) flow. The WCB contributes to an intensifying upper level ridge over the North Atlantic (Pfahl et al., 2015). This results in anticyclonic Rossby wave breaking downstream, the southern flank of which extends into a cyclone-inducing PV streamer over the Mediterranean. This process was demonstrated for a set of a hundred intense Mediterranean cyclones in reanalysis (Raveh-Rubin and Flaounas, 2017) as well as several semi-idealized simulations (Scherrmann et al., 2023). Additional works further highlighted specific links within this mechanism:

65 North Atlantic cyclones and RWBs (Pantillon et al., 2015; Portmann et al., 2020); RWBs and Mediterranean cyclones (Tamarin-Brodsky and Harnik, 2024); and the role of WCBs throughout (Ziv et al., 2010; Madonna et al., 2014; Berkovic and Raveh-Rubin, 2022; Joos et al., 2023). Alternatively, some western Mediterranean cyclones are directly impacted by their North Atlantic counterparts via clustering. In this case, a secondary smaller low is formed near an existing storm (Ziv et al., 2015; Saaroni et al., 2017; Priestley et al., 2020).

70 The Atlantic-Mediterranean connection is also supported by subseasonal Rossby wave packets (RWPs). These intermediate scale waves ($k \sim 5$) propagate mostly zonally over long distances along the jet stream. They do so with little to no phase speed, which means that they create persistent anomalous ridge-rough pairs which can inhabit the same region for several days. RWPs with meridional anomalies over the central-eastern Mediterranean are a prominent feature of extreme winters over Israel (Feldstein and Dayan, 2008), depending on their phase. Other studies have also found a similar wave configuration in

75 relation to Mediterranean rainfall (Saaroni et al., 2015; Redolat et al., 2019; Ali et al., 2021; Berkovic and Raveh-Rubin, 2022).

While considerable efforts have been made to understand the large scale dynamical drivers of Mediterranean cyclonic activity, their relevance to the eastern part of the basin remains an open question. As it is further downstream, the eastern Mediterranean is generally weakly correlated to modes like the North Atlantic Oscillation (Nissen et al., 2010), and upper level anomalies (e.g., RWBs, streamers) are more prominent closer to the Atlantic. Additionally, as Eastern Mediterranean lows are

80 shallower compared to the west, they are often mostly filtered out in studies examining intense storms.

Therefore, in this work we investigate the relation between the North Atlantic region and Eastern Mediterranean cyclonic activity and rainfall, and examine the dynamical mechanisms at the basis of this link . Our focus is on the North Atlantic Storm Track, due to its relevant signal on multiple time scales (from single synoptic systems to seasonal flow regimes) and because it is recognized in the literature as having significant influence on the various components on Mediterranean cyclogenesis

85 (Brayshaw et al., 2010; Novak et al., 2015; Raveh-Rubin and Flaounas, 2017). The overall encompassing approach chosen for this work (from the large scale through cyclones to rainfall), is meant to explore this link as a potential proxy for climate predictability in the region. especially important given the climate models' inherent uncertainties with regards to Mediterranean cyclones and their environmental impacts (Hochman et al., 2020; Voskresenskaya et al., 2022; Reale et al., 2022).

Data and methods are detailed in Section 2, results are presented in Section 3, followed by their discussion in Section 4.

2   Data & Methods

This work is based on data from the European Center for Medium-Range Weather Forecasts (ECMWF) reanalysis v5 dataset (Hersbach et al., 2020, ERA5). The fields used are mean sea level pressure (SLP), upper level geopotential height (z) and horizontal wind components (u, v) at 500 hPa and 300 hPa. Additionally, the ERA5 isentropic potential vorticity (PV) field is taken from the 315K potential temperature level. The North Atlantic domain used in the analysis is set between $90^oW - 40^oE$ and $25^oN - 70^oN$. When relevant, cosine latitude weighting was applied to the data. All fields are analyzed for the mid-winter months (December-February, DJF) between 1979 and 2019 and have a spatial resolution of $1.25^o x 1.25^o$. The interpolation from the ERA5 default resolution (0.25^o) to a coarser one was operated by the Copernicus Climate Change Service (C3S). This was done to reduce smaller scale noise and to allow for better comparisons to global climate models in future works.

Rain values in the Mediterranean are taken from ERA5 at default resolution. For Israeli rainfall, we use measurements from 21 rain stations produced by the Israel Meteorological Service (IMS). Stations cover central and northern Israel and represent the diverse rain conditions in the region, from the elevated and rainier northern stations to the semi-arid southern coastal plane. Accumulated annual rainfall amounts can therefore range from 200 mm to 1000+ mm, depending on location.

Monthly NAO index values were calculated by NOAA-CPC via Rotated Principal Component Analysis (RPCA) and a linear interpolation from daily to monthly time series.

Cyclone track data is taken from the Composite Track Dataset (Flaounas et al., 2023). The dataset is the combined result of 10 cyclone detection and tracking methods, where the degree of agreement between the methods define the confidence level of each track. For the chosen confidence level ($CL = 5$, meaning that at least half of the methods agree on each track), 1058 tracks were identified in the Mediterranean area ($10^oW - 40^oE$, $25^oN - 50^oN$) during the study period. Each cyclone track refers to the entire life cycle, including locations outside the domain.

