Abstract.

As global warming progresses, weather conditions like daily temperature and precipitation are changing due to changes in their means and distributions of day-to-day variability. In this study, we show that changes in variability have a stronger influence on the number of extreme precipitation days than the change in the mean state in many locations. We analyze daily precipitation and maximum temperatures at four levels of global warming and under different emission scenarios for the Northern Hemisphere (NH) summer (June – August). Our analysis is based on initial condition large ensemble simulations from three fully coupled Earth System Models (MPI-ESM1-2-LR, CanESM5, and ACCESS-ESM1-5) contributing to the Climate Model Inter-comparison Project phase 6 (CMIP6). We also use information from the Precipitation Driver Response Model Inter-comparison Project (PDRMIP) to discern the influence of different climate drivers (notably aerosols and greenhouse gases). We decompose the total changes in daily NH summer precipitation and daily maximum temperature into mean and variability components (standard deviation and skewness). Our results show that in many locations, variability exerts a stronger influence than mean changes on daily precipitation. Changes in the widths and shapes of precipitation distributions are especially dominating over mean changes in Asia, the Arctic and Sub-Saharan Africa. In contrast, temperature changes are primarily driven by changes in the mean state. For the near future (2020-2040), we find that reductions in aerosol emissions would increase the likelihood of extreme summertime precipitation only over Asia. This study emphasizes the importance of incorporating daily variability changes into climate change impact assessments and advocates that future emulator and impact model development should focus on improving the representation of daily variability.

1 Introduction

In 2023, many regions experienced an unusually hot summer with record-breaking temperatures, widespread wildfires and heavy rainfall followed by severe flooding events (Rantanen and Laaksonen, 2024; Cop, 2023; wmo, 2023). Changes in climate can be driven by different natural factors, like volcanic emissions and ocean variability, as well as different anthropogenic drivers, like anthropogenic aerosol and CO₂ emissions. Aerosols and CO₂ affect regional climates differently: CO₂ blocks surface upwelling longwave radiation. Sulfate aerosols reflect incoming solar radiation which results in surface cooling during

daytime. In contrast, absorbing aerosols, like black carbon, absorb incoming solar radiation and thus lead to a warming of surrounding air masses. (Nordling et al., 2021; Szopa et al., 2021). These different climate forcings not only affect temperatures differently but also wet and dry extremes (Sillmann et al., 2019) and the diurnal cycle (Stjern et al., 2020). However, while the effects of carbon dioxide are relatively well constrained, the impact of aerosols constitutes still one of the major uncertainties in climate science Chen et al. (2021). For instance, while the global temperature impact of absorbing aerosols is relatively weak, they play a possibly large but still uncertain role in regional precipitation changes Samset (2022). The aerosol effect on climate is further complicated by the fact that the induced climate response is dependent on the location of the aerosol emissions (Persad, 2023; Westervelt et al., 2020; Persad and Caldeira, 2018) and that the aerosol effects of locally emitted aerosols can reach far beyond their local emission regions (Wilcox et al., 2019; Fahrenbach and Bollasina, 2023). For example, Asian aerosol emissions have pronounced effects on Arctic temperatures (Merikanto et al., 2021) and the Australian monsoon (Fahrenbach et al., 2024). Thus, it is certainly plausible that regional aerosol emission changes induce changes in daily weather and extremes in local and remote regions.

Daily weather variability, in particular, plays a key role in extreme events and is of utmost importance when it comes to adapting to climate change as climate risk mitigation strategies depend on our understanding of day-to-day weather patterns. Changes in weather extremes are influenced by both changes in the mean climate conditions, which are influenced by global warming and variability on decadal timescales, as well as day-to-day variations in weather, which are driven primarily by daily-to-annual scale internal climate variability. We have observed that extreme weather events have already changed and are continuing to do so as our planet warms (Myhre et al., 2019; Sippel et al., 2020). For example, the unprecedented summer heatwave in Europe in 2019 would have been impossible without anthropogenic climate change (Ma et al., 2020).

Previous studies have investigated changes in probability density functions (PDFs) of precipitation under global warming. Pendergrass et al. (2017) showed that the variability of weather patterns is increasing across most regions under a warming climate. This is evident in the widening of PDFs, indicating a growing range of possible weather outcomes. Zhang et al. (2021), utilizing the HadGEM3-GC3.05 model, found that precipitation variability is increasing on all timescales, from daily variability to year-to-year differences. This study highlights that changes on short timescales are closely linked to alterations in synoptic-scale weather patterns, emphasizing the broad-reaching impacts of climate change on precipitation. Samset et al. (2019b) focused on the evolution of regional PDFs under global warming with a focus on changes in daily PDFs of temperature and precipitation. Using the CESM1 large ensemble, they discovered that even a modest increase in global temperature (+1.5°C) results in significantly more variable precipitation over regions like Africa and South America. Katzenberger et al. (2022) studied the future precipitation variability over the Indian monsoon region and found that the likelihood of extreme rainfall is expected to increase significantly (up to sixfold) by the end of this century depending on future emissions. This illustrates the severe regional impacts of climate change, particularly in areas which are already vulnerable to extreme weather events.

When it comes to temperature, there is a clear footprint of global warming on the change in temperature variability. In high latitudes, the annual temperature variability tends to decrease, whereas it increases in lower latitudes in the near future (Kotz et al., 2021). However, this pattern varies between seasons and models. Suarez-Gutierrez et al. (2020) investigated how temperature-related extreme events evolve with global warming using the MPI-GE large ensemble. They discovered that daily

temperatures exceeding 50°C become more common in the Arabian Peninsula, northern India, and Pakistan at a global warming
60 level of 2°C. However, beyond the 2°C threshold, these extreme temperatures are expected to occur on every continent. Future
emissions play an important role in shaping how variability and extreme weather events will change in the near- to far future.
For example, Wilcox et al. (2020a) shows that a reduction of aerosol emissions in the near future could lead to an increase in
the Asian summer monsoon. Understanding these dynamic changes is crucial when evaluating future extreme changes on a
regional scale.

65 In this study, we examine how daily variability in the Northern Hemisphere (NH) summer precipitation and daily maximum
temperature is evolving under global warming and different emission scenarios. Using large ensemble simulation, produced
as part of CMIP6, we investigate changes in the mean and variability (characterized by the width and shape of the PDFs)
using a similar method as in van der Wiel and Bintanja (2021); Samset et al. (2019b); Lund et al. (2023) and further identify
the key anthropogenic drivers (aerosols or greenhouse gases) of those changes. Our results show key regions where changes
70 in extremes are driven by changes in variability rather than the mean state. By examining the daily variability of weather in
the context of a changing climate, we can improve our understanding of the challenges and opportunities for climate change
adaptation.

2 Method and data

2.1 Analysis of changes in mean and variability using PDFs

75 We are using simulations from single-model initial-condition large ensembles from CMIP6, similarly as (Samset et al., 2019b)
who studied how daily weather at a regional scale changes with global warming. Figure 1 illustrates our methodology of
defining daily PDFs for precipitation and maximum temperature using daily CMIP6 data from CanESM5, MPI-EMS1-2 and
ACCESS-ESM-1-5. First, we defined the 1–4°C Global Warming Levels (GWLs) following the definition outlined in the IPCC
AR6 report (Lee et al., 2021) (see Figure 1, panel a). For this, a 20-year centered running mean of annual temperature for each
80 ensemble member is calculated and the GWL is then defined as the period ± 10 years from the first year in which the global
warming threshold was surpassed. A PDF is found in this way for each grid point, which can be used to find changes in both
mean and variability (here referred to as the "PDF of total change"). The second step involves removing the annual cycle at
each grid point for each GWL which gives a PDF that only differs in variability (shape and width of the PDF) for each GWL.
We quantify changes to the mean by calculating the difference between the means of the GWL and Pre-Industrial (PI) PDFs
85 and then shifting the PI (0 GWL) PDF by the corresponding amount. Figure 1, panel c, illustrates the PDF changes due to the
1) total change, 2) change in the mean, and 3) change in variability (standard deviation(SD) and skewness). The final step is to
calculate the number of days during which extreme weather events occur for each PDF (see figure 1 panel d). Here, an extreme
event is defined as one that exceeds the 0.999th quantile. The return period for these extremes, as simulated by the different
models, is approximately 10 years. Thus, the extreme events analyzed in this paper refer to events occurring once or less every
90 ten years in the pre-industrial era.

