10 **Abstract**

11 Volatile organic compounds (VOCs) are often subject to synergistic oxidation by different oxidants
12 in the atmosphere. However, the exact synergistic oxidation mechanism of atmospheric VOCs and
13 its role in particle formation remain poorly understood. In particular, the reaction kinetics of the key
14 reactive intermediates, organic peroxy radicals (RO₂), during synergistic oxidation is rarely studied.
15 Here, we conducted a combined experimental and kinetic modelling study of the nocturnal
16 synergistic oxidation of α -pinene (the most abundant monoterpene) by O₃ and NO₃ radicals as well
17 as its influences on the formation of highly oxygenated organic molecules (HOMs) and particles.
18 We find that in the synergistic O₃ + NO₃ regime, where OH radicals are abundantly formed via
19 decomposition of ozonolysis-derived Criegee intermediates, the production of C_xH_yO_z-HOMs is
20 substantially suppressed compared to that in the O₃-only regime, mainly because of the termination
21 of α -pinene RO₂ derived from ozonolysis and OH oxidation by those arising from NO₃ oxidation.
22 Measurement-model comparisons further reveal that the termination reactions between ozonolysis-
23 and NO₃-derived RO₂ are on average 10 – 100 times more efficient than those of OH- and NO₃-
24 derived RO₂. Despite a strong production of organic nitrates in the synergistic oxidation regime, the
25 substantial decrease of C_xH_yO_z-HOM formation leads to a significant reduction in ultralow- and
26 extremely low-volatility organic compounds, which significantly inhibits the formation of new
27 particles. This work provides valuable mechanistic and quantitative insights into the nocturnal
28 synergistic oxidation chemistry of biogenic emissions and will help to better understand the
29 formation of low-volatility organic compounds and particles in the atmosphere.

30

31 **1. Introduction**

32 The Earth's atmosphere is a complex oxidizing environment in which multiple oxidants coexist.
33 During the nighttime, NO₃ radicals (generated by the reaction of NO₂ and O₃) and O₃ contribute
34 significantly to the oxidation of volatile organic compounds (VOCs) (Huang et al., 2019), while
35 during the daytime, the fast photolysis of NO₃ radicals and rapid photochemical formation of OH
36 radicals and O₃ make the latter two the major oxidants for VOCs (Zhang et al., 2018). Therefore,
37 the degradation of ambient VOCs is subject to concurrent oxidation by different oxidants. Gas-phase
38 oxidation of VOCs from biogenic emissions (BVOCs) by these major atmospheric oxidants
39 produces a key type of reactive intermediates, organic peroxy radicals (RO₂), a portion of which can
40 undergo fast autoxidation forming a class of highly oxygenated organic molecules (HOMs) with
41 low volatilities (Jokinen et al., 2014; Mentel et al., 2015; Berndt et al., 2016; Zhao et al., 2018; Iyer
42 et al., 2021; Shen et al., 2022; Ehn et al., 2014). HOMs typically contain six or more oxygen atoms,
43 and plays a key role in the formation of atmospheric new particles and secondary organic aerosol
44 (SOA) (Kirkby et al., 2016; Berndt et al., 2018; Zhao et al., 2018; Ehn et al., 2014; Bianchi et al.,
45 2019), which have important influences on air quality (Huang et al., 2014), public health (Pye et al.,
46 2021), and Earth's radiative forcing (Shrivastava et al., 2017).

47 Due to the complexity of oxidation mechanisms of BVOCs, previous laboratory studies typically
48 featured only one oxidant and a single SOA precursor (Berndt et al., 2016; Berndt, 2021; Claffin et
49 al., 2018; Iyer et al., 2021; Boyd et al., 2015). However, the synergistic oxidation by different
50 oxidants may significantly alter the fate of RO₂ intermediates, therefore influencing the formation
51 of HOMs and SOA (Bates et al., 2022). Recently, a field study at a boreal forest site in Finland
52 observed a series of nitrate-containing HOM-dimers from the coupled O₃ and NO₃ oxidation of
53 monoterpenes (Zhang et al., 2020). At the same site, Lee et al. (2020) found that the synergistic
54 oxidation of BVOCs by OH radicals and O₃ contributed to the largest fraction of SOA. These studies
55 suggest that the synergistic oxidation of BVOCs by different oxidants plays an important role in the
56 formation of HOMs and SOA in the atmosphere and highlight the needs to investigate the synergistic
57 oxidation mechanisms of BVOCs for a better representation of atmospheric particle formation.