To determine the flow regimes of the North Atlantic storm track, k-means clustering is performed on daily upper level eddy kinetic energy (EKE) maxima. First, EKE is calculated at 300 hPa as $\frac{1}{2}(u'^2 + v'^2)$. u' and v' are the transient components of the zonal and meridional wind, respectively. A Lanczos low-pass filter is then applied to the data with a cutoff of 10 days. This represents the activity of high frequency eddies within the track, as defined in Novak et al. (2015). We then further smooth the result with a 5 day running mean. Finally, local meridional EKE maxima are found for each longitude within a 5° window (see fig. 1a). The maps of maxima locations are then processed by the clustering algorithm (described above). The clusters therefore represent only the position of the storm track and not its amplitude. Other clustering studies for the Atlantic storm track and jet stream (Woollings et al., 2010; Novak et al., 2015) find similar results in terms of positions and time scale (roughly 10 days).

A different approach that combined EKE maxima location and amplitude was tested (not shown), but we found that it required a larger number of clusters with a small sample in each. Additionally, we tested several alternative fields to define the storm track, such as low level meridional heat flux or 500 hPa v variance (Wettstein and Wallace, 2010). The clusters were similar overall (not shown), but were clearest when using the 300 hPa EKE.

The number of clusters (n) is a prescribed parameter in the k-means method. A minimum of $n = 3$ clusters is often used to describe the three typical positions of the storm track or jet stream in the Atlantic (Woollings et al., 2010; Novak et al.,

2015). In this study, $n = 4$ was chosen, with the fourth and largest cluster mostly capturing days that did not fit the other three,

125 allowing for more homogeneous groups. Variations with more clusters ($4 < n \leq 8$) were investigated (not shown), but they only split the three main clusters into smaller classes, without highlighting relevant new regimes.

For compositing purposes, we label months and day sequences as belonging to specific clusters. For some cluster C, a month is considered a C-month if it has at least 14 days labeled C by the algorithm. A C-sequence is defined as at least 6 consecutive days labeled C by the algorithm. In total, 79 months and 266 sequences are identified as associated with one of the four clusters.

130 For PV streamer detection, we used the WaveBreaking Python algorithm (Kaderli, 2023). This package is based on a method developed by Wernli and Sprenger (2007). To detect a streamer, the algorithm finds elongated filaments on a PV contour by detecting points that are geographically close (distance D) and yet have a long portion of the contour connecting them (length L). For more details on the algorithm's design and subroutines, see Kaderli (2022). In this analysis we use the 2 PV units ($1 PVU = 10^{-6} m^2 s^{-1} K kg^{-1}$) contour on the 315K potential temperature surface. We set the algorithm thresholds at

135 $D = 800 km$ and $L = 1200 km$, meaning that the two base points of a streamer are at most 800 km apart and with a contour of at least 1200 km between them (fig. 1b). These values are similar to the ones used in Wernli and Sprenger (2007), albeit with a shorter L to better capture smaller structures over the Mediterranean specifically.

Rossby wave breaking (RWB) events were identified and analyzed with an algorithm developed by Strong and Magnusdottir (2008) and modified by Tamarin-Brodsky and Harnik (2024). Similar to streamer detection, this method detects geometric

140 features on isentropic PV contours. An RWB event is defined as a large-scale overturning of PV, manifesting as a contour crossing a particular meridian more than once. This is done for PV contours between 1.5–7.5 PVU, with each event assigned to the contour with the largest overturning. By tracing the contour from west to east, it is determined whether a break is cyclonic or anticyclonic. Additional thresholds are set for the events (minimal area, longitudinal extent and depth) to filter smaller scale noise. For this work, we take the algorithm threshold values used in Tamarin-Brodsky and Harnik (2024) (breaking width of at

145 least 7° with a minimal depth of 1 PVU) and keep only anticyclonic breaking events.

Statistical significance of spatial anomalies is determined throughout with a bootstrap test with 500 samples and a confidence level of 95%.

3 Results

3.1 Atlantic Storm Track Regimes and Mediterranean Flow

150 The winter flow regimes of the North Atlantic storm track are produced by performing cluster analysis on eddy kinetic energy maxima (see Section 2). The clusters, shown in Fig. 2a-d, vary from the climatology in terms of track latitude (from 48^oN to 59^oN) and zonal extent (whether storms reach northern Europe or not). It should be noted that the clustering is based only on EKE location and not magnitude, therefore it does not represent storm intensity.

Figure 2e shows the accumulated monthly mean precipitation over Israel for each cluster. Three of the four clusters relate

155 to anomalous rainfall amounts - clusters 1 and 3 are generally drier and cluster 2 is rainier, with respective mean anomalies of -21 mm, -22 mm and +54 mm compared to climatology. Cluster 4, while largest, shows almost no signal in terms of rainfall

or cyclonic activity (not shown). Therefore, our results focus on clusters 1-3, denoted hereafter according to the average track latitude, as North (N), Middle (M) and South (S), respectively (see fig. 2a-c).

