

1 Diverging trends in aerosol sulfate and nitrate measured in the remote North Atlantic on
2 Barbados are attributed to clean air policies, African smoke, and anthropogenic emissions

11 **ABSTRACT**

12 Sulfate and nitrate aerosols degrade air quality, modulate radiative forcing and the hydrological
13 cycle, and affect biogeochemical cycles, yet their global cycles are poorly understood. Here,
14 we examined trends in 21 years of aerosol measurements made at Ragged Point, Barbados, the
15 easternmost promontory on the island located in the eastern Caribbean Basin. Though the site
16 has historically been used to characterize African dust transport, here we focused on changes
17 in nitrate and non-sea salt (nss) sulfate aerosol from 1990-2011. Nitrate aerosol concentrations
18 averaged over the entire period were stable at $0.59 \mu\text{g}/\text{m}^3 \pm 0.04 \mu\text{g}/\text{m}^3$ except for elevated
19 nitrate concentrations in the spring of 2010 as well as during the summer and fall of 2008 due
20 to the transport of biomass burning emissions from both northern and southern Africa to our
21 site. In contrast, from 1990 to 2000, nss-sulfate decreased 30% at a rate of $0.023 \mu\text{g}/\text{m}^3/\text{yr}$, a
22 trend which we attribute to air quality policies enacted in the U.S. and Europe. From 2000-
23 2011, sulfate gradually increased at a rate of $0.021 \mu\text{g}/\text{m}^3/\text{yr}$ to pre-1990s levels of $0.90 \mu\text{g}/\text{m}^3$.
24 We used the Community Multiscale Air Quality (CMAQ) model simulations from the EPA's
25 Air QUALity TimE Series (EQUATES) to better understand the changes in nss-sulfate after
26 2000. The model simulations estimate that increases in anthropogenic emissions from Africa
27 explain the increase in nss-sulfate observed in Barbados. Our results highlight the need to better
28 constrain emissions from developing countries and to assess their impact on aerosol burdens
29 in remote source regions.

30

31 **1. INTRODUCTION**

32 Sulfate and nitrate aerosol, formed from gaseous sulfur dioxide (SO₂) and nitrogen oxides (e.g.,
33 NO_x≡NO+NO₂) as well as reactive nitrogen (e.g., NO_y), contribute to aerosol direct and indirect
34 radiative forcing, impact biogeochemical cycles (Jickells et al., 2017), and degrade air quality
35 (Adams et al., 1999; Appel et al., 1978; Charlson et al., 1992; Lelieveld & Heintzenberg, 1992;
36 Murphy et al., 2006). An outstanding question is, how have sulfate and nitrate aerosol burdens in
37 remote regions changed in response to air quality policies, economic growth, and changing
38 frequency of wildfires—all of which have affected SO₂ and NO_x emissions? Answering this
39 question is important as remote regions are an important barometer of changing global emission
40 inventories, contain ecosystems sensitive to changing chemical inputs (Galloway et al., 2008;
41 Mahowald et al., 2017), and are most sensitive to fluctuations in aerosol burdens that alter aerosol-
42 cloud interactions (Carslaw et al., 2013). Long-term measurement records in remote regions can
43 provide insight into this question as well as further advance current chemical transport and global
44 climate models. However, there are few long-term measurement records in remote regions. In this
45 work, we leverage 21 years of nitrate and sulfate aerosol concentrations measured at Ragged Point,
46 Barbados, a remote site in the eastern North Atlantic marine boundary layer, and use simulations
47 from a hemispheric chemical transport model—the Community Multiscale Air Quality (CMAQ)
48 model within the EPA’s Air QUALity Time Series (EQUATES) (Foley et al., 2023)—to link our
49 observed changes in nitrate and sulfate to changing emissions inventories and meteorological
50 conditions. In turn, comparing the EQUATES model output to our time series provides guidance
51 on where in-situ measurements are needed to improve emissions inventories and measurement-
52 model agreement.

53 Ragged Point, Barbados provides a unique opportunity to understand changes in the nitrate
54 and sulfate aerosol burden in the remote North Atlantic marine boundary layer. Aerosol sampling
55 began in 1971 and continues to this day generating an ~50-year measurement record—the longest
56 modern speciated aerosol record, to the best of our knowledge (Prospero et al., 2021; Prospero &
57 Mayol-Bracero, 2013). The site serves as a lynchpin for understanding the impact of long-range
58 aerosol transport on the remote North Atlantic marine boundary layer and Caribbean. The site’s
59 primary objective has been to understand the factors affecting the long-range transport of African
60 dust to the Caribbean and North America, which peaks in boreal summer in association with the
61 seasonal northward shift in the intertropical convergence zone (ITCZ). Summer dust events are
62 caused by the strong heating of northern Africa, which causes hot, dry dust-laden desert air to be
63 carried to high altitudes, e.g., 4 – 6 km. African Easterly Waves propagate dust westward within
64 an elevated air layer known as the Saharan Air Layer (SAL) that overrides the cool, moist marine
65 boundary layer (Adams et al., 2012; Carlson & Prospero, 1972; Goudie & Middleton, 2001;
66 Tsamalis et al., 2013). Background emissions at the site are dominated by sea spray and marine
67 biogenic emissions of dimethyl sulfide (DMS) that contribute non-sea salt (nss)-sulfate (Andreae
68 et al., 1985; Barnes et al., 2006; Savoie et al., 2002). Along with dust, anthropogenic emissions
69 from Europe (Lelieveld et al., 2002), North America, and northern Africa are also transported to
70 Barbados (Savoie et al., 2002). Transport from Africa takes ~5-7 days to reach our site while
71 transport from the U.S. and Europe takes longer, typically 7-10 days.

72 Anthropogenic emissions of SO₂ and NO_x that impact Ragged Point have changed in recent
73 decades due to the opposing effects of decreasing emissions mandated by national air quality
74 policies, implemented mostly in developed countries, and increasing emissions linked to rapid
75 economic growth in developing countries. The United States (U.S.) curbed emissions of NO_x and
76 SO₂ with the implementation of the Clean Air Act (amended in 1990), resulting in a 92% reduction
77 in SO₂ and a 71% reduction in NO_x emissions from 1990-2022 (Aas et al., 2019; Hand et al., 2012;
78 <https://gispub.epa.gov/air/trendsreport/2023/>; Smith et al., 2011; Zhao et al., 2017). Countries
79 within the European Union (EU) passed similar policies resulting in analogous reductions (Aas et
80 al., 2019; Rafaj et al., 2015; Smith et al., 2011; Yang et al., 2020). Notably, reductions in SO₂ can
81 reduce aerosol acidity resulting in increased nitrate aerosol. Further, reductions in pollutant gases
82 can relieve oxidant limitations leading to more efficient oxidation and, therefore, reductions in SO₂
83 and NO_x may not reduce sulfate and nitrate aerosol as much as expected (Shah et al., 2018). In
84 contrast to the U.S. and EU, emissions in regions such as the Middle East, India, and Africa are
85 continuing to increase due to rapid economic growth with emissions from India predicted to
86 overtake China as the world's largest emitter of SO₂ (Lelieveld et al., 2009; Li et al., 2017;
87 McDuffie et al., 2020). Due to a lack of in-situ measurements in many of these regions, chemical
88 transport and emissions inventory models combined with remote sensing have been key tools to
89 understand changing pollutants.

90 In addition to fossil fuel emissions, biomass burning is also a major source of SO₂ and NO_x
91 that can impact the Atlantic (Andreae, 2019; Andreae & Merlet, 2001; Rickly et al., 2022; Roberts
92 et al., 2009; Zuidema et al., 2018). Wildfire activity has a distinct seasonality linked to the dry
93 seasons in Africa. Burning is most intense in Sub-Saharan Africa from the equator to 20°N from
94 November through May while from May through October, the savannah regions of Sub-Saharan
95 Africa from the equator to 25°S are the most active fire sources (Giglio et al., 2006; Kganyago &
96 Shikwambana, 2019; Roberts et al., 2009; Van der Werf et al., 2003). African smoke can be
97 transported to Barbados from Sub-Saharan Africa north of the equator in winter and spring (Quinn
98 et al., 2022; Royer et al., 2023; Wex et al., 2016) and, less frequently, from southern hemispheric
99 Africa in fall (Trapp et al., 2010). Conditions thought to be related to African climate (e.g., the
100 North Atlantic Oscillation and the position of the Azores High) can cause large quantities of
101 northern African dust (and smoke) to be transported during the winter and spring in elevated,
102 mixed aerosol layers (Chiapello et al., 2005; Doherty et al., 2008, 2012; Gutleben et al., 2022)
103 when dust is also carried to northeastern South America (Barkley et al., 2019; Prospero et al., 1981,
104 2014). Prescribed burns in the southeastern U.S. in winter and spring may also contribute biomass
105 burning emissions to the aerosol burden observed in Barbados (Nowell et al., 2018).

106 Here we highlight different trends in nitrate and sulfate aerosol over the remote North Atlantic
107 marine boundary layer and relate them to changing emissions. We then compare our observations
108 to simulated concentrations of nitrate and sulfate aerosol using the CMAQ model from EQUATES,
109 which was chosen due to its skill at modeling changes in nitrate and sulfate chemistry within the
110 U.S. (Benish et al., 2022) as well as its ability to simulate constituents and sources of air pollution
111 in remote regions, such as Dhaka, Bangladesh (Sarwar et al., 2023). Our results highlight the
112 importance of long-term atmospheric observations to understand the net outcome of changing

113 global SO₂ and NO_x emissions on both the aerosol burden as well as air quality in distant
114 populations.