58 Several laboratory studies have attempted to address the role of synergistic oxidation of BVOCs in
59 the formation of new particles and SOA (Kenseth et al., 2018; Inomata, 2021; Liu et al., 2022; Li et

60 al., 2024). Kenseth et al. (2018) identified a suite of dimer esters in flow tube experiments that can
61 be only formed from the OH and O₃ synergistic oxidation of β-pinene. These dimers exhibit
62 extremely low volatility and contributed 5.9 – 25.4% to the total β-pinene SOA. Similarly, Inomata
63 (2021) found that the presence of OH radicals during α-pinene ozonolysis is a key factor for the
64 production of low-volatility organic species and significantly promotes new particle formation
65 (NPF). On the other hand, the addition of O₃ in the monoterpene photooxidation system also
66 significantly increases the SOA mass yield (Liu et al., 2022). In addition, a recent chamber study
67 by Bates et al. (2022) showed that the synergistic oxidation of α-pinene by NO₃ radicals and O₃ can
68 significantly enhance the SOA yield compared to the NO₃ + α-pinene regime, which has nearly 0%
69 SOA yield (Fry et al., 2014; Hallquist et al., 1999; Mutzel et al., 2021), and they revealed that the
70 SOA yield in the NO₃ + O₃ oxidation system largely depends on the RO₂ fates. Most recently, Li et
71 al. (2024) found that during α-pinene ozonolysis, the presence of nitrooxy-RO₂ radicals formed from
72 NO₃ oxidation can significantly suppress the production of ultralow-volatility organic compounds
73 (ULVOCs) and thereby NPF. These laboratory studies together provide growing evidence that
74 synergistic oxidation of BVOCs by different oxidants have profound impacts on atmospheric
75 particle formation. However, the specific synergistic mechanisms of different oxidants and
76 oxidation pathways remain obscure. Although a few studies underscored the importance of the RO₂
77 fates (Bates et al., 2022; Li et al., 2024), the exact interactions between RO₂ species derived from
78 different oxidants are still unclear, and quantitative constraints on the reaction rate of different RO₂
79 species are quite limited.

80 Here we conducted an investigation of the synergistic O₃ + NO₃ oxidation of α-pinene, one of the
81 most abundant monoterpenes in the atmosphere, using a combination of laboratory experiments and
82 detailed kinetic modelling, and focusing on the fate of RO₂ intermediates arising from different
83 oxidation pathways. The α-pinene oxidation experiments were conducted in a custom-built flow
84 reactor. The molecular composition of RO₂ species and HOMs in different oxidation regimes was
85 characterized using a chemical ionization atmospheric pressure interface time-of-flight mass
86 spectrometer (CI-API-ToF) employing a nitrate ion source. The measured distributions of specific
87 RO₂ and HOMs across different oxidation regimes were fitted with a kinetic model using Master
88 Chemical Mechanisms (MCM v3.3.1) updated with recent advances of α-pinene RO₂ chemistry

89 (Wang et al., 2021; Iyer et al., 2021; Shen et al., 2022; Zang et al., 2023), which allows for
90 quantitative constraints on RO₂ kinetics and synergistic oxidation mechanisms. Atmospheric
91 relevance of the experimental results was evaluated by modelling the investigated oxidation
92 chemistry under typical nocturnal atmospheric conditions.