The rainy M cluster is characterized by an eastward extension of the storm track, with the most active section located south of
160 Greenland and storms reaching Scandinavia. The increase in precipitation is apparent throughout Israel, but the central region (South Coast and Judea) has the largest anomaly, up to 75% more than the climatological mean (black markers in fig. 2e). The dry N cluster combines an eastward extension and a northern shift of the storm track. It displays similar local differences to the M cluster, with the same areas having the largest relative negative response. The S cluster is closest to the climatological state of the track, albeit slightly more zonally oriented towards western Europe. The dry clusters also have a statistically significant
165 over-representation of extremely dry months, with 6 of the 10 driest months in the dataset belonging to either cluster N or S ($p < 0.05$ under a hypergeometric test).

The precipitation anomalies over Israel are a part of a basin-wide response of cyclonic activity. The different configurations of the North Atlantic storm track correspond to changes in the distribution of PV streamers that breach into the Mediterranean from the north (hatches in Fig. 3a,c,e). In the presence of more streamers, baroclinicity increases and enhances cyclone formation
170 and its deepening downstream. The three clusters hint at an optimal range of influence of Atlantic storm track latitudes for Eastern Mediterranean rainfall (around the M configuration), in which PV extends more easily into the region. This is followed by a higher density of cyclone tracks, resulting in increased precipitation (Fig. 3d). When the Atlantic storm track is shifted even more poleward (N cluster), streamers are less probable to reach the eastern part of the basin, perhaps due to its more equatorward position compared to the rest of the Mediterranean. The aforementioned drying of central Israel is also apparent
175 (Fig. 3b) within the overall drier conditions of the southeastern coast. The S cluster's drying effect is possibly due to its shorter zonal extent. It thus captures the known east-west gradient in cyclonic activity, with abundant stormy weather over Genoa while cyclonic activity to the east is suppressed.

The large-scale flow over the North Atlantic reveals some well known weather regimes (fig. 4). Composite anomalies of 500 hPa geopotential height show an Atlantic Ridge regime in the N cluster. Meanwhile, the S cluster does not have a clear weather
180 regime analog, but both dry clusters feature a statistically significant anticyclonic flow in the upper levels over the Eastern Mediterranean. Months in the M cluster show a more zonal signal, and are in fact a subset of the positive phase of the North Atlantic Oscillation (this connection is further explored in subsection 3.3). The jet stream (thick black curve in fig. 4) is shifted poleward and more extended to the east (fig. 4b). An upper tropospheric trough can be seen over the Eastern Mediterranean, enhancing cyclonic activity. As expected, EKE anomalies follow the latitudinal position of the clusters themselves. However,
185 two particular signals are notable: energy being carried further downstream north of the Mediterranean in cluster M (fig. 4b), and the positive EKE anomaly over the Mediterranean in cluster N (fig. 4a). The latter is not related to the North Atlantic storm track, but might be associated with stronger Mediterranean cyclones and intense rainfall over Greece and Turkey (see Fig. 3b).

Rossby wave breaking (RWB) events play a major role in the formation of PV streamers into the Mediterranean. Our results demonstrate a coherent relation between RWB events and streamers for each cluster. Figure 4d shows the longitudinal
190 distribution of such events, averaged between 40^oN-60^oN (see box in fig. 4a). Each cluster contains a similar number of events (99-120), but their median location varies considerably. The climatological median longitude is 4^oW. The dry cluster medians

are located more upstream (9^oW and 6^oW for N and S, respectively). Cluster M has more RWBs in the central and eastern Mediterranean (the median longitude is the prime meridian, denoted by the green vertical line in fig. 4d). Therefore, months with RWBs further downstream tend to have matching PV streamers further east over the Mediterranean.

3.2 A Mechanism for Eastern Mediterranean Rainfall Enhancement

Rainy cluster M months are a subset of the NAO+ phase. Using the monthly NAO index (taken from NOAA-CPC, see Section 2), we find that all 10 cluster M months have positive NAO values. The cluster average NAO index is +1.8 standard deviations.

To increase the sample size and to investigate the temporal evolution of the signal, we used a composite of daily data. Each sequence is a continuous series of 6 or more days classified as M. Lag 0 of each sequence is defined as the time of maximum area averaged positive SLP in the western Mediterranean (black box in fig. 5e). This metric represents the western blocking high found in previous studies exploring Atlantic-Mediterranean links (Watanabe, 2004; Feldstein and Dayan, 2008).

Figure 5 shows the time lag composite development of 60 such sequences (on average, 1.5 samples per winter). SLP anomalies organize as a quasi-stationary zonal wave (shading in the left column of fig. 5) that precedes the western Mediterranean high. This pattern, slightly shifted to the west, can also be observed in the upper levels via the meridional wind field (not shown). RWB events, denoted by black dots, tend to form over the central Mediterranean (as demonstrated in fig. 4). This is followed by increased density of PV streamers downstream of the RWB centers, reaching the northern coast of the Eastern Mediterranean (fig. 5c,e,g). Over the subsequent days, a composite low deepens and propagates eastwards near Cyprus (purple contours in fig. 5h,j), alongside positive precipitation anomalies over Israel and the Levant. During these sequences, cyclone paths tend to cover shorter zonal distances ($\Delta\lambda = \lambda_{lysis} - \lambda_{genesis}$, where λ is the longitude) compared to the climatology, especially in the Western Mediterranean (not shown). This is in agreement with the findings of Tamarin-Brodsky and Harnik (2024), which show that Mediterranean cyclones located south of an anticyclone are often more stationary.