115

116 2. METHODS

117 **2.1 Aerosol Collection at the Barbados Atmospheric Chemistry Observatory:** Aerosols were
118 collected daily at the University of Miami’s Barbados Atmospheric Chemistry Observatory (UM
119 BACO: <https://baco.rsmas.miami.edu/>) located at Ragged Point, Barbados—the easternmost
120 promontory on the east coast of the island (13.16504N, 59.43207W). The site has been operated
121 by UM since 1971, and aerosol data has been used to document the long-range transport of African
122 dust to the Caribbean and the Americas carried by the easterly trade winds as it is the first landmass
123 encountered by African emissions transported across the Atlantic Ocean (Prospero et al., 2021).
124 The site is approximately 4500 km from the west coast of northern Africa, 3000 km from the east
125 coast of the U.S. and 6000 km from the west coast of the EU. Since 1989, aerosols have been
126 collected at the top of a 17-m sampling tower that stands atop a 30-m bluff (see Fig 1).

127

128 **Figure 1:** Photo of the Barbados Atmospheric Chemistry Observatory (BACO) including the 17-
129 m sampling tower, two shipping container laboratories, and an Advanced Global Atmospheric
130 Gases Experiment (AGAGE) laboratory.

131 A high-volume sampler pulls air at a nominal rate of 0.75 m³/minute across a 20cm x 25cm
132 Whatman-41 filter. The upper particle size limit for our filter collection method is approximately
133 80-100µm or greater based on the geometry of our sampling rain hat (Barkley et al., 2021). Filters
134 were collected daily (e.g., every 24 hours); however, a few multiday samples were also collected

135 that typically span 2 days. Mass collection efficiencies are 90% for sulfate, 95% for nitrate, and
136 99% for dust (Savoie & Prospero, 1982). Filters are then folded into quarters under a laminar flow
137 hood, placed in a clean Ziploc bag, and periodically shipped to UM for processing. To ensure that
138 local island emissions are not sampled, the sampling pump is only operational when the wind
139 blows directly from the ocean (from 335 degrees through N and E to 130 degrees) with speeds
140 greater than 1 m/s. A timer is used to record the “run time”, the total amount of time that the
141 sampling pumps are on during the sampling interval between filter changes. Data with a run time
142 less than 10% of the sampling interval are discarded to minimize the impact of low-speed and
143 flukey wind conditions that might carry aerosols from local sources. These deletions account for
144 less than 10% of all data collected over the record highlighting the steady easterly winds measured
145 at the site year-round. Procedural blanks are collected weekly by placing a Whatman-41 filter in
146 the filter cassette with the sampling pump off for 15 minutes then placing the filter in a clean Ziploc
147 bag; the blank is subsequently processed along with the daily filter samples.

148 This work focuses on aerosol measurements conducted over 1990-2011, a period that overlaps
149 with the implementation of more stringent air quality policies in the U.S. and Europe. Seasonal
150 trends are also shown where winter is represented by December (from the previous year), January,
151 February (DJF); spring is March, April, May (MAM); summer is June, July, August (JJA); fall is
152 September, October, November (SON). African dust peaks annually at BACO in JJA with episodic
153 transport in DJF and MAM in some years (Prospero & Mayol-Bracero, 2013; Quinn et al., 2022;
154 Royer et al., 2023). Trends presented in this work are derived from Theil-Sen regression.
155 Significance is calculated using paired samples t-tests.

156 **2.2 Quantification of Dust and Soluble Ion Mass Concentrations:** A one-quarter filter section
157 is extracted three times with a total volume of 20 mL of Milli-Q water to remove soluble material.
158 The extracted filter is placed in a combustion oven (500°C) overnight. The resulting ash is weighed
159 ($m_{filter\ ash}$) and subsequently corrected for the blank by subtracting the ash obtained from
160 performing the same technique on the procedural blank ($m_{procedural\ blank}$). The gross ash weight is
161 adjusted by a factor of 1.3 to account for losses during the extraction and combustion process
162 (Prospero, 1999; Zuidema et al., 2019). This corrected ash mass concentration is equated to
163 mineral dust concentrations present on the filter based on previous comparisons between filter ash
164 and concentrations of aluminum, a tracer for mineral dust (Prospero, 1999; Trapp et al., 2010).

$$165 \quad Dust = (m_{filter\ ash} - m_{procedural\ blank\ ash}) * 1.3 \quad (1)$$

166 The filtrate from the sample extraction process and procedural blanks are used to quantify
167 soluble ion concentrations. Anions (e.g., chloride (Cl⁻), nitrate (NO₃⁻), and sulfate (SO₄²⁻)) were
168 measured using ion chromatography (IC). Cations (sodium (Na⁺), potassium (K⁺), and calcium
169 (Ca²⁺)) were measured with a flame photometer after 2004 while flame atomic absorption
170 spectrophotometry was used prior to 2004 limiting cation analysis to sodium (Savoie, et al., 2002).
171 In addition to total soluble ion concentrations, we also report concentrations of non-sea salt (nss)
172 sulfate, which is a useful tracer of sulfur from marine biogenic and pollution emissions, and nss-
173 potassium, a tracer of biomass burning emissions (Andreae, 1983; Keene et al., 1986).
174 Concentrations of nss-SO₄²⁻ and nss-K⁺ are calculated using the following mass-based equations
175 and assuming that Na⁺ is a conservative tracer of sea spray aerosol:

176 $nss - SO_4^{2-} = [SO_4^{2-}] - (0.2517 * [Na^+])$ (2)

177 $nss - K^+ = [K^+] - (0.03595 * [Na^+])$ (3)

178 Filter samples with undetectable amounts of dust and soluble ions compared to procedural blanks
179 are removed from our analysis.

180 **2.3 EQUATES Model Products**

181 EPA's Air QUALity Time Series (EQUATES) Project uses the Community Multiscale Air Quality
182 (CMAQ) model, a 3-D chemical transport air quality model, to simulate air quality over a
183 continuous 2002-2019 period (Foley et al., 2023). CMAQ accounts for gas, cloud, and aerosol
184 chemistry, including processes such as in-cloud sulfate formation from the oxidation of SO₂.
185 EQUATES uses CMAQv5.3.2 (Appel et al., 2021) to model the Northern Hemisphere using 108-
186 km resolution and 44 vertical layers (Mathur et al., 2017). Meteorological data are derived from
187 the Weather Research and Forecasting model (WRFv.4.1.1). Emissions from outside the
188 contiguous U.S. and China are generated using the Hemispheric Transport of Air Pollution version
189 2 inventory for the year 2010 (HTAPv2.2) and are scaled to other years using the Community
190 Emissions Data System (CEDS) for the years 2002-2019. The Fire INventory from NCAR (FINN)
191 is used to generate biomass burning emissions (Wiedinmyer et al., 2011), lightning NO_x emissions
192 are derived from the Global Emissions IniAtive (GEIA), biogenic volatile organic compounds
193 (VOCs) are from MEGAN2, and soil NO_x is from CAMSv2.1.

194 In this study, EQUATES was used to better understand observed trends, namely in nss-sulfate,
195 after 2000 when observed concentrations unexpectedly increased. EQUATES also simulated
196 concentrations of locally emitted gases, including SO₂(g) and NO_x(g), which are not measured at
197 Ragged Point. The model product is not available for the years prior to 2000. The analysis focused
198 on dust, sea spray, nitrate, sulfate, and gaseous SO₂ and NO₂. In addition to anthropogenic sources
199 of SO₂, natural sources from the oxidation of DMS were included in model runs. Species
200 predictions were extracted from the lowest CMAQ model layer (~10m in thickness) for a source
201 area over the Atlantic Ocean to the east of the island from 59.5627°W to 56.5448°W longitude and
202 14.3989°N to 11.4566°N latitude (equivalent to 16 grid cells with one cell over Ragged Point and
203 the others to the east of the site). Simulated concentrations of aerosol sulfate, nitrate, calcium,
204 potassium, and sodium were obtained for fine mode aerosol (e.g., Aitken and accumulation mode,
205 PMF model outputs) and coarse mode aerosol (Total PM – PM_{2.5}, PMC model outputs). Previous
206 studies have shown that most of the aerosol mass at Ragged Point is below 10 μm diameter
207 (Prospero et al., 2001). Because aerosol filters collected at BACO capture total suspended
208 particulate matter, model outputs of fine and coarse mode aerosol concentrations were combined
209 (e.g., PMF + PMC model outputs) to give total aerosol mass concentrations of sulfate, nitrate,
210 sodium, potassium, and calcium. Total concentrations of nss-sulfate and nss-potassium were
211 calculated using Equations 2 and 3, respectively, and model outputs of total sodium mass
212 concentrations, total sulfate mass concentrations, and total potassium mass concentrations from
213 combined coarse and fine mode aerosol model outputs. We calculated concentrations of nss-
214 calcium, which has been shown to be a good tracer for mineral dust in Barbados (Savoie &
215 Prospero, 1980), and dust mass concentrations were then calculated using the average upper crustal

216 abundance of calcium in soil (an average of 4.1%) (Scheuvens et al., 2013; Taylor & McLennan,
217 1985) as shown in Equations 4 and 5.

$$218 \quad nss - Ca^{2+} = [Ca^{2+}] - (0.0376 * [Na^+]) \quad (4)$$

$$219 \quad Dust = [nss - Ca^{2+}] * 24.1 \quad (5)$$

220 We first assessed the ability of the EQUATES CMAQ simulations to capture trends in different
221 aerosol types observed at Ragged Point. Simulations of sodium and dust from EQUATES capture
222 seasonal and monthly observed trends in dust (see Fig S1 and S2 of the Supporting Information
223 (SI)). However, the model overpredicts sodium (Na^+ , a proxy for sea spray) by a factor of 3-4 (Fig
224 S1) and underpredicts dust by an average factor of ~ 7 . This low bias for dust in CMAQv5.3.2 is
225 consistent with CMAQ development that occurred after the EQUATES simulations were
226 complete. A bugfix to the online dust emissions module in CMAQv5.4 increases dust emissions
227 by a factor of 3-7 over the Sahara Desert and parts of Asia (see the CMAQv5.4 release notes for
228 further information; <https://www.epa.gov/cmaq/cmaq-documentation#release-notes>).