93 **2. Materials and Methods**

94 **2.1 Flow Tube Experiments**

95 Experiments of α -pinene oxidation in different regimes (i.e., synergistic O₃ + NO₃ oxidation vs. O₃-
96 only) were carried out under room temperature (298 K) and dry (relative humidity < 5%) conditions
97 in a custom-built flow tube reactor (FTR, Figure S1). O₃ and NO₂ were added into a glass tube
98 (Figure S1) to form NO₃ radical and its precursor N₂O₅:

101 O₃ was generated by passing a flow of ultra-high-purity (UHP) O₂ (Shanghai Maytor Special Gas
102 Co., Ltd.) through a quartz tube housing a pen-ray mercury lamp (UV-S2, UVP Inc.) and its
103 concentration was measured by an ozone analyzer (T400, API). NO₂ was obtained from a gas
104 cylinder (15.6 ppm, Shanghai Weichuang Standard Gas Co., Ltd.). The total air flow in the NO₃
105 generation glass tube was 0.6 L min⁻¹ and 0.4 L min⁻¹ for the gas-phase HOM and SOA formation
106 experiments, respectively. The produced N₂O₅ and NO₃ radicals, as well as the excessive O₃ were
107 added into the FTR to initiate α -pinene oxidation. For the O₃-only experiments, only O₃ was added
108 into FTR.

109 The α -pinene gas was generated by evaporating a defined volume of their liquid (99%, Sigma-
110 Aldrich) into a cleaned and evacuated canister (SilcoCan, RESTEK), and then added into FTR
111 through a movable injector at a flow rate of 22 – 108 mL min⁻¹. The initial concentration of α -pinene
112 in the flow reactor ranged from 100 – 500 ppb. In some experiments, the gas of cyclohexane (~ 100
113 ppm), which was generated by bubbling a gentle flow of UHP N₂ through its liquid (LC-MS grade,
114 CNW), was added into the flow reactor as a scavenger of OH radicals formed from α -pinene
115 ozonolysis.

116 For experiments characterizing the formation of HOMs, the total air flow in the FTR was 10.8 L

117 min⁻¹ and the residence time was 25 seconds. The short reaction time and the small amount of
118 reacted α -pinene (see Table S1) in these experiments prevented the formation of particles. For the
119 experiments characterizing the formation of SOA particles, a larger FTR was used, with a total air
120 flow of 5 L min⁻¹ and a residence time of 180 seconds. A summary of the conditions including the
121 simulated concentrations of N₂O₅ and NO₃ radicals in different experiments are shown in Table S1.
122 The gas-phase RO₂ radicals and closed-shell products were measured using a nitrate-based CI-API-
123 ToF (abbreviated as nitrate-CIMS; Aerodyne Research, Inc.), which has been described in detail
124 previously (Zang et al., 2023). A long ToF-MS with a mass resolution of ~10000 Th/Th was used
125 here. The mass spectra within the m/z range of 50-700 were analyzed using the tofTools package
126 developed by Junninen et al. (2010) based on Matlab. A scanning mobility particle sizer (SMPS,
127 TSI), consisting of an electrostatic classifier (model 3082), a differential mobility analyzer (model
128 3081), and a condensation particle counter (model 3756), was employed to monitor the formation
129 of particles in different oxidation experiments.

130 2.2 Estimation of HOM Volatility

131 A modified composition-activity method was used to estimate the saturation mass concentration
132 (C^*) of HOMs in this study according to the approach developed by Li et al. (2016):

$$133 \log_{10}C^* = (n_C^0 - n_C)b_C - n_O b_O - 2 \frac{n_C n_O}{n_C + n_O} b_{CO} - n_N b_N - n_S b_S$$

134 where n_C^0 is the reference carbon number; n_C , n_O , n_N , and n_S are the atom numbers of carbon,
135 oxygen, nitrogen, and sulfur, respectively; b_C , b_O , b_N , and b_S are the contribution of each atom
136 to $\log_{10}C^*$, respectively; b_{CO} is the carbon-oxygen nonideality (Donahue et al., 2011). These b -
137 values were provided by Li et al. (2016).