The overall process is reminiscent of the RRF17 mechanism (Raveh-Rubin and Flaounas, 2017), combined with a precursory Rossby wave packet crossing the Atlantic. The logic of this mechanism and its relation to patterns described in the literature will be discussed in Section 4.

3.3 Two Mid-Winter Test Cases: DJF 1991-1992 and 1983-1984

Two mid-winter seasons were chosen to demonstrate the Atlantic-Mediterranean flow and its weather impacts during extended cluster regimes. The winter of 1991-1992 (1992 season hereafter) is the rainiest season in the study period (and for some locations in Israel, the rainiest ever recorded). It has several extreme spells in terms of length and precipitation rate (Rostkier-Edelstein et al., 2014). Conversely, the winter of 1983-1984 (1984 season hereafter) had multiple prolonged dry spells of little to no rain (Saaroni et al., 2015, 2019), making it the second driest season on record since 1979.

We study these winters through the string of features discussed previously: storm track regimes, RWB events, PV streamers and Mediterranean cyclones. Table 1 summarizes some of these statistics for each season. The 1992 season had 44% of its days identified as the rain enhancing M cluster. Meanwhile, the dry 1984 season had 27 N cluster days and 19 S cluster days, just over half of the period classified into a dry regime. Additionally, 26 days belong to the M cluster. Indeed, the composites

225 of SLP anomalies for cluster-labeled days support the previously shown monthly-based cluster composites of upper level flow patterns (fig. 4a-c): a zonal wave culminating with a high over western Europe for cluster M, and an east-west pressure dipole with pronounced low over the British Isles for the dry clusters (similar to the pattern discussed in Ziv et al. 2006).

The two seasons have a similar number of RWB events and roughly as many Eastern Mediterranean cyclones. However, the extremely rainy winter has almost twice as many days with detected PV streamers reaching southward into the eastern domain

230 (bottom green box in Fig. 6a).

An investigation of the temporal evolution of each season reveals evidence that correspond to the rainfall enhancement mechanism discussed above. Out of the six major rainy spells in the 1992 season, three (r1, r3 and r4 is fig. 6b) show a similar dynamical progression. First, a cluster M flow dominates the North Atlantic for several days. Then, at least one RWB event occurs east of the prime meridian (within the top green box in fig. 6a), followed by 2-5 days where a PV streamer crosses

235 the Eastern Mediterranean, inducing cyclonic activity and rainfall (in terms of fig. 6b, this translates to light blue shading, followed by a black marker, hatches and a peak in rainfall). This is of course not the only possible rain producing progression. For example, r5 doesn't follow this order at all: rainfall starts after several days of a dry storm track configuration, and is then amplified by recurring PV streamers independent of a breaking upstream. For the 1984 test case a common progression is less apparent. However, longer rain spells (as well as RWBs and streamers) mostly happen during or shortly after M cluster days.

240 In fact, 42.5% (84 mm) of the total seasonal rainfall amount were concetrated between January 1st and January 18th, a period consistently classified as M cluster.

We now focus on the extreme r3 rainy spell (December 18th 1991 to January 3rd 1991), as it serves as a clear recurring expression of Eastern Mediterranean rain enhancement. An average of over 200 mm were recorded in Israel during this period, which is more than the annual total for some stations. Figure 7 shows the large scale circulation prior to the rain event (a) and

245 during it (b-f). The first several days include two major elements of an M cluster flow: a high pressure center (red contours) over the eastern Atlantic, and EKE (blue contours) extending northeast into Scandinavia. The eastern blocking high (which seems to belong to a zonal wave train) persists throughout the period for over two weeks, while directing eddies poleward. The western high weakens gradually, but is noticeable through the rain spell. The northward propagating eddies serve as perturbations that instigate RWB events (yellow markers), which in turn drive PV streamers equatorward into the Eastern Mediterranean. In total,

250 4 RWB events were detected during the rain spell (the markers in (a) and (b) refer to the same breaking), followed by 5 distinct PV streamers in fast succession.

4   Conclusions

This work explored the connection between North Atlantic circulation and Eastern Mediterranean cyclonic activity and rainfall. This link has been discussed in previous literature (Trigo et al., 2000; Brayshaw et al., 2010; Ahmadi-Givi et al., 2014; Raveh-

255 Rubin and Flaounas, 2017; Seager et al., 2020). However, the unique conditions of the Eastern part of the basin are often overlooked in this context, i.e., smaller and shallower cyclones, overall higher mean SLP, land-sea interaction over the eastern coast. Some studies also specifically investigated the large scale drivers of Eastern Mediterranean rainfall (Eshel and Farrell,

2000; Feldstein and Dayan, 2008; Black, 2012; Saaroni et al., 2015), but usually in the context of a specific mode (like the NAO or the EA/WR), or through the lens of statistical and climatological analysis. Black (2012) tied the NAO+ phase to enhanced precipitation in Israel, but without addressing the dynamical link behind this connection.