229 In addition to simulating observed aerosol concentrations, EQUATES was also used to examine
230 trends in gaseous indicators of anthropogenic and biomass burning emissions, oxidant
231 concentrations and oxidant ratios important for investigating changes in the oxidation efficiency
232 of locally emitted pollutant gases and the subsequent formation of nitrate and sulfate aerosol.
233 Further, EQUATES was used to investigate whether the oxidation efficiency of $SO_2(g)$ changed
234 during the 2002-2011 period. The oxidation ratio was calculated from Equation 6 (Shah et al.,
235 2018):

$$236 \quad Oxidation\ Ratio = \frac{nss - SO_4^{2-}}{nss - SO_4^{2-} + SO_2} \quad (6)$$

237 For this calculation, we used EQUATES model data for $SO_2(g)$ concentrations and filter-based
238 observations of nss-sulfate.

239 **2.4 HYSPLIT Back-trajectory Analysis**

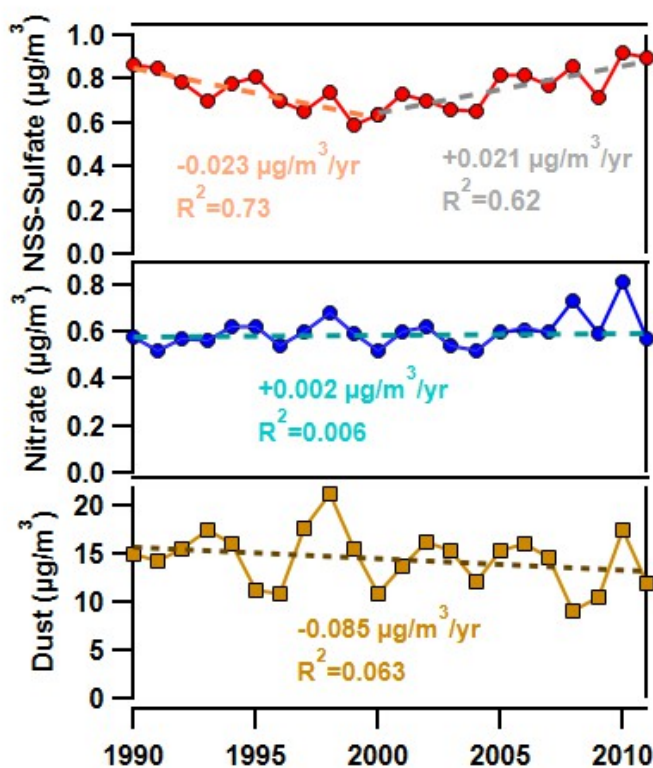

240 Air mass back-trajectory analysis was performed using NOAA's Hybrid Single-Particle
241 Lagrangian Integrated Trajectory (HYSPLIT) model (Draxler & Rolph, 2011; Rolph et al., 2017;
242 Stein et al., 2015). 13-day back-trajectories were initiated at heights of 500, 1000, and 2000-m to
243 capture both SAL and boundary layer transport. Frequency plots were also generated for the entire
244 sampling period (1990-2011) to illustrate seasonal differences in air mass transport and origin and
245 to explore any interannual variability. We used the global National Center for Environmental
246 Prediction (NCEP) reanalysis data that extends back to the beginning of our dataset in 1990
247 (Kramer et al., 2020). The finer resolution Global Data Assimilation System (GDAS) dataset (1°
248 resolution) was used to examine trends in air mass back trajectories in 2008, 2009, and 2010 when
249 transport conditions strongly impacted nitrate aerosol concentrations. We emphasize the
250 challenges in characterizing long-range transported aerosol due to the remoteness of the site, the
251 location of Barbados in the middle of the ocean, and the fact that air layers of smoke and dust
252 change in height during transport. As such, we caution against the over-reliance on HYSPLIT

253 analysis to extensively characterize long-range transport aerosol dynamics and instead use this
254 analysis to quantitatively describe major changes in transport patterns.

255 3. RESULTS

256 3.1 Measured Trends from 1990-2011 at Ragged Point.

257 Figure 2 shows yearly averaged mass concentrations of non-sea salt (nss) sulfate and nitrate
258 from 1990 through 2011. Nitrate concentrations are remarkably stable from 1990 to 2011
259 ($R^2=0.006$, $p>0.05$ (not significant)) with an average concentration of $0.59 \mu\text{g}/\text{m}^3 \pm 0.04 \mu\text{g}/\text{m}^3$.
260 However, two anomalous peaks in nitrate are observed in 2008 and 2010 with annual average
261 nitrate concentrations of 0.73 and $0.81 \mu\text{g}/\text{m}^3$, respectively. Similarly, dust mass concentrations
262 also show no trend over this period ($R^2=0.06$). In contrast, nss-sulfate decreases by 30% from an
263 average concentration of $0.84 \mu\text{g}/\text{m}^3$ starting in 1990 to a minimum of $0.64 \mu\text{g}/\text{m}^3$ in 2000 at a rate
264 of $-0.023 \mu\text{g}/\text{m}^3/\text{yr}$. Subsequently, sulfate gradually increased to $0.91 \mu\text{g}/\text{m}^3$ in 2010 and 0.90
265 $\mu\text{g}/\text{m}^3$ in 2011, maximums across the entire record. The trends in the yearly average mass
266 concentrations of nitrate and nss-sulfate are significantly different ($p\text{-value} < 0.005$), which can be
267 explained by either different sources or different rates of change for precursor NO_x and SO_2
268 emissions or different responses in nitrate and sulfate aerosol production to changing emissions of
269 NO_x and SO_2 as has been shown in North America (Shah et al., 2018; Vasilakos et al., 2018).

270
271 **Figure 2:** Yearly averages of non-sea salt sulfate (NSS Sulfate, red line, top panel), nitrate (middle panel,
272 blue line), and dust (bottom panel, brown line with squares) measured at Ragged Point, Barbados, from

273 1990-2011. Dashed lines show changes in NSS Sulfate pre-2000 (orange), post-2000 (gray line), nitrate
274 (teal line) without the spikes in 2008 and 2010 considered, and dust (brown line) over the 1990-2011
275 period.
276

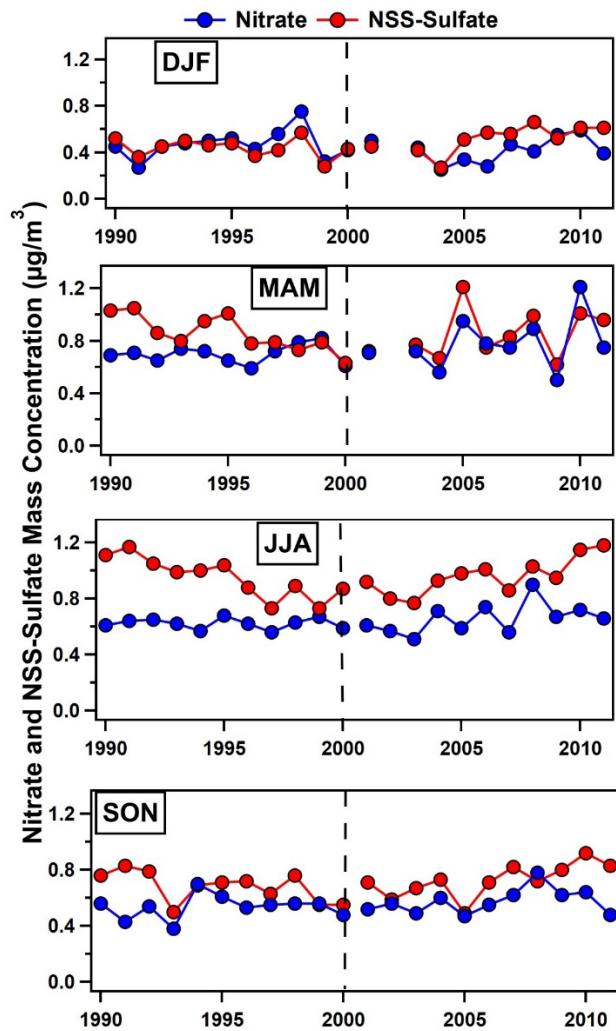

277 The Barbados yearly concentrations differ from long-term observations of aerosol and
278 precipitation chemistry measured at Tudor Hill, a site on the west coast of Bermuda, from 1989-
279 1997 and from 2006-2009 as part of the same program as that at Barbados (AEROCE) and using
280 the same protocols including sampling only when winds are over the ocean (Keene et al., 2014;
281 Savoie, et al., 2002). At the Bermuda site, the prevailing winds come from the West so that the
282 sampling sector extends from 180° through West to 330°. Aerosol nitrate is constant at both sites.
283 However, the nitrate annual mean at Bermuda is $\sim 1.05 \mu\text{g}/\text{m}^3$, roughly double the nitrate observed
284 at Ragged Point (Keene et al., 2014; Savoie, et al., 2002). Also, the decline in nss-sulfate observed
285 in Bermuda, from $\sim 2.59 \mu\text{g}/\text{m}^3$ in 1989 to $\sim 1.63 \mu\text{g}/\text{m}^3$ in 2009, is greater than our observations at
286 Ragged Point (Keene et al., 2014). Furthermore, sulfate aerosol in Bermuda declines over the
287 entire record and does not exhibit the same reversal in the 2000s that we observe at Barbados. The
288 difference in concentrations and trend in nss-sulfate observed at Ragged Point compared to that at
289 Bermuda is not surprising given that the Bermuda site is located 1100 km from the east coast of
290 the U.S. and is more directly influenced by anthropogenic emissions compared to Barbados, which
291 is more remote and could be influenced by a multitude of emission sources (Savoie, et al., 2002).
292 Also, the trend in nss-sulfate at Barbados differs from long-term observations measured at an
293 IMPROVE site in the Virgin Islands. Sulfate shows no trend from 2004-2021 (Hand et al., 2024).
294 The difference in trend in nss-sulfate between Ragged Point and the IMPROVE site in the U.S.
295 Virgin Islands is likely due to more influence from the U.S. and less influence from African
296 emissions. Further, the IMPROVE site does not follow a sector-controlled sampling protocol as
297 does the site in Barbados.