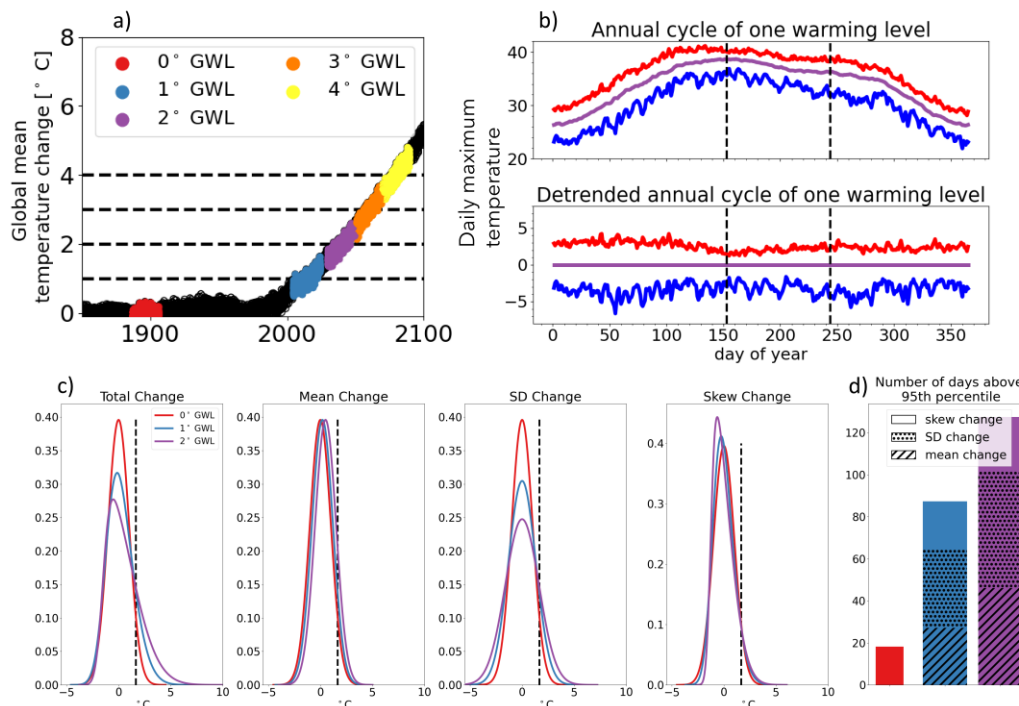

Figure 1. Method description. a) Selection of years for each global warming level. b) Example of regional daily maximum temperature without and with subtracting off the annual cycle to extract daily variability. c) Idealized PDFs of the total changes, the decomposition in mean, standard deviation and skewness changes as well as changes in the number of extreme days.

For the near-future analysis, we follow the same process described above to define the PDFs but calculate the PDFs for four different Shared Socioeconomic Pathway (SSP) scenarios (SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5; O'Neill et al., 2016) over three distinct time periods (2025–2034, 2035–2044, and 2045–2054) instead of using GWLs. For each time period and each SSP scenario, there is an overlaying PDF, which we refer to as the PDF of total change, similar to the GWL analysis. We then remove the annual cycle, similarly to the GWL analysis, to obtain a PDF that contains only changes attributable to variability (change in standard deviation and skewness). Here, we quantify changes to the mean by calculating the difference between the means of the given SSP (and timeperiod) and the PI PDF, and then shifting the PI (0 GWL) PDF by the corresponding amount.

These time periods are chosen to represent the largest differences in aerosol pathways across the different SSPs where the full range of uncertainty in greenhouse gas emissions has not yet emerged (although they are not negligible and are included in our simulated climate response) (Lund et al., 2019a; Wilcox et al., 2020b; Guo et al., 2021). SSP1-2.6 includes a rapid reduction in global aerosol emissions until 2050, except for an increase over southern Africa due to rapid industrialization. The aerosol emissions in SSP2-4.5 and SSP5-8.5 show a similar, but weaker, pattern, with a decrease over the NH and increase in the Southern Hemisphere (SH) as well as a strong Asian aerosol dipole (i.e., a large increase over South Asia and large

105 decrease over East Asia) until the 2040s (Wilcox et al., 2020b; Samset et al., 2019a). The main difference between SSP2-4.5
and SSP5-8.5 lies in the black carbon (BC) emissions from South Asia which show an increase and decrease until the 2040s,
respectively, as well as the aerosol emissions over South America related to different rates of deforestation (Lawrence et al.,
2016). SSP3-7.0 also shows an NH decrease and SH increase in emissions. However, the sulfur dioxide (precursor of sulfate
110 aerosols) emissions stay nearly constant over East Asia but increase over South Asia, with opposite changes in BC emissions
(Wilcox et al., 2020b). The comparison of climate responses under these different SSPs, thus, allows us to investigate the
influence of anthropogenic aerosols on the PDF changes.

2.2 Data

2.2.1 CMIP6 data

We utilize large-ensemble simulations for the SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 scenarios performed by three
115 CMIP6 models, namely MPI-ESM1-2-LR (Mauritsen et al., 2019), CanESM5 (Swart et al., 2019) and ACCESS-ESM5-
1(Ziehn et al., 2020). Table 1 gives the model resolutions and number of ensemble members for each model. We use the
same models as Lund et al. (2023) for which the summertime variability of precipitation and daily maximum temperature was
verified using ERA-5 data.

Table 1. List of the CMIP6 Large ensemble models used in this study which performed the required SSP1-2.6, SSP2-4.5, SSP3-7.0 and
SSP5-8.5 simulations. The equilibrium climate sensitivity values are taken from Zelinka et al. (2020).

Model	Ensembles	Horizontal resolution	ECS value	Aerosol forcing	Reference
ACCESS-ESM1-5	29	$1.9^{\circ} \times 1.3^{\circ}$	3.88	Interactive	Ziehn et al. (2020)
CanESM5	23	$2.8^{\circ} \times 2.8^{\circ}$	5.64	Interactive	Swart et al. (2019)
MPI-ESM1-2-LR	11	$1.9^{\circ} \times 1.9^{\circ}$	3.03	MACv2-SP	Mauritsen et al. (2019)

2.2.2 PDRMIP data

120 We also use idealized single forcing simulations from the Precipitation Driver Response Model Intercomparison Project (PDR-
MIP; (Myhre et al., 2017)) to assess the expected impacts of different anthropogenic drivers on daily weather variability. In
particular, we focus on experiments simulating a global doubling of CO₂ concentrations (hereafter CO₂×2), a five-fold in-
crease in sulfate concentrations or emissions (hereafter SUL×5) and a ten-fold increase in black carbon concentrations or
emissions (hereafter BC×10) relative to the year 2000. We use the multi-model mean across eight CMIP5-generation models
125 which participated in PDRMIP to get a robust estimate of daily variability changes (Table 2). Throughout the analysis, we ex-
amine the years 50–100 of single coupled simulations, discarding the first decades as spin-up. For the extreme event definition
for PDRMIP, we use the 0.90 percentile threshold to ensure that enough data is available to accurately estimate variability.

Table 2. List of models which participated in PDRMIP and performed the coupled global experiments (CO₂×2, SUL×5, BC×10).

3 Results

3.1 Expected change in daily variability due to different anthropogenic drivers

130 Here, we first examine changes in daily weather variability in response to global increases in CO₂, sulfate and black carbon aerosols simulated as part of PDRMIP. Figure 2 shows how a five-fold global increase in sulfate emissions (first column), tenfold increase in black carbon emissions (second column) and doubling of CO₂ concentrations (third column) affect the number of days of precipitation above the 90th percentile in preindustrial conditions. In CO₂×2, all models show an increase in intense summertime precipitation over Asia, although the exact pattern over Asia differs between models (Figure A1).
 135 NorESM1 shows the smallest changes in intense precipitation overall, with strong increases being located around the Tibetan plateau. These changes correlate with changes in the SD. Other common features among the models include a drying over the southern part of Europe. Spatial correlation values between change in SD and change in number of days of extreme vary from 0.22 to 0.49. Therefore, changes in the SD can explain some of the changes in extremes but not all.

The impact of aerosols differs from those of CO₂. The climate response in SUL×5 shows a similar pattern but of opposite sign to those of CO₂, as expected since sulfate aerosols cool the climate while greenhouse gases warm it. For instance, HadGEM3 shows a decrease in precipitation extremes over Asia, Sub-Saharan Africa and an increase over Europe, with all these signals being opposite to the response in the doubling of CO₂. Additionally, all models simulate a decrease in the number of extreme days across the high latitudes in the NH. The spatial correlation between the SD and the number of extreme days for SUL×5 varies from 0.42 to 0.61 and are significant using the Kolmogorov–Smirnov test test.
 140

145 For BC×10, the spatial correlation between changes in SD and changes in the number of extreme days is quite variable and ranges from 0.44 to 0.74. The high correlation between changes in SD and extremes for the aerosol simulations indicates that changes in the shape of the underlying PDF are more dependent on aerosol emissions than changes in CO₂ concentration.