We chose the North Atlantic storm track as the basis for this study, as it embodies a wide range of scales in space and time (from a single storm to large scale Eulerian structures), and it is known to interact with many elements which affect Mediterranean cyclogenesis, such as the jet stream (Novak et al., 2015), subseasonal waves (Ahmadi-Givi et al., 2014) and individual Mediterranean cyclones (Ziv et al., 2015; Priestley et al., 2020).

By combining these North Atlantic storm track regimes with objective detection of important links in the cyclogenesis chain (RWBs, PV streamers, cyclones), we have demonstrated a configuration that enhances cyclonic activity, and thus rainfall, in the Eastern Mediterranean. When North Atlantic storms are able to propagate far enough northeast, the resulting upper level perturbations and PV streamers tend to form more eastward, specifically between 10^oE-40^oE. The upper level PV injected into the region excites cyclogenesis and contributes to the intensification of Mediterranean lows. Our results show that this process has a subseasonal time scale (up to 10 days), from the initial North Atlantic perturbation to the enhanced precipitation over the Eastern Mediterranean (see r1, r2 and r4 spells in fig. 6). This scale is typical for weather regimes in the Atlantic (Novak et al., 2015).

However, this configuration exhibits a "Goldilocks" type behavior, meaning that a relatively narrow set of values produce the effect. In this case, rain enhancement is only achieved for a specific storm track configuration. When the Atlantic storms don't follow the preferable path (overshooting towards Greenland in the N cluster or undershooting into western Europe in the S cluster), the Eastern Mediterranean is generally drier and more stable. This is likely due to Mediterranean cyclones forming and reaching their peak more upstream (along the northern coast or near Genoa).

The M cluster configuration is in fact an Eastern Mediterranean variant of the RRF17 mechanism (Raveh-Rubin and Flaounas, 2017). Both are prompted over the North Atlantic by upper level disturbances that develop into downstream jet undulations, which eventually drive PV into the Mediterranean region (via a RWB-based PV streamer).

However, while RRF17 hinges on the role of warm conveyor belts in the Atlantic, our results can be related to additional observed patterns, like a preceding Rossby wave train or a blocking high. This helps tie our results to other modes in the literature and explains why the cyclogenetic effect manifests further east. Specifically, the South Levant pattern (Feldstein and Dayan, 2008) is linked to extreme precipitation in Israel, and it has a zonal wave reminiscent of the M cluster SLP pattern. Also, several studies of the NAO pointed out that its positive phase (which has some overlap with our M cluster) can sometimes induce upper level convergence that can result in perturbations downstream (Watanabe, 2004; Athanasiadis et al., 2010).

It is worth noting that our results highlight one aspect of Mediterranean cyclonic activity. Cyclones and their weather impacts in the region are highly variable. This is made apparent by the various counter examples that were found in our analysis (like rain spells during dry cluster days). It is well documented (Flaounas et al., 2022, and references therein) that Mediterranean storms are very sensitive to local conditions (diabatic heat fluxes, orography, mesoscale flows). They are certainly not driven exclusively by large scale processes upstream. However, our findings accentuate the multi-scaled nature of Mediterranean

cyclogenesis - from ocean-spanning structures, through intermediate scale waves and to synoptic patterns interacting across all levels of the troposphere.

Finally, while this analysis focused on present day climatology, it has further potential as a useful tool in studying future
295 trends in the Eastern Mediterranean, and specifically its projected drying (Zappa et al., 2015). Mediterranean cyclones are a known pitfall for coarse gridded climate models, as they are unable to simulate crucial local processes that affect the storm's life cycle and path. However, studying Mediterranean drying as it relates to better-captured large scale Atlantic circulation might serve as a good proxy for this trend. A robust signal of anthropogenic climate change is the future poleward shift of the Atlantic jet stream and storm track (Tamarin-Brodsky and Kaspi, 2017; Stendel et al., 2021). However, its direct impact on the
300 Mediterranean remains an open question, due to considerable model spread (Harvey et al., 2020) and uncertainty concerning future NAO trends (Deser et al., 2017; Cusinato et al., 2021). Future work will utilize the findings described in this paper to address this topic.