298 To assess whether annual trends in nss-sulfate and nitrate observed in Barbados are associated
299 with African aerosol transport conditions, annual average measured dust mass concentrations are
300 also shown in Fig 2 and show no appreciable increase or decrease from 1990-2011 ($R^2=0.06$).
301 Therefore, annual trends in nss-sulfate aerosol, which show a decrease from 1990-2000 and an
302 increase from 2000-2011, are not correlated with African dust mass concentrations ($R^2=0.001$).
303 This suggests that the increase in nss-sulfate after the year 2000 is not due to an increase in sulfate
304 associated with heterogeneous reactions between $\text{SO}_2(\text{g})$ and dust or to more favorable transport
305 from Africa. Nitrate aerosol, in contrast, is modestly correlated with dust ($R^2=0.30$). Comparing
306 seasonal nitrate and dust mass concentrations by year reveals tighter correlations between nitrate
307 and dust for DJF and MAM (0.46 and 0.4, respectively, see Fig S3). DJF and MAM are not the
308 peak dust transport seasons to the Caribbean, but they are the seasons that favor co-transport of
309 dust and biomass burning emissions from Sub-Saharan Africa north of the equator (Royer et al.,
310 2023). Transport of African smoke to Barbados has been shown to be associated with elevated
311 concentrations of nitrate, which likely explains the association between winter- and spring-time
312 dust and nitrate (Quinn et al., 2021; Savoie & Prospero, 1982).

313 **3.1.2 Seasonal Patterns in Air Mass Trajectories and Nitrate Concentrations**

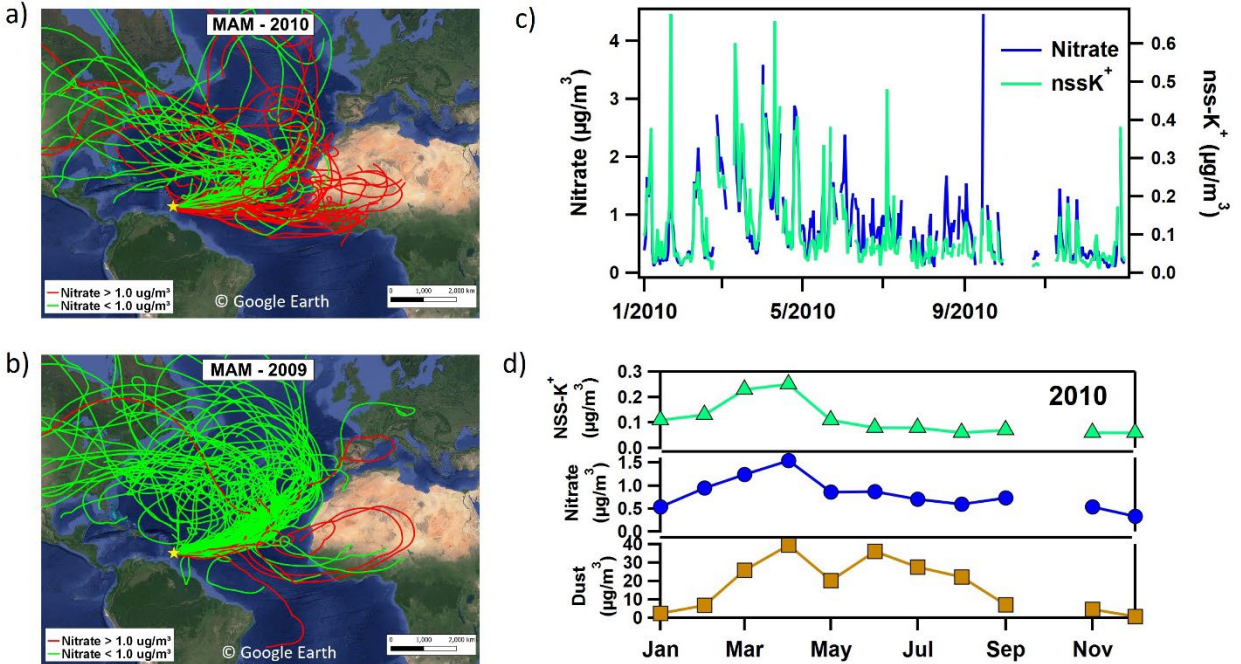

314 HYSPLIT air mass back-trajectories reveal similar seasonal patterns each year with
315 predominantly easterly transport to the site year-round (see Fig S4, which shows 5-day air mass
316 back-trajectory frequency plots for the entire 1990-2011 period and similar patterns year to year).
317 As has been documented in prior work (Prospero et al., 2021), the dominant transport pathways
318 are over the ocean and traversing the African continent. Some trajectories do intercept North
319 America and come close to Europe while few (<10%) air masses come near South America, which
320 is outside of our sampling sector. Air masses typically take 5-7 days to be transported from
321 northern Africa and longer than 7 days to intercept the E.U. and North America. From Figure S4,
322 DJF has some trajectories that intercept North America and some from the northern part of the
323 Atlantic Ocean toward Europe, MAM trajectories are easterly, JJA trajectories are from the west
324 coast of Africa, and SON trajectories are from the east with some from the southeast. We note that
325 the directional tendencies of the trajectories did not noticeably change in 2000, when the
326 concentration trends in nss-sulfate changed.

327 Figure 3 shows trends in nss-sulfate and nitrate during different seasons (e.g., DJF, MAM, JJA,
328 and SON). Increases in nitrate in 2008 are driven by high nitrate concentrations in JJA and SON
329 in 2008, with most of the increase in September, while high nitrate levels in 2010 are primarily
330 observed during MAM. In 2010, a transition from an El Niño to the strongest La Niña event on
331 record occurred (Wolter & Timlin, 2011; Zhang et al., 2019), and long-range transport from Africa
332 was anomalously high during the springtime as evidenced by high mass concentrations of dust in
333 the spring of 2010 (Zuidema et al., 2019). Daily air mass back-trajectories passed more frequently
334 over the African continent in MAM of 2010 compared to MAM of 2009 (26 vs 6 days) (Fig 4a
335 and b), and nitrate levels exceeded $1 \mu\text{g}/\text{m}^3$ on over half of those days when trajectories traversed
336 the northern African continent. Figure 4 focuses on trajectories initiated at 500-m height. If
337 trajectories initiated at 1000-m are also included, then transport over the North African continent
338 occurs on 36 days in MAM of 2010, i.e., 82% of days when nitrate levels exceeded $1 \mu\text{g}/\text{m}^3$.
339 However, during the summertime peak (JJA) in African dust transport in 2010, nitrate does not
340 show the same increase as dust despite frequent transport from northern Africa (see Fig 4d).
341 Further, Fig 4c and 4d compare daily and monthly mean concentrations of nitrate, dust, and non-
342 sea salt potassium (e.g., nss- K^+), which is a marker for biomass burning emissions (Andreae &
343 Merlet, 2001). Nitrate and nss- K^+ clearly track each other and are both elevated in the spring of
344 2010. Although biomass burning peaks in December and January while MAM is the tail end of
345 the burn season in northern Sub-Saharan Africa (Giglio et al., 2013; Roberts et al., 2009), the high
346 nitrate loadings observed in 2010 in spring are likely due to strongly favorable transport conditions
347 that transport both dust and smoke to Barbados during this year.

348

349 **Figure 3:** Average concentrations of nitrate (blue markers), and nss-sulfate (red markers) for winter (DJF),
 350 spring (MAM), summer (JJA), and fall (SON). The vertical black dashed line denotes the year 2000 when
 351 nss-sulfate trends shifted from decreasing to increasing.

352
 353 **Figure 4:** 13-day air mass back-trajectories initiated at 500-m for MAM a) 2010 and b) 2009. Back-
 354 trajectories labeled in green are for days where nitrate concentrations measured at Ragged Point were < 1
 355 $\mu\text{g}/\text{m}^3$ while trajectories labeled in red had nitrate > $1 \mu\text{g}/\text{m}^3$. Maps are from Google Earth (©Google Earth).
 356 c) Daily comparison of nitrate and non-sea salt potassium (nss- K^+), a biomass burning marker, show a tight
 357 correlation ($R^2=0.62$). d) Monthly average concentrations of dust (brown), nitrate (blue), and nss- K^+ (green)
 358 for 2010.