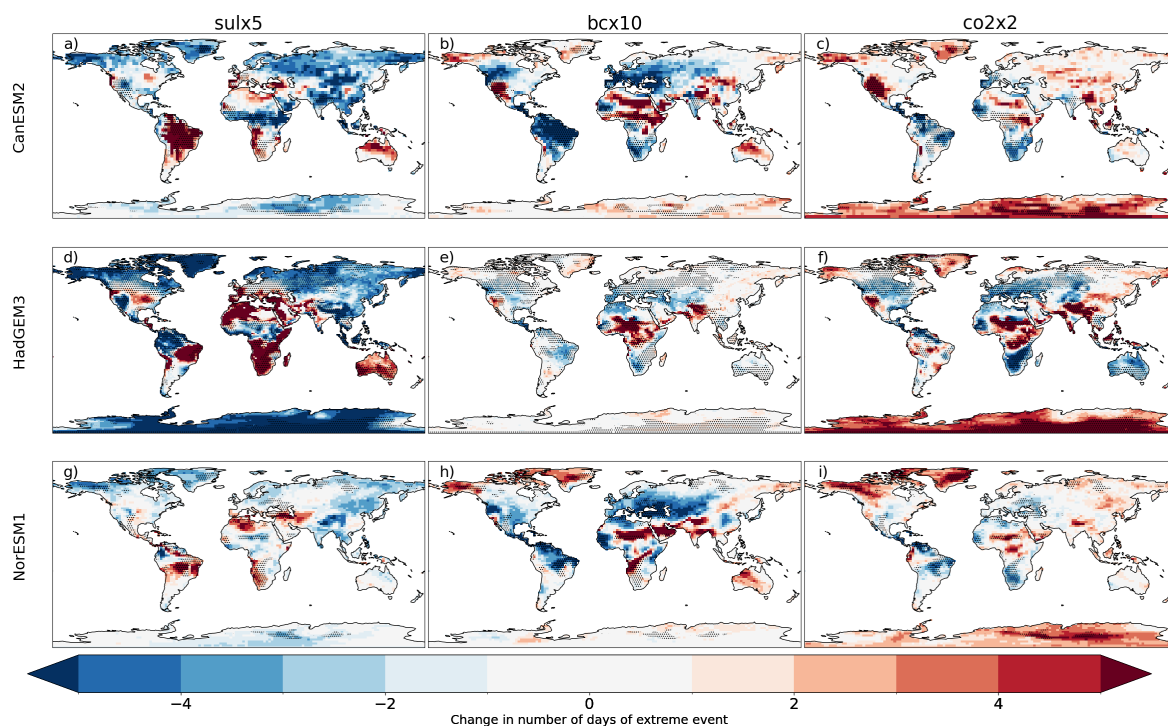

Figure 2. Changes in the average number of days per year of extreme (0.90 quantile) precipitation due to global doubling of CO₂ concentrations (CO₂×2), five-fold sulfate emissions (SUL×5) and ten-fold black carbon (BC×10) emissions as simulated by three different PDRMIP models. Panel titles indicate if a model is emission- (emi) or concentration-driven (conc). Stippling indicates where changes in underlying PDFs are significant at the $p > 5\%$ level.

3.2 Changes in extreme events under global warming

Changes in the probability of extreme precipitation events (>99th percentile) due to global warming can be attributed to two primary factors: changes in the mean state and variability. The combined impact of these two contributing factors is depicted in Figure 3, which illustrates how extreme precipitation events are evolving in response to global warming. The spatial pattern of these changes in extreme precipitation closely follows the overall pattern of annual precipitation changes, as discussed in (IPCC, 2021). In essence, regions that were already dry are experiencing increased aridity, while areas with high climatological levels of precipitation are becoming even wetter (Feng and Zhang, 2015; Xiong et al., 2022). To provide a more detailed understanding of the total changes highlighted in Figure 3, one can decompose these changes into two components: changes in variability (as shown in Figure 4) and changes in the mean state (as shown in Figure 5).

Figure 4 shows how changes in precipitation variability are changing the likelihood of extreme precipitation events, defined as those events that occur more than once every decade in the pre-industrial era. This phenomenon is observed globally, with an overall increase in the number of such extreme events in most regions. However, there are notable exceptions: In regions like

160 the Amazon basin, South Africa, and Australia, there is a slight decrease in extreme precipitation events during the summer months. Already, a one-degree change in global warming shows a significant increase in the likelihood of extreme precipitation, especially over the Sahel region, as simulated by MPI-ESM1-2-LR and CanESM5.

While there is broad agreement among the models about the increase in extreme precipitation, particularly in Asia, there are differences in the exact location of these changes. The most significant changes in extreme summer precipitation due to 165 variability are seen in three main regions: Asia, Sub-Saharan Africa, and the Arctic region. Each of these areas shows a distinct pattern in the increase of extreme precipitation events, underscoring the diverse impacts of changing precipitation variability across different parts of the world.

Changes in precipitation patterns can also be influenced by shifts in the mean state of precipitation driven by global warming. Figure 5 provides an overview of how shifts in the mean state affect the number of extreme precipitation days, although those 170 changes are not as large as those resulting from shifts in variability. A consistent increase in aridity can be seen over southern Europe and, to a large extent, northern America (Fig. 5). Figure 6 shows whether changes in the mean state (shown in brown) or variability (shown in purple) are the dominant factors influencing the overall change in extreme precipitation events. Relative importance of change in mean state and change in variability is defined by $\frac{\Delta variability - \Delta Mean}{\Delta variability + \Delta Mean}$. All three models agree on the spatial pattern of changes in variability. In particular, changes in the mean state are the dominant driver of changes in 175 extreme precipitation events over South America, South Africa, and Australia. Conversely, changes in variability play a more pronounced influence on extreme precipitation changes over Eurasia.

The behaviour of daily maximum temperature during summer is quite different from that of daily precipitation (Fig. 6). While changes in daily precipitation are primarily driven by changes in variability, daily maximum temperatures are pre- 180 dominantly influenced by changes in their mean state. On a global scale, all regions experience an increase in extreme daily maximum temperatures due to shifts in the average daily maximum temperature. In a four-degree warmer world, the daily maximum temperature distributions in almost every region are shifted outside pre-industrial ranges. However, there is some variability among climate models in terms of the specific spatial patterns of this increase in daily maximum temperatures. For instance, only the ACCESS-ESM1-5 model predicts that all summer days in Alaska will surpass rarely observed pre-industrial temperatures in a four-degree warmer world.

185 3.3 Different climate drivers in the near future

In the near future, the Earth's climate will be influenced by different anthropogenic drivers depending on different future emission scenarios and associated emission reductions. Above, we have shown, using idealized simulations performed as part of PDRMIP, the influence of different anthropogenic drivers on Earth's climate 3.1. It is not evident that different anthropogenic drivers have an effect on rare extreme events that occurred only once per decade during the pre-industrial period in the near 190 future SSP scenarios. However, when examining more frequent extreme events (events which occur once per year), differences between aerosol-driven changes and greenhouse gas-induced warming become evident. Figures B1,B2,B3 show changes in the likelihood of these extremes in the near future under different SSP scenarios (particularly, SSP1-2.6, SSP2.4-5, SSP3-7.0, and SSP5-8.5) for all three models due to changes in variability. Similar to the changes in extremes under global warming, the

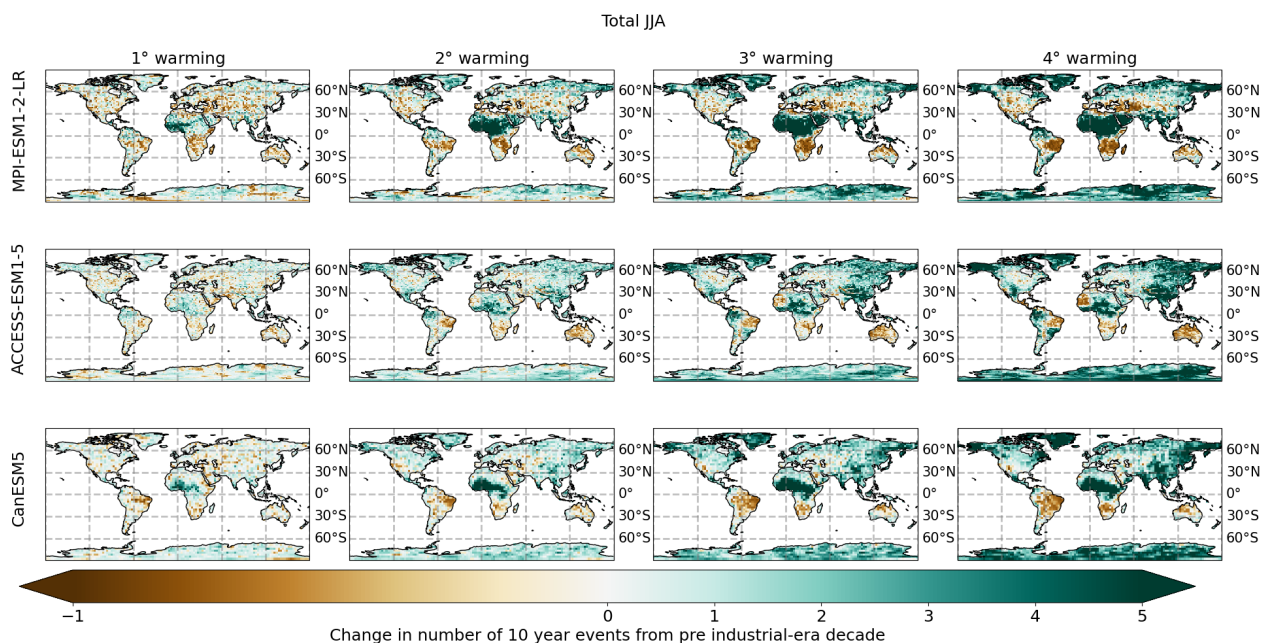

Figure 3. Total change in the number of days of intense precipitation events during JJA under different global warming levels. Stippling indicates regions where changes in PDFs are significant at $p > 0.05$

most distinct near-future changes are seen in Sub-Saharan Africa, where greenhouse gas emissions are expected to dominate.
 195 In contrast, most of the reduction in aerosol emissions is expected to occur over Asia in the future (Lund et al., 2019b).