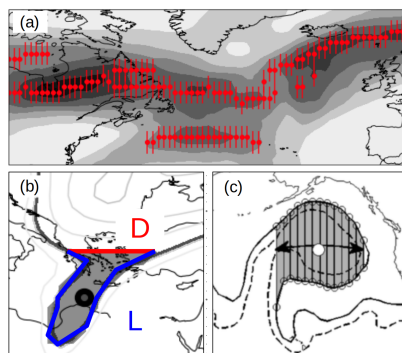

Figure 1. Examples of objectively detected features used in the analysis. (a) A snapshop of the daily EKE field (shading) and the EKE maxima used in the clustering (markers) for an example date (February 2nd 1979). The red markers denote the local meridional maxima in a 5 range, marked by vertical lines. (b) A PV streamer detected using the WaveBreaking algorithm. The thick grey isentrope is the 2PVU contour on a 315K surface. Shading marks the area of the streamer, and the red and blue lines mark its scale parameters (geographical distance D and contour length L, respectively). The center of the streamer is denoted by a circle marker. (c) An anticyclonic wave breaking event identified by the Strong & Magnusdottir algorithm. The solid and dashed lines mark the 5 and 3 isentropic PV contours on a 350K surface. Arrows show the zonal extent of the breaking and the white circle its centroid. (c) is adapted with permission from Figure 1 in Strong & Magnusdottir (2008).
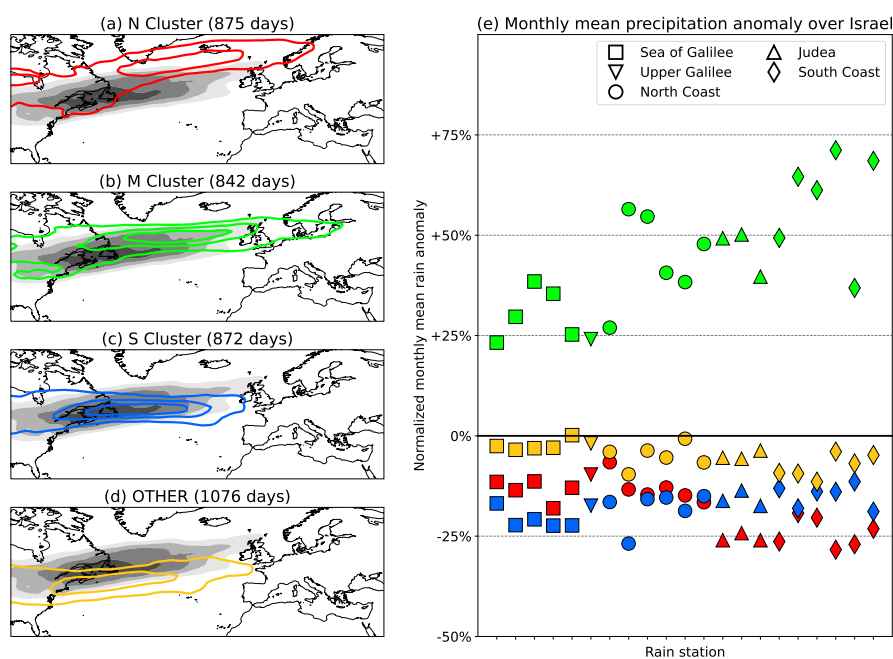

Figure 2. (a-d) North Atlantic storm track regimes, using k-means clustering on normalized daily DJF EKE data at 300 hPa. The clusters are represented by contours and the 1979-2019 climatology is in shading (contour interval is 0.05 for both). (e) The normalized mean monthly precipitation anomaly (%) for 21 rain stations in Israel for each cluster. Each anomaly is divided by the 1979-2019 DJF rain climatology of the corresponding station. The color of each marker denotes its cluster and its shape denotes its geographical location.
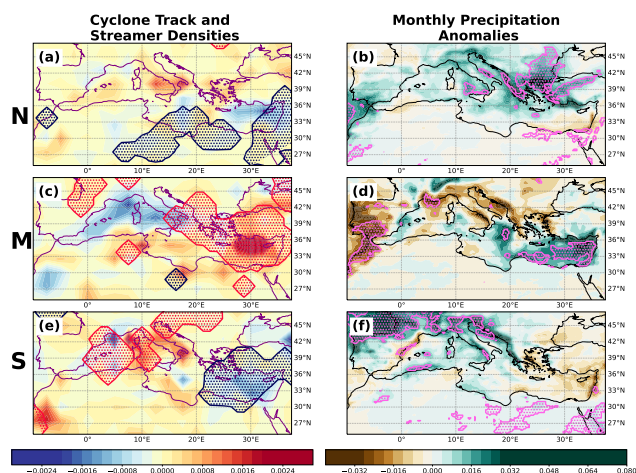

Figure 3. Composite cyclonic activity and precipitation for clusters N, M and S (top, middle and bottom row respectively). (a,c,e) Monthly cyclones track density anomaly (shading) and PV streamer density anomaly (hatches). For streamers, only statistically significant anomalies are shown (95% confidence on a 500 sample bootstrap test). (b,d,f) Monthly precipitation anomalies (shading). Areas with over 95% statistical significance are highlighted in pink hatches.
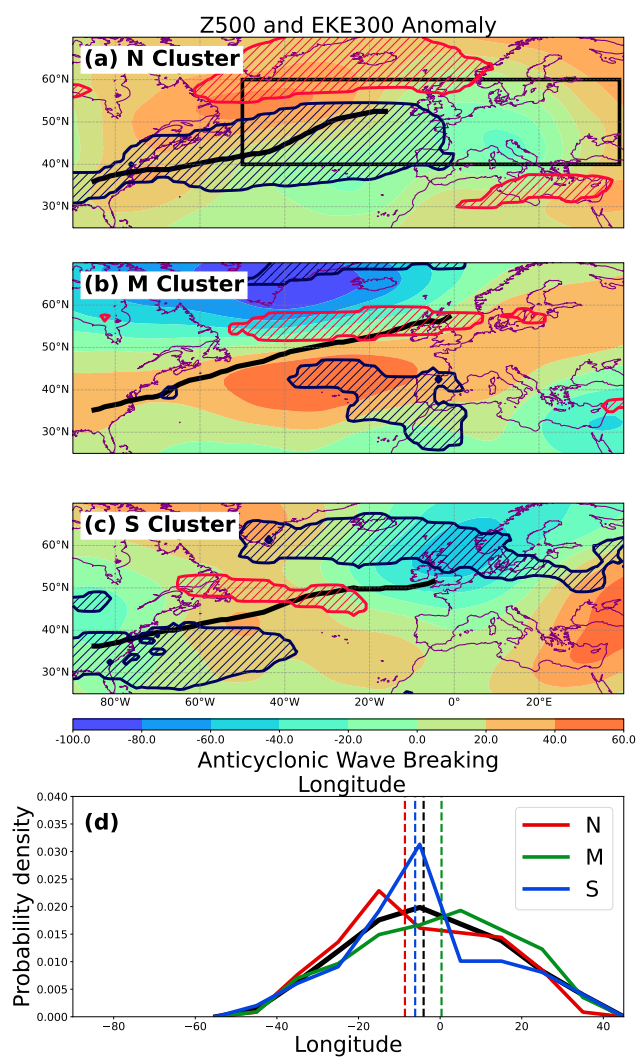