359 Similar to 2010, air mass back-trajectories traversed the African continent on just 40% of the
 360 days in JJA but 82% of days in September of 2008 with nitrate concentrations > $1 \mu\text{g}/\text{m}^3$ (Fig S5
 361 and Fig 5a). If trajectories initiated at the 1000-m level are included, then African transport occurs
 362 on 64% of days in JJA with nitrate concentrations > $1 \mu\text{g}/\text{m}^3$, consistent with higher level transport
 363 in JJA. In JJA, most of the air mass back-trajectories pass through Africa north of the equator.
 364 However, in September, trajectories take a more southerly route traversing near the South
 365 American coast and Sub-Saharan Africa south of the equator (Fig 5a). Figure 5b shows trajectories
 366 for September but in 2009, when fewer trajectories take a southerly route and nitrate concentrations
 367 rarely exceed $1 \mu\text{g}/\text{m}^3$. September is during the peak of the burn season in Sub-Saharan Africa
 368 south of the equator and also dovetails with strong smoke transport over the Atlantic Ocean due to
 369 the increased intensity of the African Easterly Jet (Adams et al., 2012; Adebisi & Zuidema, 2016;
 370 Zuidema et al., 2018). Air mass back-trajectories in September from Sub-Saharan Africa south of
 371 the equator to our measurement sites in Barbados and Cayenne have been linked with African
 372 smoke transport (Barkley et al., 2019; Trapp et al., 2010) further suggesting a link between
 373 elevated concentrations of nitrate measured at Barbados with transported African smoke. Biomass
 374 burning in the Amazon also peaks in SON (Adams et al., 2012) and could also explain some of
 375 the increase in nitrate in this season in 2008.

376
 377 **Figure 5:** 13-day air mass back-trajectories initiated at 500-m for September a) 2008 and b) 2009. Back-
 378 trajectories labeled in green are for days when nitrate concentrations measured at Ragged Point were < 1
 379 $\mu\text{g}/\text{m}^3$ while trajectories labeled in red had nitrate > 1 $\mu\text{g}/\text{m}^3$. The maps are from Google Earth (©Google
 380 Earth).

381

382 3.1.3 Trends in Non-Sea Salt-Sulfate and Emissions of SO_2

383 Figure 3 reveals that the decrease in sulfate and subsequent increase are measured during most
 384 seasons. Table 1 further provides correlation coefficients and the rate of change in either nitrate or
 385 sulfate in $\mu\text{g m}^{-3}\text{yr}^{-1}$ for data collected pre- and post-2000 when the trend in nss-sulfate changed.
 386 Pre-2000, nss-sulfate shows a consistent decline in each season with the weakest decline in winter
 387 and the strongest reduction measured in JJA at $-0.036 \mu\text{g m}^{-3}\text{yr}^{-1}$ ($R^2=0.72$, Table 1). Post-2000,
 388 nss-sulfate increased during every season with comparable increases in every season. In JJA, nss-
 389 sulfate increased at $+0.028 \mu\text{g m}^{-3}\text{yr}^{-1}$ ($R^2=0.61$, Table 1). In contrast, nitrate shows no trend (e.g.,
 390 $R^2<0.2$) in any season except a slight increase of $+0.012 \mu\text{g m}^{-3}\text{yr}^{-1}$ post-2000 in JJA. Unlike nitrate
 391 which showed intermittent spikes associated with increased biomass burning aerosol transport

392 periods, the persistent increases in nss-sulfate observed during all seasons more likely reflect either
 393 increased emissions or more efficient oxidation of SO₂.

394 **Table 1:** Seasonal trends in nitrate and nss-sulfate shown pre- and post-2000. The rate of change in μg/m³/yr
 395 is shown and the correlation coefficient is also included. Values of R²<0.2 were denoted as having
 396 “No Trend”. DJF represents winter, MAM represents spring, JJA represents summer, and SON
 397 represents fall.

Season	Compound	Pre-2000 Rate of Change (μg/m ³ /yr)	Post-2000 Rate of Change (ug/m ³ /yr)
DJF	Nitrate	-0.0005 (R2=0.05, No Trend)	+0.013 (R2=0.07, No Trend)
	NSS-Sulfate	-0.0070 (R2=0.05, No Trend)	+0.035 (R2=0.48)
MAM	Nitrate	+0.0037 (R2=0.01, No Trend)	+0.028 (R2=0.08, No Trend)
	NSS-Sulfate	-0.034 (R2=0.64)	+0.033 (R2=0.09, No Trend)
JJA	Nitrate	-0.002 (R2=0.02, No Trend)	+0.012 (R2=0.21)
	NSS-Sulfate	-0.036 (R2=0.72)	+0.028 (R2=0.61)
SON	Nitrate	+0.0003 (R2=0.02, No Trend)	+0.013 (R2=0.13, No Trend)
	NSS-Sulfate	-0.023 (R2=0.29)	+0.026 (R2=0.44)

398
 399
 400 Figure 6 compares yearly trends in Ragged Point nss-sulfate along with SO₂ emissions reported
 401 from the Community Emissions Data System (CEDS) (McDuffie et al., 2020). We focus on the
 402 most likely sources to impact Ragged Point: the U.S., EU, and Africa. A similar figure comparing
 403 nitrate concentrations measured at Ragged Point and nitrogen dioxide (NO₂) emissions from
 404 CEDS can be found in the SI (Fig S6). Our near-constant nitrate mass concentrations do not match
 405 the decline in NO₂ observed in the EU and U.S. and the increase in NO₂ in Africa. In contrast,
 406 decreases in nss-sulfate observed from 1990-2000 at Ragged Point closely follow the 32% and
 407 58% reductions of SO₂ emissions in the U.S. and Europe, respectively (Fig 6) (Aas et al., 2019;
 408 Hand et al., 2012; McDuffie et al., 2020; Rafaj et al., 2015; Yang et al., 2020). Our finding that
 409 changing SO₂ emissions in the EU and U.S. is reflected in our record at Ragged Point agrees with
 410 previous work examining both anthropogenic and biogenic sulfate (Savoie et al., 2002). Figure 6
 411 also compares the trends of nss-sulfate observed at Ragged Point to increasing emissions of SO₂
 412 from Africa (McDuffie et al., 2020). Before 2000, SO₂ emissions from Africa oscillated around
 413 4.44±0.19 Tg S/yr but show no consistent trend (R²=0.027). However, after 2000, emissions of
 414 SO₂ from Africa steadily increase by 37% from 2000-2011 (4.33 Tg S/yr in 2000 and 5.95 Tg S/yr
 415 in 2011, R²=0.88). The rate of increase in SO₂ is on par with the rate of increase in nss-sulfate of
 416 29% observed in Barbados suggesting that anthropogenic emissions from Africa are affecting the
 417 nss-sulfate trends measured in Barbados.

418 We next utilized the CMAQ model results from EQUATES to gain further insight into the
 419 observed recovery of nss-sulfate (post-2000). We first note that EQUATES also predicts an
 420 increase in SO₂ emissions from northern hemispheric Africa after 2002 (see Figure S7). However,
 421 we use EQUATES to determine if other factors such as changes in the oxidation efficiency of
 422 locally emitted SO₂ and meteorological changes affected our observations.