We can estimate the effects of aerosols by subtracting the changes seen in SSP3-7.0 from SSP1-2.6, where the most drastic aerosol reductions occur over South East and South Asia (Lund et al., 2019b). While greenhouse gas emission and land use changes will also contribute, previous work has found this method to give a reasonable first approximation of the aerosol influence over the coming decades (Wilcox et al., 2020a). Figure 7 shows the effect of aerosol emission reductions according to the SSP1-2.6 scenario for the three different climate models over Asia (for global see B4). There is no model agreement on the pattern or sign of change over most land regions. The CanESM5 model suggests that with a continuous reducing aerosol emissions, the increase in the likelihood of extreme precipitation events is continuously reduced in the near future. In contrast, MPI-ESM1-2-LR indicates a slight decrease in extreme weather events from 2025 to 2034, followed by an increase from 2035 to 2044. This would indicate that reducing aerosol emissions might make extreme weather more likely during this later period.
 205 The ACCESS-ESM1-5 model shows the most significant effect: A reduction of aerosol emissions leads to a clear rise in the chance of extreme rain or snow events between 2035 and 2044. This seems aligned with previous results which showed that anthropogenic aerosols suppress precipitation, including extreme precipitation, over Asia (Yang et al., 2022; Wilcox et al., 2020a; Persad, 2023).

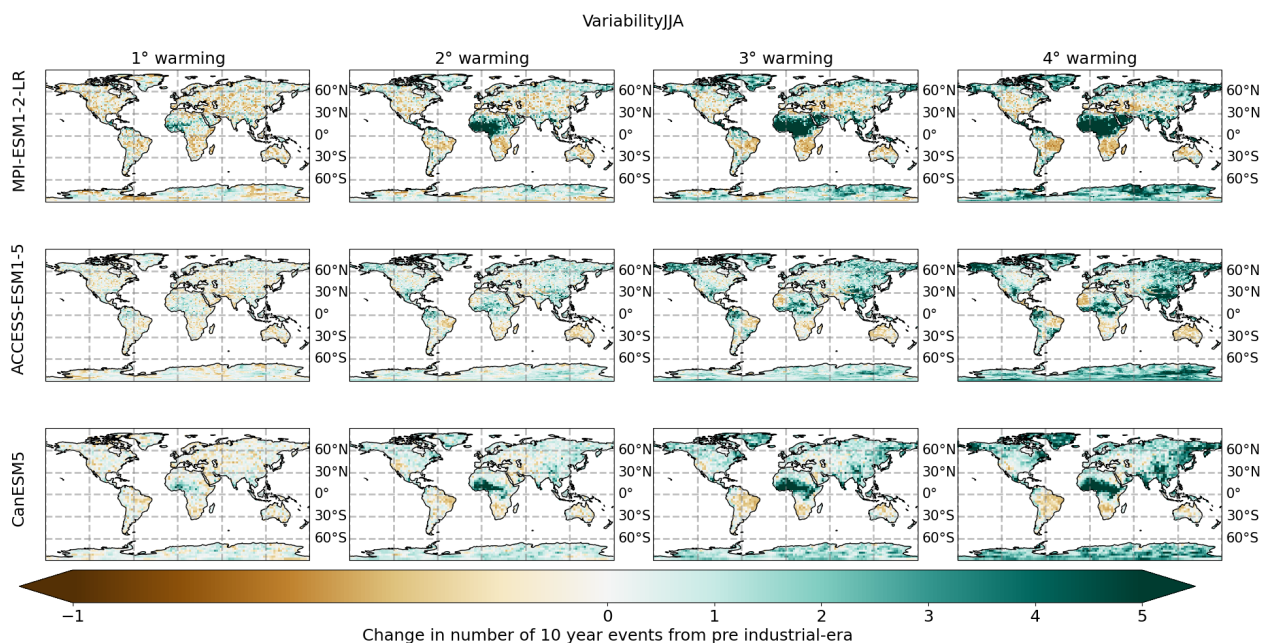

Figure 4. Changes in the number of days of intense JJA precipitation events due to changes in variability under different global warming levels. Stippling indicates regions where changes in PDFs are significant at $p > 0.05$

These model differences likely stem from differences in the implementation of aerosols as well as the model's sensitivity to greenhouse gases. MPI-ESM1-2-LR uses a simplified approach, namely the MAC-SPv2 parametrization (Stevens et al., 2017), to represent aerosols (black carbon and sulfate) which only accounts for the first indirect effect without considering more complex interactions. CanESM5 has a very high climate sensitivity (see Table 1), leading to greenhouse gas-dominated responses even when aerosol emissions are reduced. CanESM5, further, has a high atmospheric absorption value due to black carbon which is likely masking part of the cooling effect of due to sulfate aerosols (Fiedler et al., 2023). ACCESS-ESM1-5, on the other hand, employs the CLASSIC aerosol model (Ziehn et al., 2020; Bellouin et al., 2011a; Mackallah et al., 2022), which is a very detailed representation considering seven different aerosol types.

3.4 Model discrepancies

While all models used here show similar regional changes in the likelihood of summertime extreme precipitation, they have different underlying PDFs and associated impacts on the likelihood of extremes. Figure 8 shows regional mean PDFs for total changes in daily summertime precipitation for South Asia (SAS), West Africa (WAF) and North West North America (NWN) (using the region definitions from the IPCC report (Iturbide et al., 2020)).

For SAS, the underlying PDFs are quite different between the individual models: MPI-ESM1-2-LR shows a skewed normal distribution during the pre-industrial period, which evolves towards a normal distribution under global warming. In contrast,

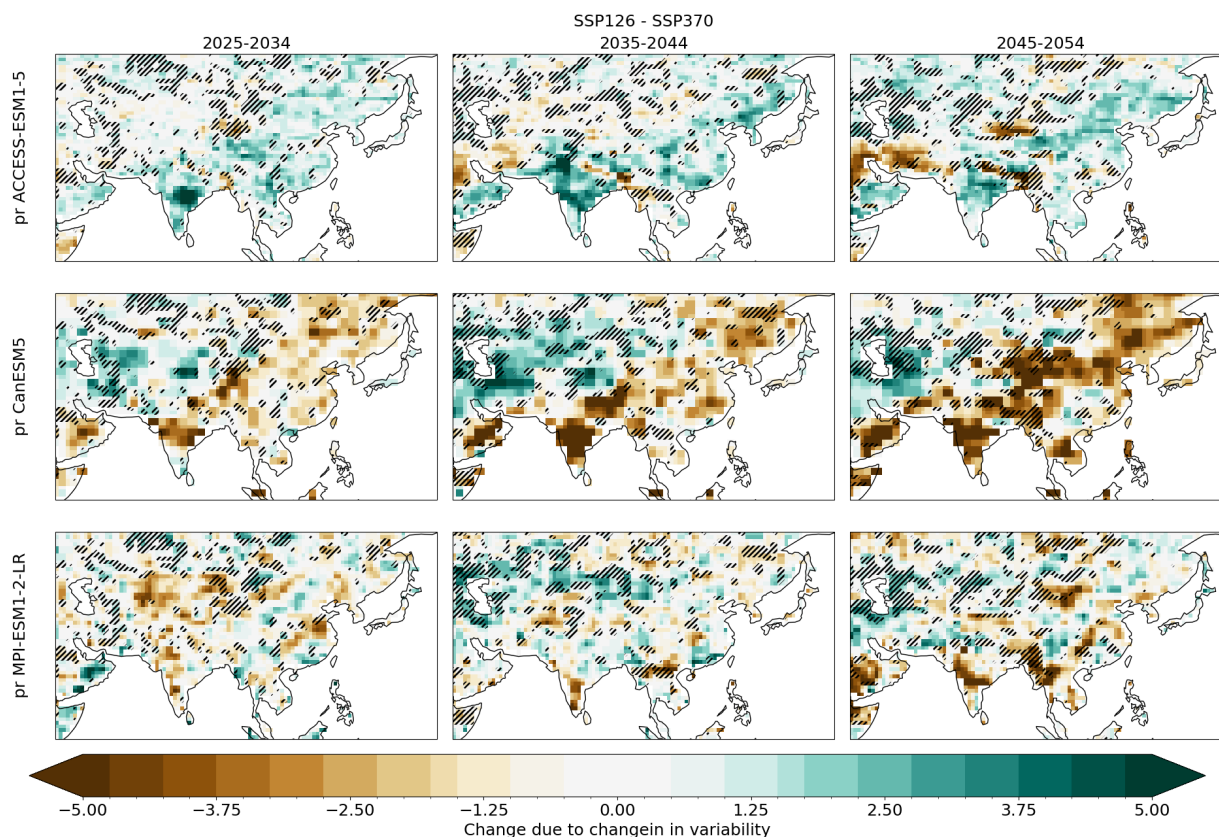

Figure 7. Change in the likelihood of days of extreme JJA precipitation between SSP1-2.6 and SSP3-7.0 over Asia for three different models ACCESS-ESM1-5 (row 1), CanESM5 (row 2) and MPI-ESM1-2-LR (row 2). Hatching indicates regions where all three models agree on the sign of the change.