Figure 4. (a-c) Composite monthly geopotential height anomalies at 500 hPa (shading, 15m contour interval) and statistically significant EKE anomalies (defined the same as in fig. 2). Positive EKE anomalies are marked by red hatches, and negative in blue hatches. The thick curve denotes the average location of the Atlantic jet stream axis (300 hPa U maxima). (d) Longitude distribution of anticyclonic Rossby wave breaking events occurring at 200 hPa over the eastern Atlantic and northern Europe (black box in (a)). The climatological distribution in shown by the thick black histogram. Dashed vertical lines denote the median longitude of the climatology and of every cluster.
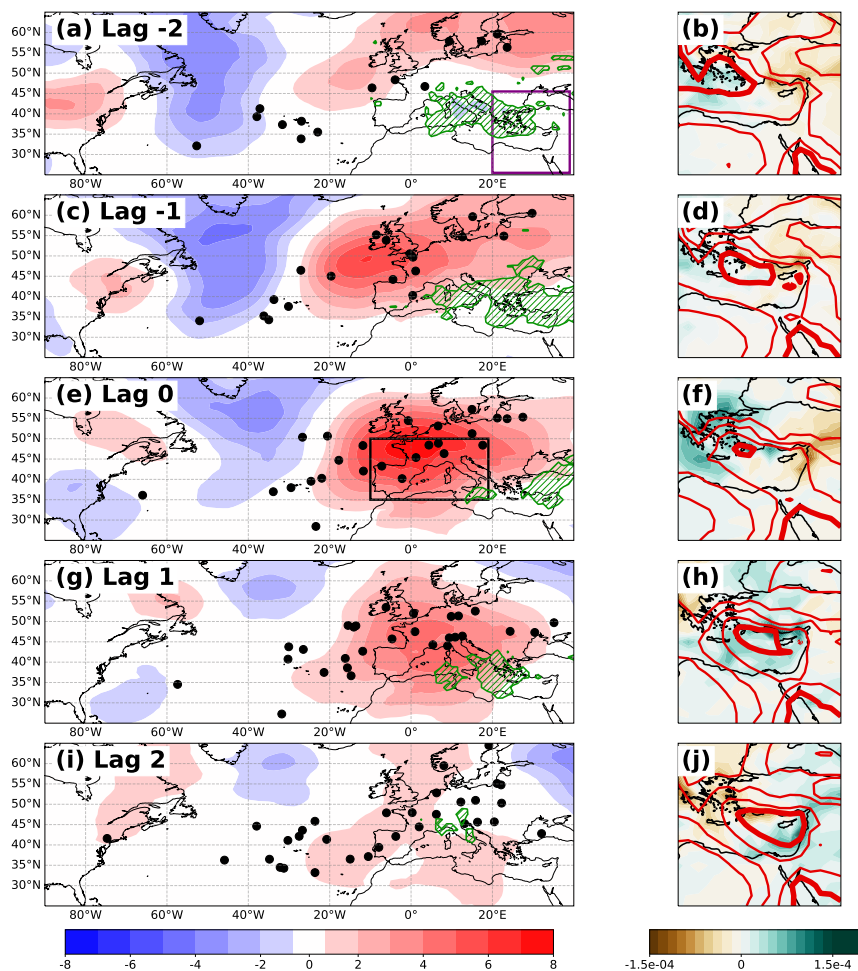