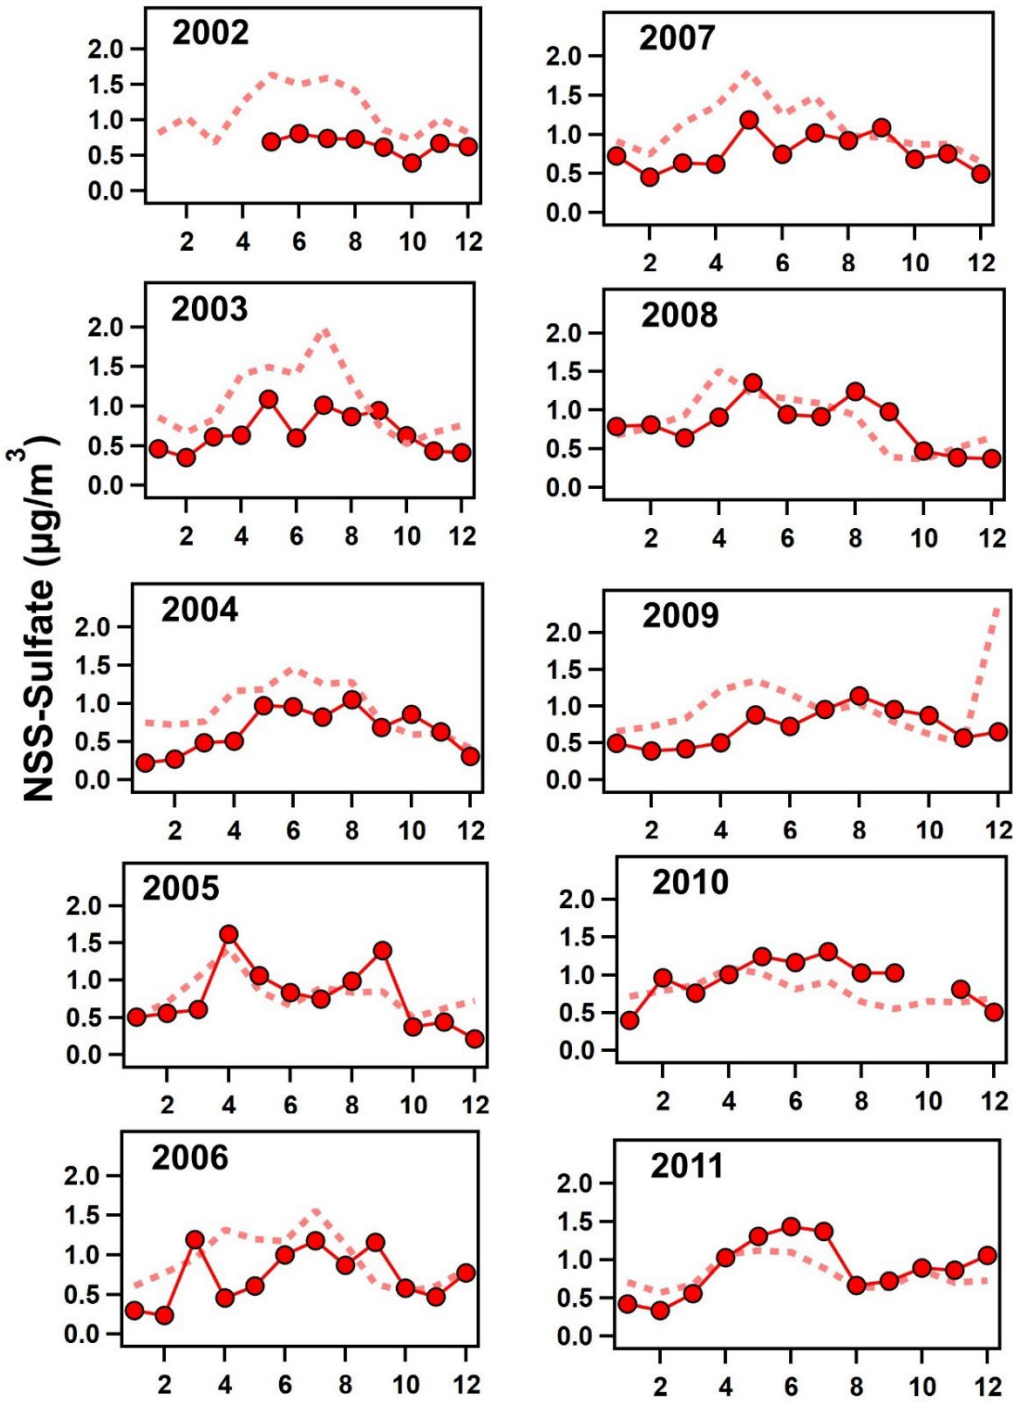

423

424 **Figure 6:** Percent changes in NSS-Sulfate mass concentrations measured at Ragged Point from 1990-2011
 425 are shown in red. NSS-Sulfate mass decreases from 0.87 $\mu\text{g}/\text{m}^3$ in 1990 to 0.64 $\mu\text{g}/\text{m}^3$ in 2000 and
 426 subsequently increases to 0.90 $\mu\text{g}/\text{m}^3$ in 2011. The data are normalized to the maximum NSS-sulfate mass
 427 concentration, 0.92 $\mu\text{g}/\text{m}^3$ measured in 2010. The percent changes in emissions of sulfur dioxide (SO₂)
 428 from the CEDS emissions inventory from McDuffie et al., 2020 are included for comparison. Decreasing
 429 emissions of SO₂ from the U.S. and EU are shown in blue lines. U.S. SO₂ reduces from 21.12 to 5.85 Tg
 430 S/yr and EU SO₂ reduces from 28.06 to 7.74 Tg S/yr. Percentages are calculated by normalizing to the
 431 maximum values in SO₂ emissions observed in 1990 for both the U.S. and EU. SO₂ emissions from Africa
 432 increased from 4.13 to 5.95 Tg S/yr; they are normalized to the maximum SO₂ emissions observed in 1990
 433 at 6.16 Tg S/yr.

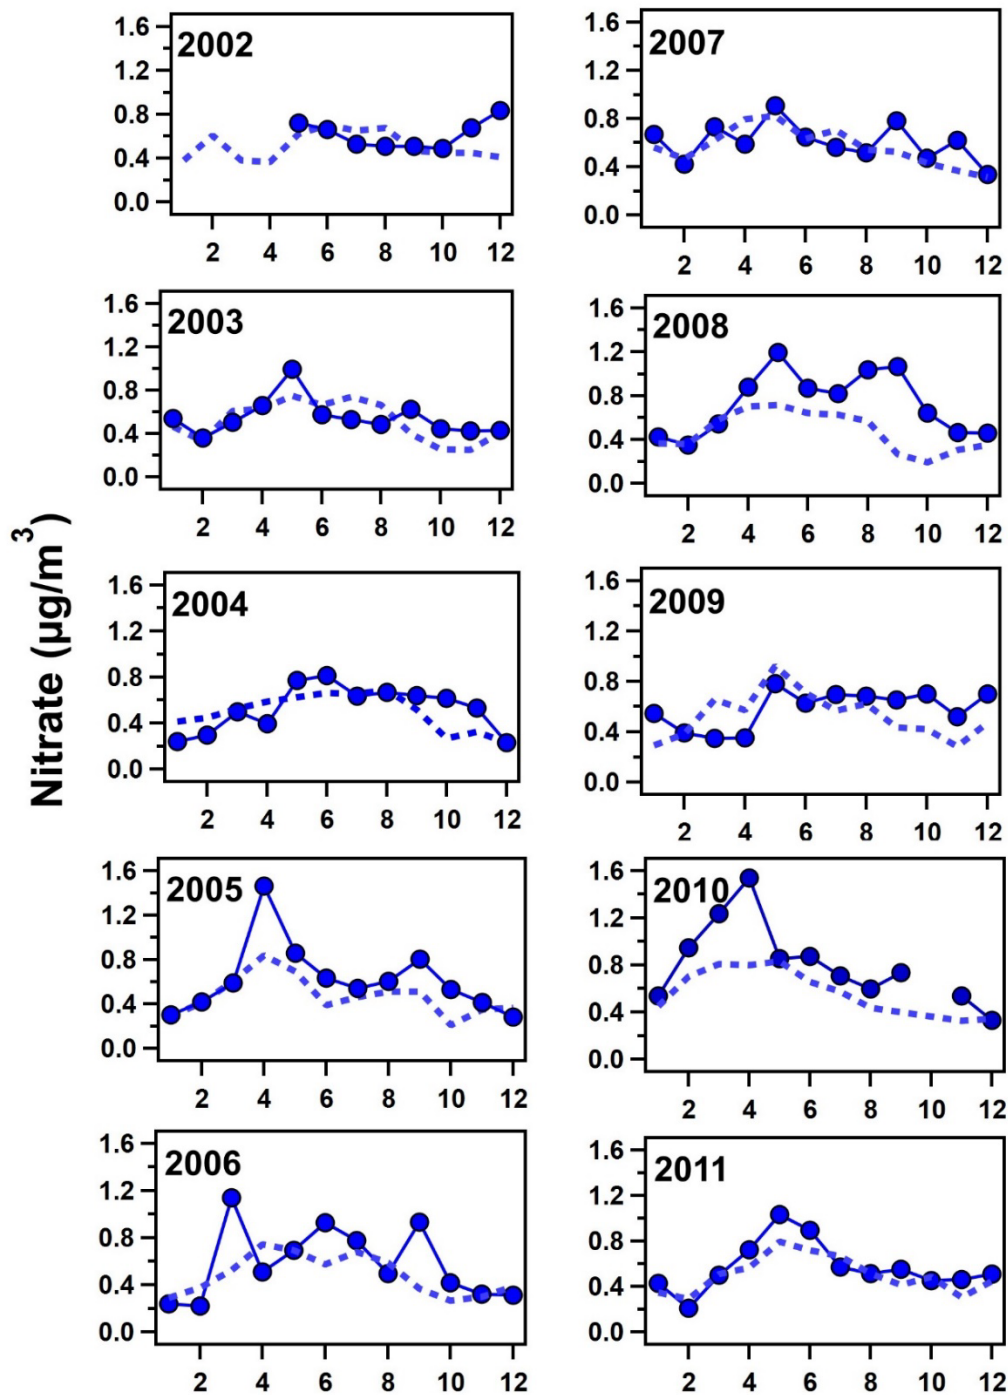

434

435 3.2 Comparison of Measured and Modeled Trends of Nitrate and Sulfate Aerosol

436 Monthly concentrations of simulated nss-sulfate and nitrate (for both the fine and coarse
 437 mode combined) were compared with mass concentrations measured on filters collected at Ragged
 438 Point (see Fig 7 and 8, respectively). The model simulates similar concentrations both at Ragged
 439 Point and the area to the east of the site implying that emissions on Barbados are minimal.
 440 EQUATES predicts nitrate concentrations in fine and coarse aerosol sizes. A greater proportion of
 441 fine nitrate is predicted in DJF (40% of the total modeled nitrate) and MAM (26% of the total
 442 modeled nitrate) during all years compared to JJA and SON (18% of the total modeled nitrate for
 443 both seasons, see Fig S8). This seasonality is likely due to increased contributions of nitrate from
 444 fine biomass-burning aerosol produced in Sub-Saharan Africa north of the equator in winter and
 445 spring. This point is highlighted in MAM of 2010 when the amount of modeled fine nitrate was
 446 elevated (35% of total modeled nitrate). Nss-sulfate is predicted to be almost exclusively in fine
 447 mode aerosol. While previous observations have shown that nss-sulfate dominates the fine mode
 448 in Barbados, some of the nss-sulfate is also present in the coarse mode likely due to heterogeneous
 449 reactions between SO₂ and coarse sea spray and mineral dust aerosols (Adams et al., 2005;
 450 Alexander et al., 2005; Li-Jones & Prospero, 1998). EQUATES does not seem to be capturing this
 451 minor yet important budget of nss-sulfate.