CanESM5 shows a gamma-like distribution for all different GWLs. The PDFs of the ACCESS-ESM1-5 model show an exponential distribution on the upper and lower end of the spectrum.

Over the WAF region, MPI-ESM1-2-LR and ACCESS-ESM1-5 both exhibit similar skewed Gaussian distributions during the pre-industrial era. With global warming, these distributions are getting wider, which indicates an increase in daily variability and the associated increase in extremes on both ends. While CanESM5 shows a widening of the PDF, similar to the other two models, it also shows a clear change in the mean of the distribution. As a result, the likelihood of extreme values is primarily increasing in the high end of the tails.

Over NWN, all three models exhibit similar PDF shapes. However, the model responses diverge regarding the PDF evolution under global warming. Despite these discrepancies in underlying PDFs, all three models show a robust increase in summertime variability under global warming, which leads to an increased likelihood of precipitation extremes in the Arctic, Asia and Africa.

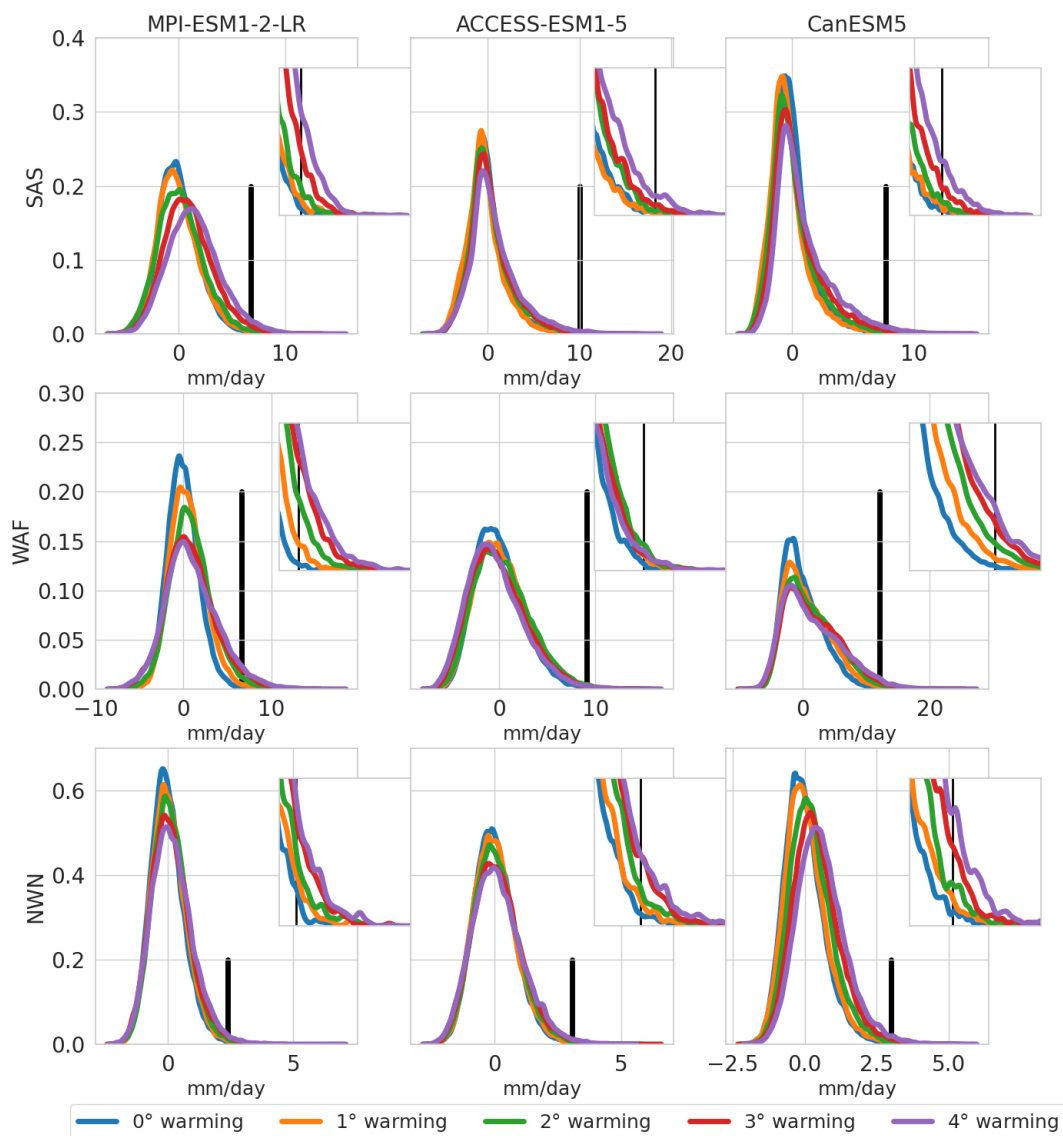

Figure 8. PDFs of total changes in JJA precipitation over South Asia (SAS), West Africa (WAF) and North West North America (NWN) under different global warming levels for all three models. Inserts show the upper tail of the distributions and the black horizontal line indicates the 0.999 quantile threshold.

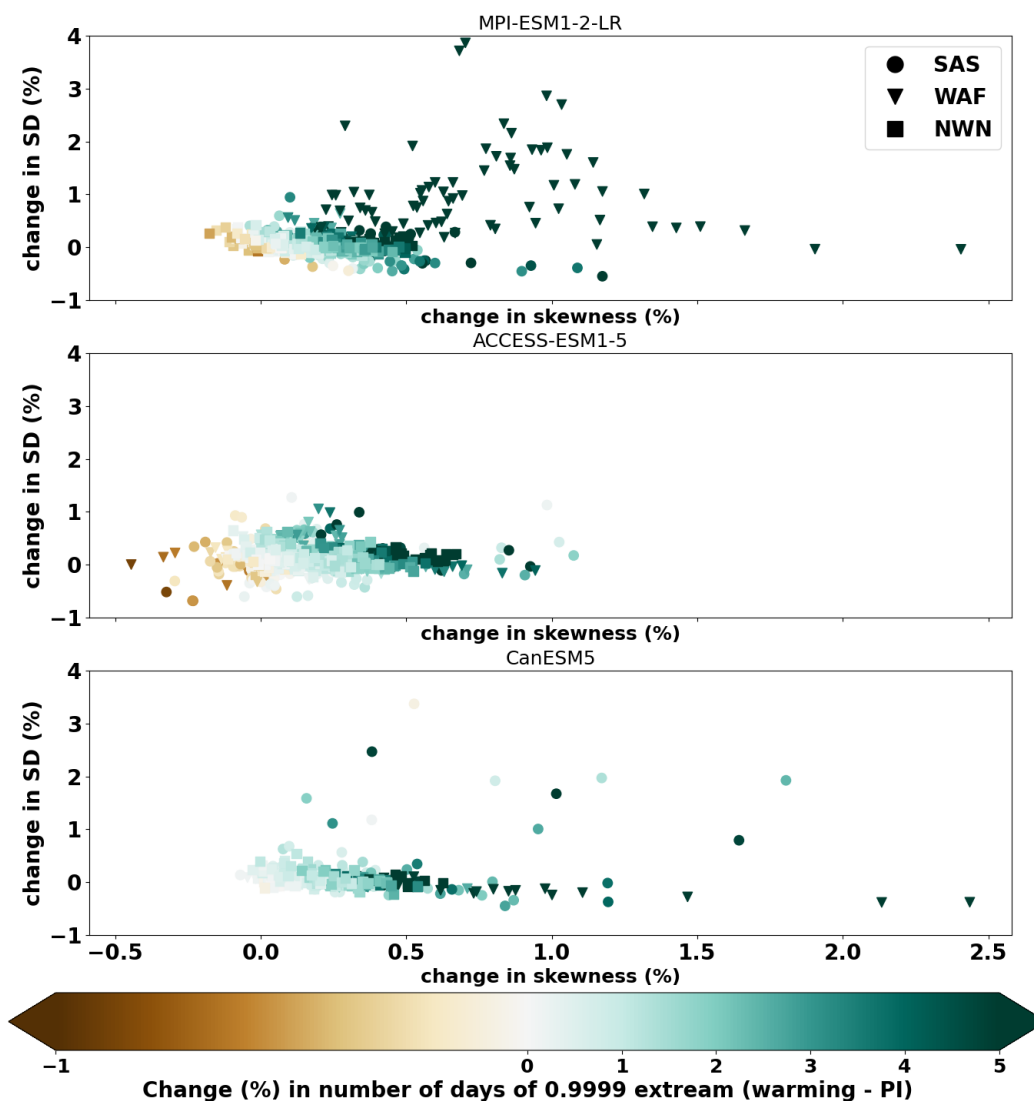

Figure 9. Regional changes in the SD and skewness for extreme JJA precipitation events are shown for SAS, WAF and NWN and three models.