Figure 5. Time lag composite for the development of M cluster events. Lag 0 is defined as the day with maximum SLP value averaged over the Western Mediterranean (black box in (e)). (a,c,e,g,i) daily SLP anomalies (shading), RWB locations (full black circles) and statistically significant PV streamer positive density anomaly (green hatches). Negative anomalies omitted for clarity. (b,d,f,h,j) Time lag composite for the Eastern Mediterranean (purple box in (a)). Daily precipitation anomaly is shown in shading and SLP in contours (contour interval is 1 hPa and the lowest value is highlighted by a thick line).
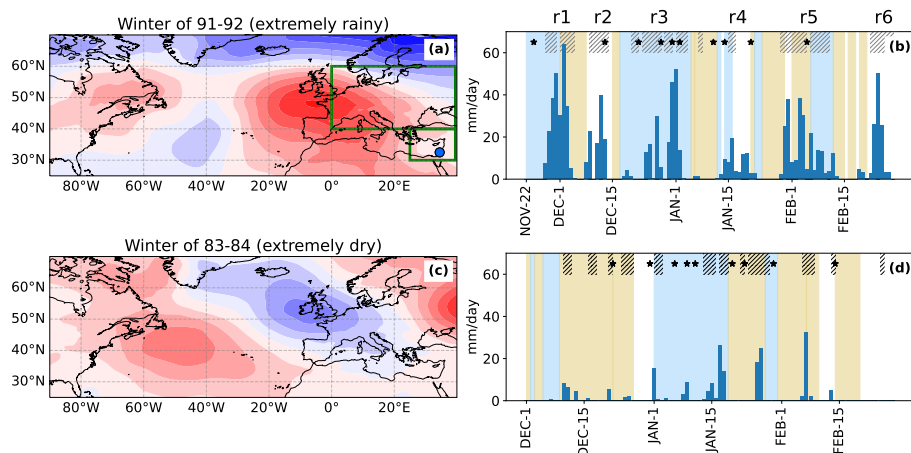

Figure 6. The course of two extreme winters in the Eastern Mediterranean. The top row shows the extremely rainy winter from December 1991 to February 1992, and the bottom row shows the December 1983-February 1984 dry winter. (a,c) SLP anomaly composites for all days belonging to the prominent cluster (cluster M for 91-92 and cluster S for 83-84). Blue and red shading denote negative and positive values, with a contour interval of 2 hPa. The top and bottom green boxes in (a) bound the domains used for RWB and PV streamer subset detection seen in (b,d). (b,d) Daily time series showing labeled days for the M cluster (blue shading), and the N+S clusters (yellow shading). Also shown are RWB events (star markers), PV streamers in the Eastern Mediterranean (hatches) and daily mean rainfall over Israel (blue bars; approximate rain gauge location marked by the blue circle in (a)). Both series show the entire season (DJF), with (b) extended back to November 22nd. The six major rain events during the 91-92 winter are labeled as r1-r6.
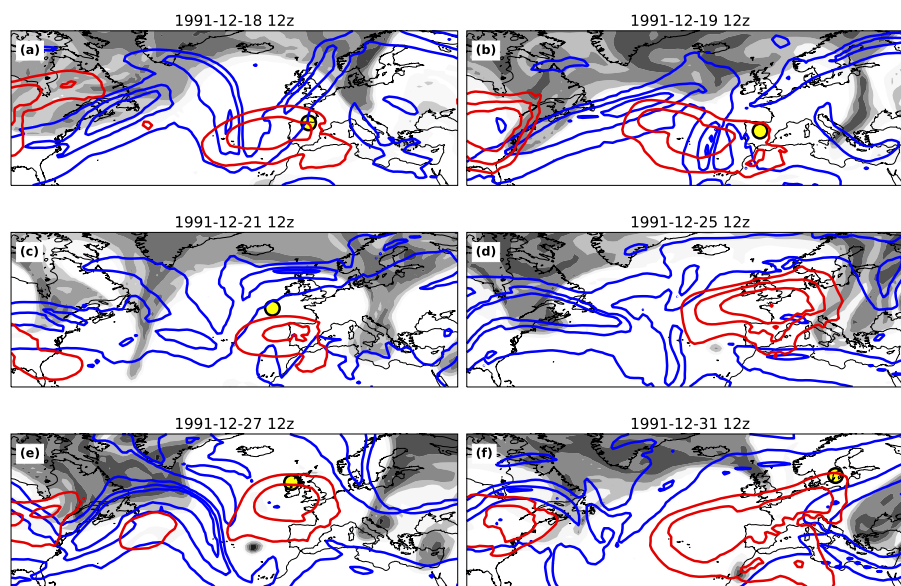

Figure 7. The progression of large scale flow during a 17-day rainy spell in Israel between Dec-18 1991 and Jan-3 1992 (r3 in figure 6b). Select days are shown to highlight the preceding conditions (a) and the following five PV streamers that crossed the region in succession (b-f). PV on a 315K isentropic surface is shown in shading (2 PVU minimal value, 1.5 PVU contour interval). The 300 hPa EKE field is denoted by blue contours (1000 $\frac{m^2}{s^2}$ contour interval) and SLP is denoted by red contours (1030 hPa minimal value, 5 hPa interval). Yellow circles mark anticyclonic wave breaking events.

Table 1. Rain and circulation statistics for two test case winters: 1991-1992 and 1983-1984 (December-February). Rain values refer to the station average of 21 rain gauges over Israel. The cluster with the most daily classifications is considered the main cluster. Rossby wave breaking events were tallied over the top green box in fig. 6a. For PV streamers and cyclones, only cases in the bottom green box were counted.

	Accumulated rainfall (mm)	Rain days	Maximum daily rain (mm)	Main cluster	Main Cluster days	RWB events	E.Med cyclones	Days with E.Med streamers
Dec 91-Feb 92	870	73	64	M	39	10	16	45
Dec 83-Feb 84	200	42	33	N	27	9	12	26