452
 453 **Figure 7:** Monthly averages of non-sea salt sulfate (nss-sulfate) mass concentrations measured at Barbados
 454 on filters (solid red line with red circles) compared to monthly averages of NSS-sulfate calculated from
 455 EQUATES model simulations of combined fine and coarse mode sodium (Na) and sulfate using equation
 456 2 (dashed red line) for 2002-2011.

457

458 **Figure 8:** Monthly averages of nitrate mass concentrations measured in Barbados on filters (solid blue line
 459 with blue circles) compared to monthly averages of combined fine and coarse mode nitrate calculated from
 460 EQUATES model simulations (dashed blue line) for 2002-2011.

461

462

463 To assess the performance of the model compared to our observations, we calculated the
464 normalized mean bias (NMB) and Pearson correlation coefficient (r) for monthly averaged
465 concentrations of nss-sulfate and nitrate (see Table S1 (Boylan & Russell, 2006)). Additional
466 calculations of the mean bias (MB) and root-mean-square error (RMSE) can also be found in Table
467 S1 of the SI. NMB for nitrate was generally within $\pm 20\%$, better than predictions of nitrate within
468 the U.S. (Kelly et al., 2019), except for 2005 (-24.18%) as well as 2008 (-35.06%) and 2010 (-
469 28.72%) when the model underpredicted measurements likely due to the elevated African smoke
470 transport events. The model overpredicts nss-sulfate in the earlier years (2002-2007) then
471 converges closer to our measurements at Ragged Point after 2008 as shown in Fig 7. Because
472 trends in sea salt (e.g., sodium from EQUATES, Figure S1) show a constant high bias in all years,
473 the overprediction of nss-sulfate reflects biases in sources of sulfate (other than sea spray) or biases
474 in the conversion of SO_2 to sulfate. Further, the NMB for nss-sulfate also reflects the model
475 overprediction of nss-sulfate as high values are observed in 2002 (+81.45%) then the model begins
476 to fall within $\pm 20\%$ starting in 2008 (see Table S1). As such, trends in nss-sulfate simulated by
477 EQUATES show a decrease over time rather than an increase post-2000 (see Fig S9). The decrease
478 in EQUATES simulations of nss-sulfate post-2000 compared to the increase observed in Barbados
479 could be related to a changing bias over time. For example, recent predictions for 2019 indicate
480 CMAQ underpredicts sulfate by about 50% in the eastern U.S. (45% underestimate across entire
481 U.S.) (Vannucci et al., 2024). Previous simulations for 2002 and 2016 indicated more modest
482 normalized mean biases of 20% or less (Appel et al., 2021; Sarwar et al., 2011). As a result,
483 EQUATES may simulate a stronger decline in transported U.S. sulfate over 2002-2019 than
484 observations indicate. This overestimate in declining sulfate in the U.S. may mask trends
485 (including stronger increases in sulfate) in other regions. Pearson correlation coefficients range
486 from -0.22 to 0.88 by year for nitrate with a mean of 0.54. The poorest correlation (-0.22) occurs
487 for 2002 when Barbados filter measurements were unavailable from January until May. For nss-
488 sulfate, r ranges from 0.23 to 0.82 by year with a mean of 0.59. The greatest variation between the
489 model and measurements is for 2009 (see Fig 7), which was also the year that had an erroneously
490 high model concentration of sea spray aerosol in winter. Overall, the model is capturing both the
491 magnitude and seasonal and interannual variation of nss-sulfate and nitrate at our remote location
492 in the tropical North Atlantic.

493 3.2.1 Using EQUATES to Determine Contributions to Aerosol Sulfate

494 Figure 9 shows a decrease in SO_2 simulated by EQUATES within the modeled grid space
495 over Ragged Point and to the east of the site. Consistent with a predicted decrease in SO_2 and the
496 observed increase in nss-sulfate, the oxidation ratio of SO_2 increases in the region near Barbados.
497 We note that because the lifetime of SO_2 is predicted to be ~ 20 hours and as much as ~ 40 hours
498 depending on the latitude of the source of SO_2 and the season (Green et al., 2019; Lee et al., 2011),
499 our oxidation ratio estimates here are most relevant for local emissions, including sulfur emitted
500 from marine phytoplankton (e.g., DMS). However, prior measurements at Bermuda suggest a
501 longer lifetime for long-range transported SO_2 compared to local oceanic emissions from DMS,
502 which are subject to strong condensational losses to sea spray in the marine boundary layer (Keene
503 et al., 2014). As such, long-range transported sources from Africa, the U.S., and EU have likely
504 been converted to sulfate upwind of Barbados and SO_2 concentrations shown here most likely

505 reflect oceanic sources though some contribution from long-range transport is also possible.
 506 Locally emitted hydrogen peroxide (H₂O₂) concentrations also increased over this period (see Fig
 507 10) and is likely linked to decreases in locally emitted SO₂, which is a major sink of H₂O₂ during
 508 the aqueous phase formation of sulfate (Manktelow et al., 2007). We note that the predicted
 509 oxidation ratios are likely an overestimate because EQUATES overpredicts nss-sulfate compared
 510 to observations and the overprediction decreases with time. As such, the increase in the oxidation
 511 ratio, which is small from Figure 9, likely has a minimal influence on the observed trends in nss-
 512 sulfate observed at our site.

513
 514 **Figure 9:** Annual trends in locally emitted sulfur dioxide (SO₂) simulated by the EQUATES model and the
 515 calculated oxidation ratio at Ragged Point. Linear fits and corresponding correlation coefficients are also
 516 shown.
 517

519 **Figure 10:** Annual trends in select gas phase species including benzene (pink trace, bottom panel), carbon
520 monoxide (CO) (orange trace, middle panel), and hydrogen peroxide (H₂O₂) (purple trace, top panel)
521 simulated by the EQUATES model at Ragged Point. Linear fits and corresponding correlation coefficients
522 are also shown.
523

524 Changes in biomass burning, anthropogenic emissions, oxidant concentrations, and
525 meteorological parameters were also investigated using EQUATES. Fine mode non-sea salt
526 potassium (nss-K⁺) was used as our tracer for smoke emissions. We used EQUATES data rather
527 than our nss-K⁺ observations, which were non-existent for most years from 2002-2011. Also, our
528 measurements included total (i.e., fine and coarse mode) nss-K⁺ including contributions from
529 African dust (Savoie & Prospero, 1980). EQUATES simulations of nss-K⁺ were a factor of 2-3
530 higher than our measurements except for the dust and smoke transport event that occurred in MAM
531 of 2010. No significant increase in simulated nss-K⁺ was estimated (Fig S10). Meteorological
532 parameters (temperature, relative humidity (RH), wind speed, wind direction) were constant over
533 time showing no shift in rainfall, winds, temperature, or RH (Fig S10). Concentrations of the
534 hydroxyl radical ([•]OH) did not show a significant change from 2002-2011 (Fig S10). EQUATES
535 concentrations of benzene (a tracer for fossil fuel combustion) and carbon monoxide (CO, a tracer
536 for combustion from fossil fuels and biomass burning) both increased modestly from 2002-2011
537 (Fig 10). Our results suggest that an increase in the oxidation efficiency of locally emitted SO₂ to
538 sulfate may contribute to the increase of nss-sulfate post-2000, but the contribution is likely small
539 compared to long-range transported sulfate.

540 4. DISCUSSION & CONCLUSIONS

541 Our 21-year record (1990-2011) of nitrate and nss-sulfate aerosol shows two distinct trends
542 over the tropical North Atlantic. Nitrate shows no significant change other than two spikes in JJA
543 and September of 2008 and MAM of 2010. Variations in winter- and spring-time dust transport
544 explained interannual oscillations in nitrate concentrations while increased transport of smoke
545 from Sub-Saharan Africa north of the equator in MAM 2010 and from south of the equator and,
546 possibly, South America in September 2008 caused the increased levels of nitrate observed in
547 those years. Nitrate has been shown to be enhanced in smoke by up to 5-fold over background due
548 to high emissions of NO_x that are rapidly converted to nitrate (Adon et al., 2010; Hickman et al.,
549 2021; Perron et al., 2022; Schlosser et al., 2017). Notably, nitrate was not enhanced in JJA of 2010
550 even though high quantities of dust were transported to Barbados. We speculate that the lack of
551 enhanced nitrate during summer of 2010 is due to the lack of nitrate contribution from African
552 smoke emissions during this season. This finding in addition to our observations of enhanced
553 nitrate associated with dust in DJF and MAM suggests that the nitrate associated with African
554 aerosol transport primarily originates from NO_x emissions from African wildfires that are rapidly
555 converted to nitrate prior to transport.

556 In contrast to the relatively flat trend in aerosol nitrate, nss-sulfate decreased by 30% from
557 1990-2000 then increased from 2000-2011, recovering to concentrations measured in the early
558 1990s. Reductions in nss-sulfate observed in Barbados are most likely due to decreased emissions
559 of SO₂ in the U.S. and EU due to clean air policies implemented via technologies such as flue-gas
560 desulfurization devices installed in power plants (Aas et al., 2019; Kharol et al., 2017; Smith et al.,

561 2011). Thus, our results highlight that regulations aimed to improve national and regional air
562 quality also impact more distant locations such as the remote North Atlantic marine boundary layer
563 and Caribbean.