235 The next question is which change dominates the overall changes: A change in the SD, or the skewness? Figure 9 shows how those two measures change in the three different regions (WAF, NWN and SAS) and for the different models, and how that relates to change in the likelihood of extreme days. Each marker in figure 9 represents one grid point. For CanEMS5 most of the changes are due to changes in the skewness (shape of the PDF) and underlying PDFs are even getting narrower. Both ACCESS-ESM1-5 and MPI-ESM1-2-LR show increase of SD together with an increase in skewness.

240 4 Discussion

Some extreme attribution studies follow the method from Philip et al. (2020) which assumes that the shape of the distribution stays constant. However, we find that this assumption cannot be made in a future climate, although the exact distribution changes remain uncertain due to large discrepancies between CMIP6 models. Nonetheless, our findings highlight the importance of including daily variability in climate change impact and attribution studies. While we find small or no change in the summertime mean precipitation, a clear increase in the number of extreme precipitation days is evident. Therefore, impact studies which only concentrate on the mean climate would inevitably underestimate the effects of extreme events.

This is further applicable to, for instance, the development of statistical emulators. Most emulators only consider global-mean temperature or precipitation effects or apply simple linear scaling (Nath et al., 2021; Watson-Parris et al., 2021). Based on the findings from this study, we recommend that the training of emulators should include training with daily weather variability to capture the complete climate change impacts. Furthermore, more work is needed such that emulators and simple climate models can fully simulate the effects of different climate drivers, as already highlighted by Persad et al. (2023). For future applications, it is relevant to know how well present ESMs can replicate observed daily climate variability. Lund et al. (2023) shows that the MPI-ESM1-2-LR and CanESM5 model capture the mean present-day precipitation rates well. However, evaluating the accuracy of climate models in predicting present-day extreme events is challenging due to sparse observational data. With only three rare extreme events recorded (based on our definition), the limited dataset hampers robust model validation, leading to uncertainty in the model's ability to reliably reproduce such rare but impactful occurrences. As different models show different kinds of underlying distributions, the limitation of this study is the small number of ESM ensembles used.

Although our findings primarily focus on the impact of climate change on wet extremes, it is essential to note that changes in both mean and variability can enhance or reduce the occurrence of dry extreme events as well. When examining total changes occurring due to changes in the variability and mean, we found that changes in the mean reduce the likelihood of dry extremes while changes in variability exacerbate changes in wet extremes. This finding underlines that it is crucial to recognize that although changes in climate variability can influence the frequency of extreme events, these effects may be offset by shifts in the mean climatic conditions for dry extremes.

5 Conclusions

This study investigates the role of changes in mean and variability separately on daily summertime precipitation and maximum temperature for three different large-ensemble CMIP6 models. We focus on changes under four different global warming levels as well as changes in the near future driven by different anthropogenic drivers.

Our main findings are listed below:

- Changes in daily variability are the main drivers of changes in the likelihood of extreme summertime precipitation. In contrast, the change in the mean state is the primary driver of changes in temperature.

- Three key regions, namely Asia, Arctic and Sub-Saharan Africa, show that changes in the width and shape of the PDFs are particularly relevant in influencing summertime precipitation.
- In the near future, aerosol emission reductions are likely to increase the likelihood of extreme summertime precipitation over Asia.

275 – Model discrepancies dominate estimates of the impact of different climate drivers in the near future.

We find that aerosol emissions play a key role in the near-future evolution of regional precipitation extremes due to the ongoing reduction of anthropogenic aerosol emissions and their strong influence on daily precipitation variability. This would suggest that simple aerosol representations, as is implemented in the MPI-ESM1-2-LR model, lead to an underestimation of aerosol impacts compared to models with more advanced aerosol schemes, like in ACCESS-ESM1-5. Still, large uncertainty remains on how regional PDFs of precipitation will change (shape and width) in the future under different emission pathways. Global warming will lead to more extreme precipitation in many regions. How the near-term mix of anthropogenic and natural drivers of change will influence the net width and shape of the distributions of daily weather, however, is still a burning topic for future research.

285 *Data availability.* Data used in this paper is available from Nordling (2024)

Appendix A: Results from PDRMIP

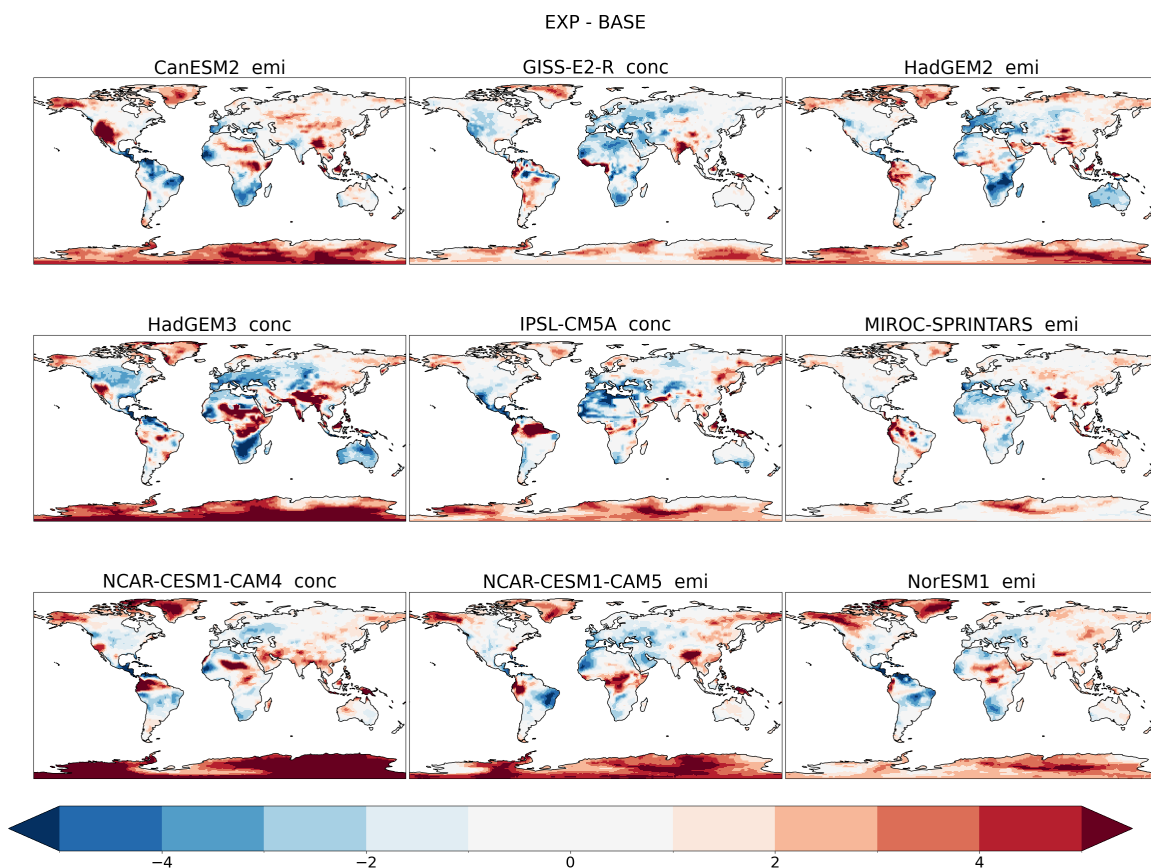

Figure A1. Changes in the average number of days per year of extreme (0.90 quantile) precipitation due to the global doubling of CO₂ concentrations as simulated by nine different PDRMIP models. Panel titles indicate if a model is emission- (emi) or concentration-driven (conc).

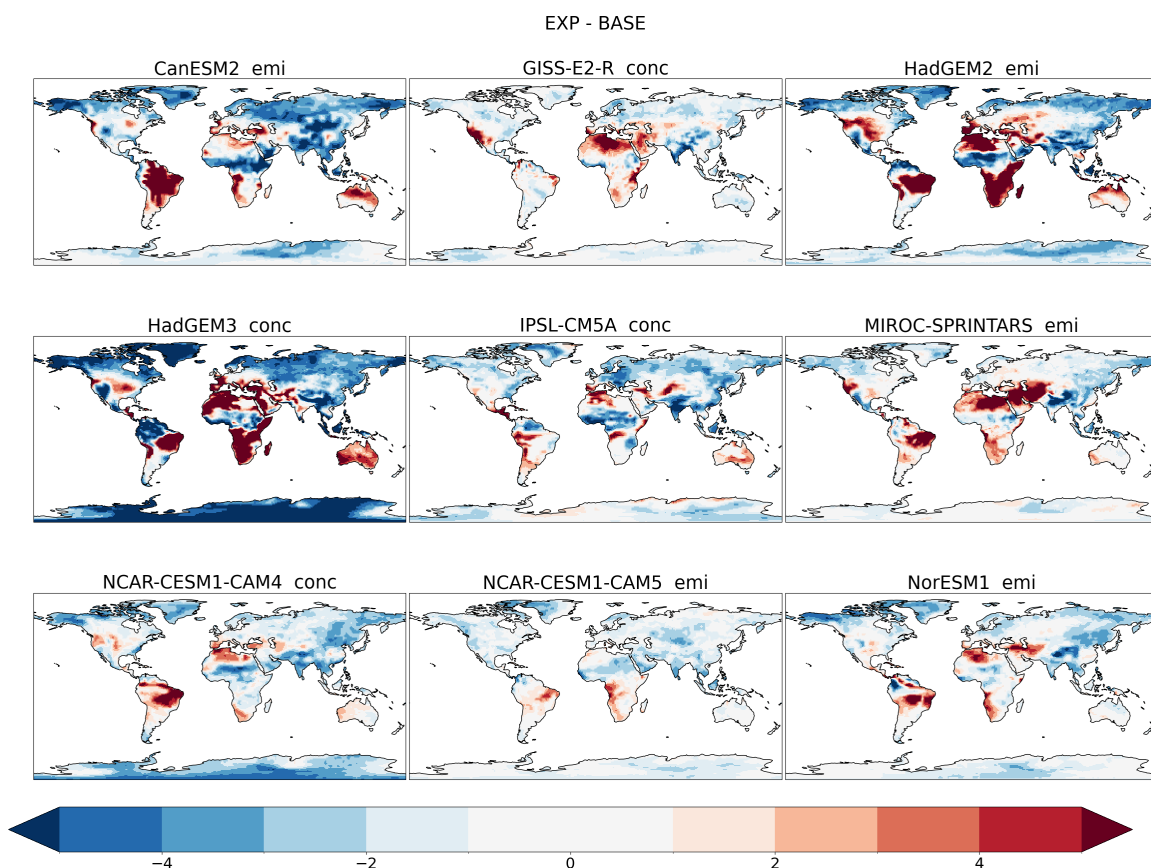

Figure A2. Changes in the average number of days per year of extreme (0.90 quantile) precipitation due to a global five-fold increase in sulfate emissions as simulated by nine different PDRMIP models. Panel titles indicate if a model is emission- (emi) or concentration-driven (conc).

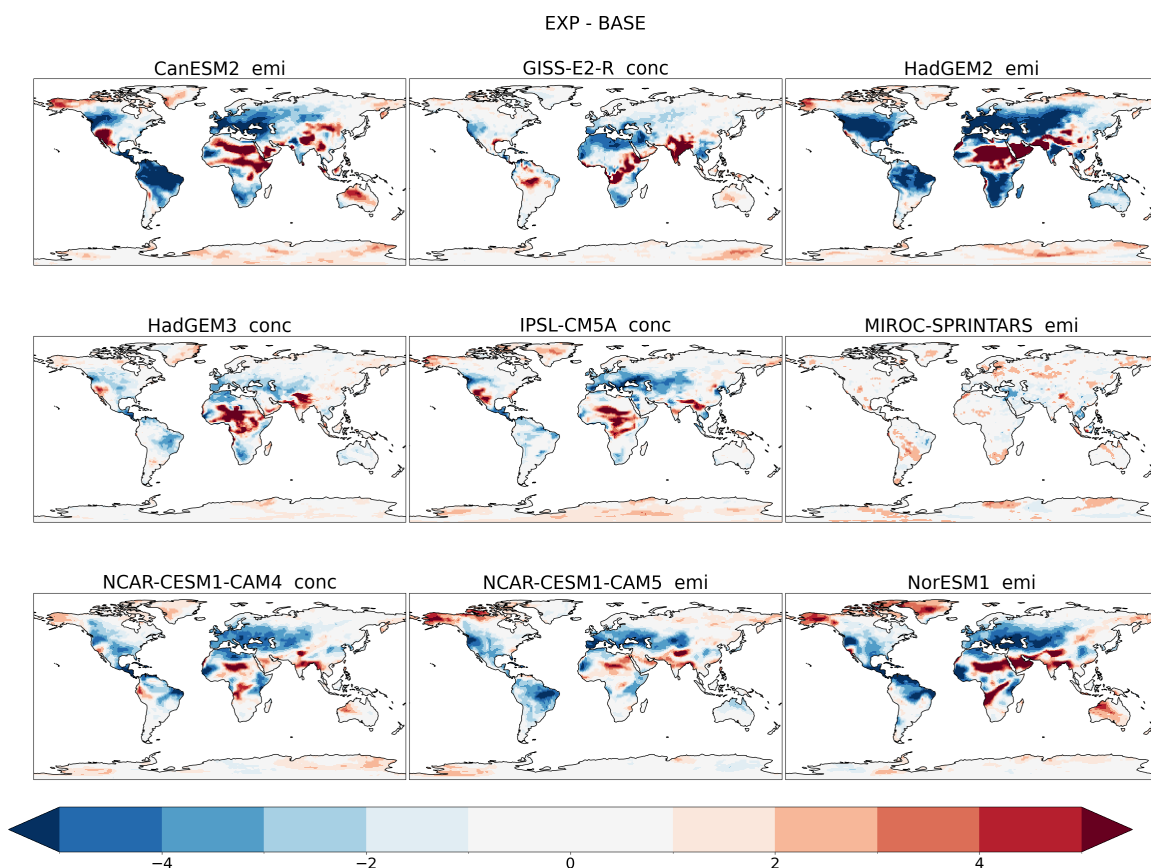

Figure A3. Changes in the average number of days per year of extreme (0.90 quantile) precipitation due to a global ten-fold increase in black carbon emissions as simulated by nine different PDRMIP models. panel titles indicate if a model is emission- (emi) or concentration-driven (conc).

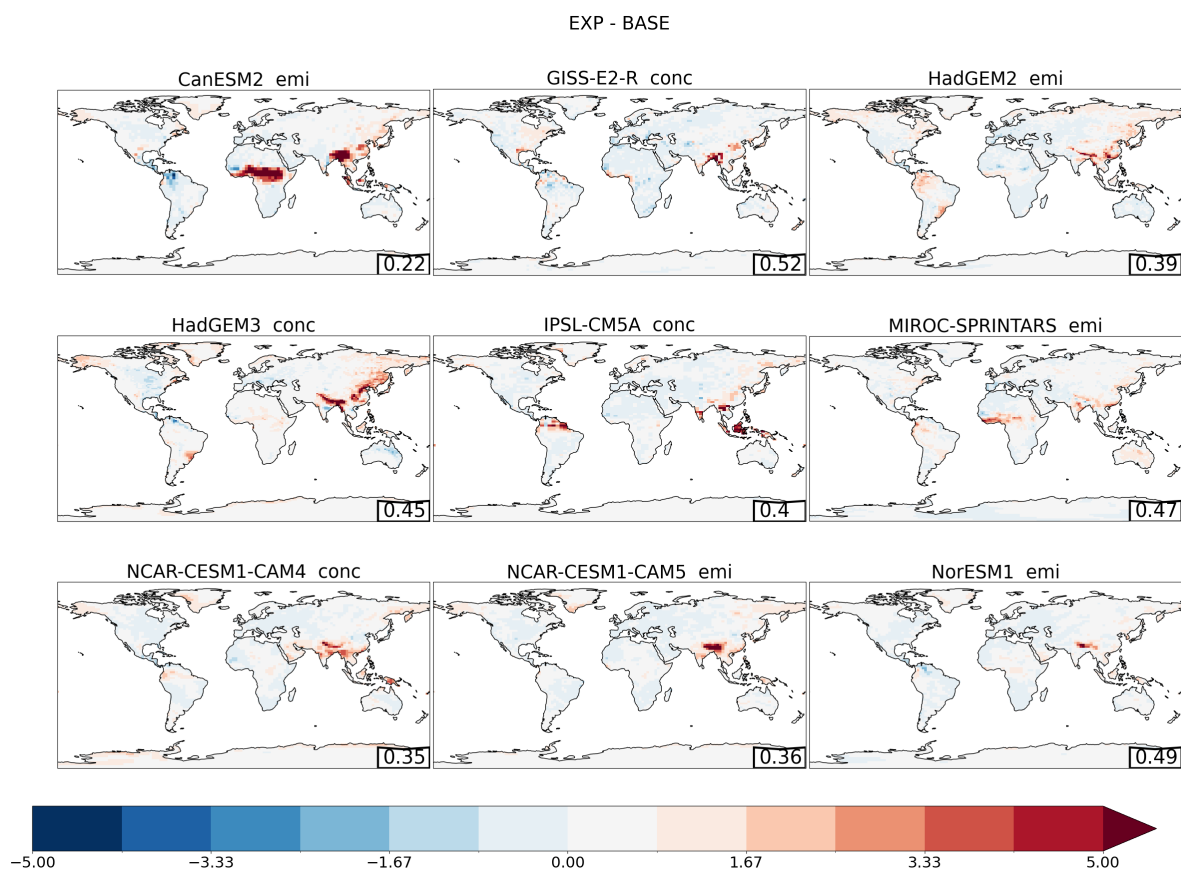

Figure A4. Changes in the daily summertime PDF standard deviation due to a global doubling of CO₂ concentrations as simulated by nine different PDRMIP models. panel titles indicate if a model is emission- (emi) or concentration-driven (conc). Correlation between standard deviation and change in extremes is shown in the corner.