564 As shown in Fig 6, increases in SO₂ in Africa, namely from anthropogenic sources, are the
565 most probable cause for the increase in nss-sulfate levels from 2000-2011 in Barbados.
566 Simulations from both CEDS and EQUATES reveal an increase in anthropogenic emissions of
567 SO₂. Further evidence for this speculation stems from the lack of change in air mass back
568 trajectories before and after 2000, suggesting that emissions rather than meteorological trends are
569 driving our observed patterns in nss-sulfate. Industrial contributions of sulfate from oil refineries,
570 coal fired power plants, and fertilizer plants along the north and northwestern coast of Africa were
571 also observed in the Cape Verde Islands (Salvador et al., 2015). Anthropogenic sources of SO₂ in
572 Africa include emissions from electricity generation, diesel combustion and transportation
573 (Assamoi & Liousse, 2010; Keita et al., 2021; Liousse et al., 2014), refineries, gas flaring, and
574 smelting (Dolumbia et al., 2019; Osuji & Awwiri, 2005). Levels of pollution in African cities are
575 on par with Asian megacities with the largest rate of increases in SO₂ observed in western Africa
576 (Adon et al., 2016; Hopkins et al., 2009; Liousse et al., 2014; Val et al., 2013). The industrial sector
577 in the Highveld region of South Africa also shows some of the highest increases in SO₂ with
578 observed increases starting in 1980 due to an increase in the number of coal-fired power plants
579 arising from an increased demand for electricity (Keita et al., 2021; Liousse et al., 2014;
580 Shikwambana et al., 2020). From 1990-2011, the CEDS inventory shows the largest increase in
581 SO₂ emissions in Africa starting in 2000, coincident with the increase in nss-sulfate observed at
582 our site (see Figure 6). The emissions inventory for Africa is also likely underestimated due to a
583 lack of measurements (McDuffie et al., 2020). Therefore, we speculate that anthropogenic SO₂
584 emissions are likely higher than shown from the CEDS model and are driving the observed
585 increases in nss-sulfate in Barbados.

586 In addition to sources of SO₂ within Africa, SO₂ emissions from other nearby countries and
587 regions have been shown to be exported to Africa (Koch et al., 2007). In particular, SO₂ emissions
588 in India have rapidly risen and overtaken China as the largest emitter of SO₂ (Li et al., 2017) while
589 remote sensing observations have highlighted that SO₂ emitted from oil and gas operations in the
590 Persian Gulf have been greatly underestimated in emissions inventories (McLinden et al., 2016).
591 While it is possible that these two regions may also contribute to the increase in nss-sulfate
592 observed at our measurement site, we can only speculate of their importance to the remote North
593 Atlantic marine boundary layer.

594 While some of the increases in nss-sulfate after 2000 could be due, in part, to marine
595 biogenic, shipping, biomass burning, and volcanic emissions, their contributions are likely not the
596 dominant cause of the observed trends. Marine biogenic sulfate is estimated to contribute up to
597 50% of nss-sulfate at Ragged Point during non-dust transport conditions (Li-Jones & Prospero,
598 1998; Royer et al., 2023; Savoie et al., 2002). However, our predictions of nss-sulfate and SO₂
599 concentrations with EQUATES includes DMS chemistry that does not explain our observed
600 trends. In fact, locally emitted SO₂, most likely from the ocean, is simulated to be decreasing from
601 2002-2011. Further, while recent studies have shown links between climate change and increased

602 DMS emissions at high latitudes, these trends have not been demonstrated at lower latitudes.
603 Instead, DMS is predicted to decrease with increasing temperature at low latitudes due to
604 stratification (Kloster et al., 2007) and increasing ocean acidification (Zhao et al., 2024) while a
605 recent modeling study, factoring in changes in phytoplankton dynamics, found that DMS
606 emissions have not appreciably changed from the preindustrial to the present-day (Wang et al.,
607 2018). As such, DMS emissions do contribute to the sulfate burden but likely do not explain the
608 recent increases in sulfate, which would also agree with findings in Bermuda where changes in the
609 nss-sulfate burden were explained by anthropogenic rather than biogenic emissions (Keene et al.,
610 2014). Shipping emissions likely do not explain our trends in nss-sulfate because Barbados is
611 somewhat isolated from proximal shipping impacts—heavy shipping is concentrated in the
612 Caribbean west of Barbados and along the north coast of South America (Czermański et al., 2021).
613 Biomass burning has declined in northern Sub-Saharan Africa starting in the early 2000s (Andela
614 et al., 2017; Andela & Van Der Werf, 2014; Zubkova et al., 2019). Further, increased nss-sulfate
615 has been observed year-round rather than just during the main burn seasons, suggesting that this
616 source alone is likely not responsible for the major increases in nss-sulfate observed at our site.
617 The largest natural source of SO₂ in Africa is volcanic emissions from Mount Nyiragongo in the
618 Goma region of the Democratic Republic of Congo, which has been shown to impact sulfate
619 aerosol at the Amazon Tall Tower Observatory (ATTO) in Brazil (Opio et al., 2021; Saturno et
620 al., 2018). Volcanic emissions likely do impact nss-sulfate measured in Barbados but there is no
621 evidence that emissions from this source are increasing. These lines of evidence further support an
622 anthropogenic source as the cause of the increase in nss-sulfate observed in Barbados.

623 In addition to increased sulfate transported from Africa, the oxidation ratio was simulated
624 to increase from 2002-2011, which would more efficiently convert locally emitted SO₂ to sulfate
625 and may represent a minor addition to the budget of nss-sulfate. Further, concentrations of H₂O₂
626 increased in the post-2000 period indicating a potential increase in the efficiency of aqueous phase
627 oxidation. We would expect that even if the total burden of SO₂ has been reduced globally
628 (McDuffie et al., 2020; Smith et al., 2011), SO₂ emitted locally is more efficiently converted to
629 sulfate due to greater availability of oxidants at lower latitudes (Manktelow et al., 2007). It is
630 important to note, however, that the oxidation ratio calculated is most appropriate for accounting
631 for changing oxidation efficiencies of SO₂ and sulfate formation near the site, and the oxidation
632 ratio does not account for changes in the oxidation efficiency of already formed sulfate aerosol
633 that has been transported to the site. For example, SO₂ emitted from Africa is likely already
634 oxidized to sulfate prior to being transported to our site.

635 One question that persists is why nitrate did not increase from 2000-2011 alongside the
636 increase in nss-sulfate? One possible explanation is a combination of reduced NO_x from smoke
637 concurrent with increased dust and smoke transport that offset any changes in nitrate other than
638 the observed spikes in 2008 and 2010. In the 2000s, biomass burning emissions declined in
639 northern equatorial Africa due to a combination of increased precipitation in DJF associated with
640 a shift from more frequent El Niño events in the 1990s to more frequent La Niña events in the
641 2000s and land use practices converting tropical savanna to cropland (Andela et al., 2017; Andela
642 & Van Der Werf, 2014; Hickman et al., 2021; Zubkova et al., 2019). The recently updated
643 Barbados dust record highlights that dust is being transported to the Caribbean earlier in the year

644 and arriving more frequently in spring (Zuidema et al., 2019), which would increase the transport
645 of biomass burning emissions and associated nitrate to the Caribbean and remote North Atlantic,
646 which may effectively cancel out the impact of reduced smoke emissions.

647 The Ragged Point site in Barbados has historically been associated with research on
648 African dust transport (Prospero et al., 2021). However, this work highlights that the site is also
649 an excellent indicator of long-term and large-scale changes in emissions and the impact of air
650 quality policies or the lack of them or poor compliance to them. Looking forward, building upon
651 the existing time series of nitrate and sulfate aerosol while also expanding the measurement
652 capabilities at Ragged Point to incorporate measurements of metals, which will increase our ability
653 to apportion aerosol sources, and carbonaceous aerosol will provide needed insight into the impact
654 of anthropogenic and biomass burning on sulfate and nitrate burdens over the remote North
655 Atlantic that complement recent work performed in the South Atlantic (Zuidema et al., 2016,
656 2018).

657
658 **Data Availability Statement:** Measured nitrate, nss-sulfate, and sea salt concentrations can be
659 found on the University of Miami's repository in addition to EQUATES simulations of nitrate,
660 nss-sulfate, sea salt, gaseous tracers (SO₂, benzene, CO, H₂O₂) and meteorological parameters
661 (<https://doi.org/10.17604/k869-9c71>). Dust mass concentrations from Barbados can be found in
662 the data repository for Zuidema et al., 2019. EQUATES data is available via the Remote Sensing
663 Information Gateway (RSIG): <https://www.epa.gov/hesc/remote-sensing-information-gateway>.

664
665 **Author Contribution:** CJG analyzed measurement and model data and wrote the manuscript.
666 JMP, LC, EB, PS collected data, operated the site, and analyzed filters for dust, sea salt, sulfate
667 and nitrate mass concentrations. KF and HOTP provided EQUATES model simulations and helped
668 with their interpretation. JAC performed HYSPLIT analysis. All authors read and edited the
669 manuscript.

670
671 **Competing Interests:** The authors declare that they have no conflict of interest.

672
673 **Disclaimer:** The views expressed in this paper are those of the authors and do not necessarily
674 represent the views or policies of the US Environmental Protection Agency.

675
676 **Acknowledgements:** C.J.G. acknowledges funding from an NSF CAREER grant (1944958) and
677 an NSF MRI grant (2214875). The authors acknowledge the NOAA Air Resources Laboratory
678 (ARL) for the provision of the HYSPLIT transport and dispersion model and READY website
679 (<https://www.ready.noaa.gov/HYSPLIT.php>). The authors acknowledge the family of H.C.
680 Manning and the Herbert C. Manning Trust for providing access to their land at Ragged Point. The

681 authors acknowledge the contributions of Dennis L. Savoie for his efforts to measure soluble ions
682 and dust mass concentrations from the AEROCE network. We thank Wyatt Appel, Kathleen Fahey,
683 and Jeff Willison for helpful comments that improved the quality of this manuscript. We thank
684 two anonymous reviewers for thoughtful reviews that improved this manuscript.