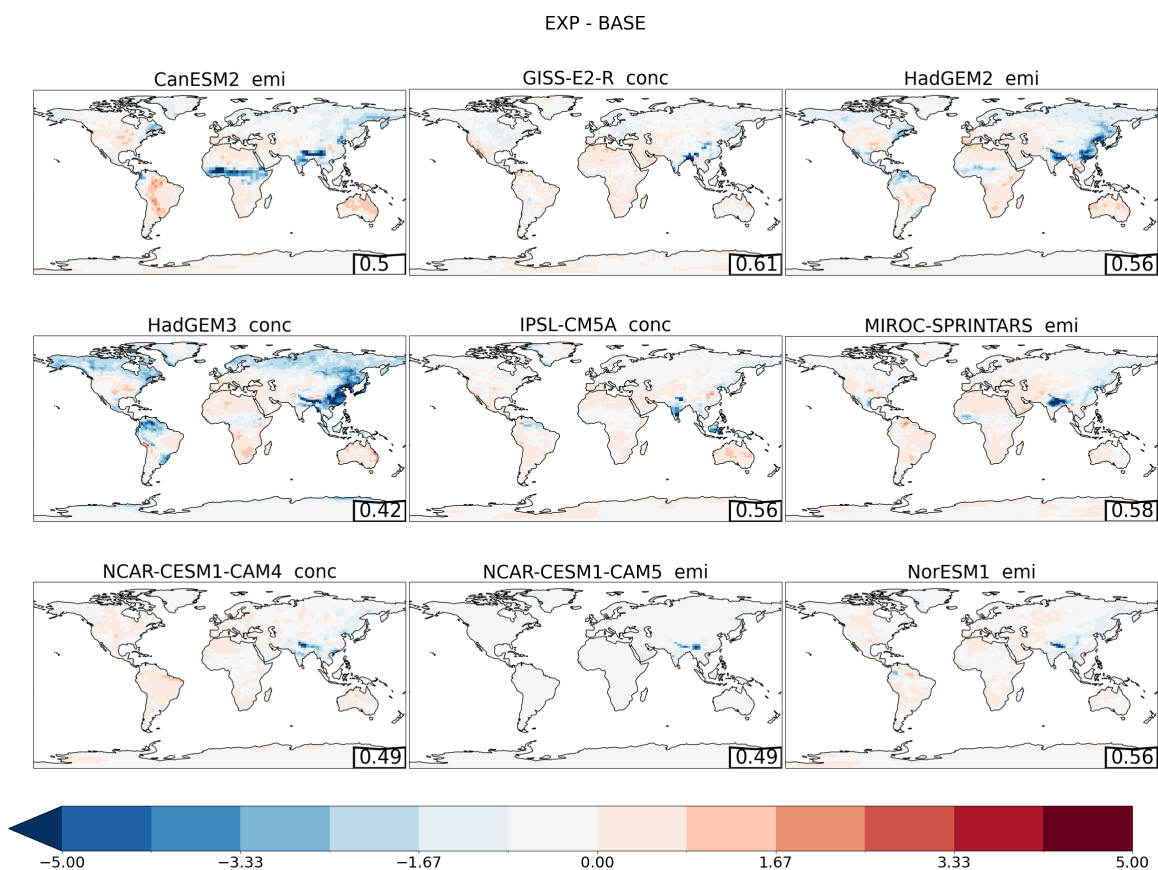

Figure A5. Changes in the the daily summertime PDF standard deviation due to a global five-fold increase in sulfate emissions as simulated by nine different PDRMIP models. panel titles indicate if a model is emission- (emi) or concentration-driven (conc). Correlation between standard deviation and change in extremes is shown in the corner.

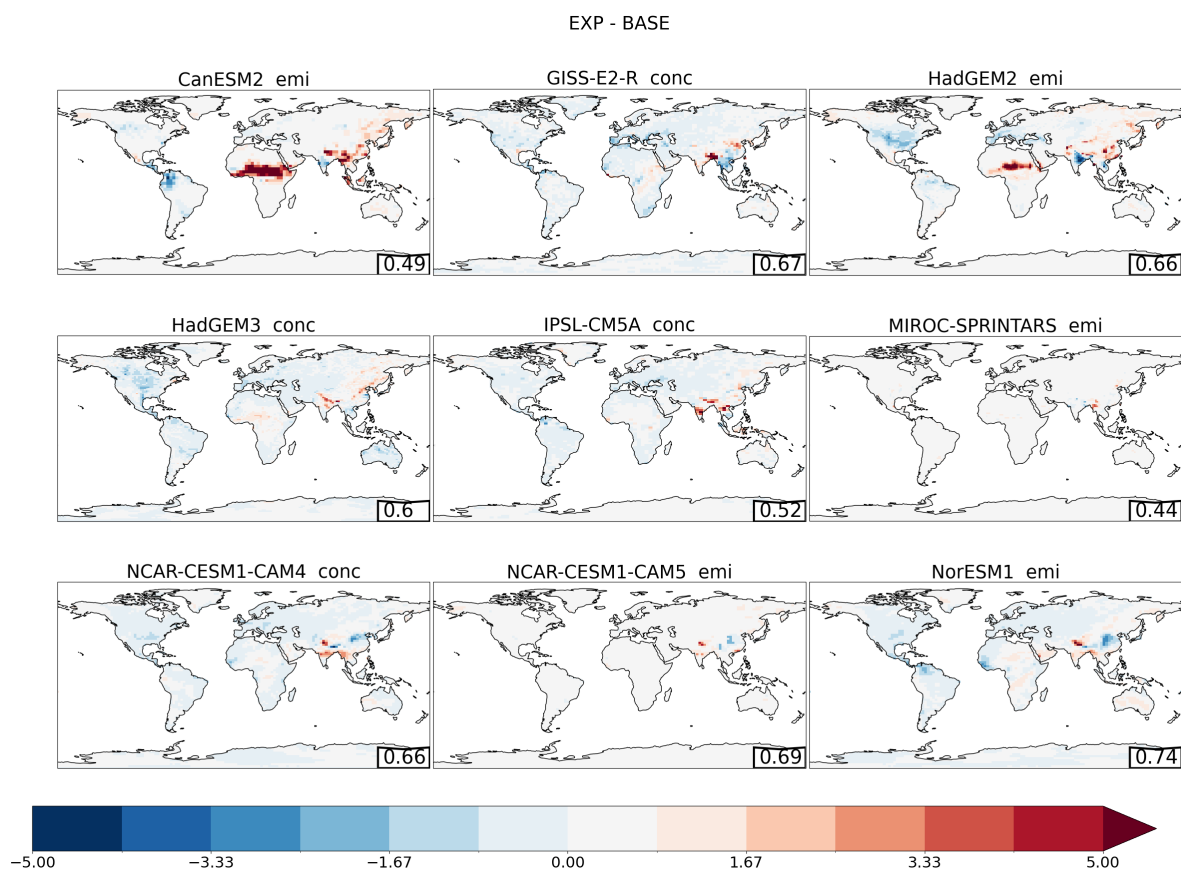

Figure A6. Changes in the daily summertime PDF standard deviation due to a global ten-fold increase in black carbon emissions as simulated by nine different PDRMIP models. panel titles indicate if a model is emission- (emi) or concentration-driven (conc). Correlation between standard deviation and change in extremes is shown in the corner.

Appendix B: Near future

Figure B1. Near-future changes in number of extreme precipitation days for MPI-ESM1-2-LR under four different SSP scenarios (columns) and for three different time periods (from left to right: 2025–2035, 2035–2045 and 2045–2050).

Author contributions. All authors contributed to the writing, BHS came up with the original concept, NLSF came up with the concept of extremes and KN performed the analysis.