138 It should be noted that the CHON compounds used in the data set by Li et al. (2016) are mostly
139 amines, amides, and amino acids, and only contain a limited number of organic nitrates (0.07%).
140 Since different types of CHON compounds have very different vapor pressures (Isaacman-Vanwertz
141 and Aumont, 2021), this formula-based approach can be biased to estimate the C^* of organic nitrates.
142 Considering that the -ONO₂ and -OH groups have similar impacts on vapor pressure and that the
143 CHON species are predominantly organic nitrates in our study, all -ONO₂ groups are treated as OH
144 groups during the estimation of vapor pressure (Daumit et al., 2013; Isaacman-Vanwertz and

145 Aumont, 2021).

146 Gas-phase HOMs are grouped into five classes based on their $\log_{10}C^*$ (Donahue et al., 2012;
147 Bianchi et al., 2019; Schervish and Donahue, 2020), that is, ULVOCs ($\log_{10}C^* < -8.5$), extremely
148 low-volatility organic compounds (ELVOCs, $-8.5 < \log_{10}C^* < -4.5$), low-volatility organic
149 compounds (LVOCs, $-4.5 < \log_{10}C^* < -0.5$), semi-volatile organic compounds (SVOCs, $-0.5 <$
150 $\log_{10}C^* < 2.5$), and intermediate-volatility organic compounds (IVOCs, $2.5 < \log_{10}C^* < 6.5$).

151 **2.3 Kinetic Model Simulations**

152 Model simulations of specific RO₂ radicals and closed-shell HOMs formed in different oxidation
153 regimes were performed to constrain the reaction kinetics and mechanisms using the Framework
154 for 0-D Atmospheric Modeling (FOAM v4.1) (Wolfe et al., 2016), which employs MCM v3.3.1
155 (Jenkin et al., 2015). The α -pinene oxidation mechanism was updated with the state-of-the-art
156 knowledge on the chemistry of RO₂ autoxidation and cross-reactions forming HOM monomers and
157 dimers, respectively (Zhao et al., 2018; Wang et al., 2021; Iyer et al., 2021; Shen et al., 2022). The
158 detailed updates have been described in our previous study (Zang et al., 2023). In particular, the
159 formation and subsequent reactions of the ring-opened primary C₁₀H₁₅O₄-RO₂, the highly
160 oxygenated acyl RO₂, as well as the C₁₀H₁₅O₂-RO₂ arising from H-abstraction by OH radicals
161 during α -pinene ozonolysis are included in the model according to recent studies (Iyer et al., 2021;
162 Zhao et al., 2022; Zang et al., 2023; Shen et al., 2022). To investigate the synergistic reactions of
163 RO₂ derived from the oxidation of α -pinene by different oxidants, we added the cross-reactions of
164 the primary nitrooxy-RO₂ derived from NO₃ oxidation (^{NO₃}RO₂) with RO₂ derived from ozonolysis
165 (^{Cl}RO₂) and OH oxidation (^{OH}RO₂). The cross-reaction rate constants of ^{NO₃}RO₂ + ^{Cl}RO₂ and
166 ^{NO₃}RO₂ + ^{OH}RO₂ and their ratios were tuned to achieve a good measurement-model agreement for
167 the distribution of specific RO₂ and HOMs in the synergistic oxidation regime. The ROOR' dimer
168 formation rates for these RO₂ radicals were assumed to be the same as their cross-reaction rates.
169 Previous studies indicated that the primary ^{NO₃}RO₂ radicals arising from α -pinene are prone to lose
170 the nitrate group and form pinonaldehyde with high volatility (Kurtén et al., 2017; Fry et al., 2014).
171 Therefore, we did not consider the autoxidation of primary ^{NO₃}RO₂ in the model. Considering the
172 presence of NO₂ in the experiments, the reactions of RO₂ + NO₂ \rightleftharpoons ROONO₂ were also included in
173 the model (Zang et al., 2023).

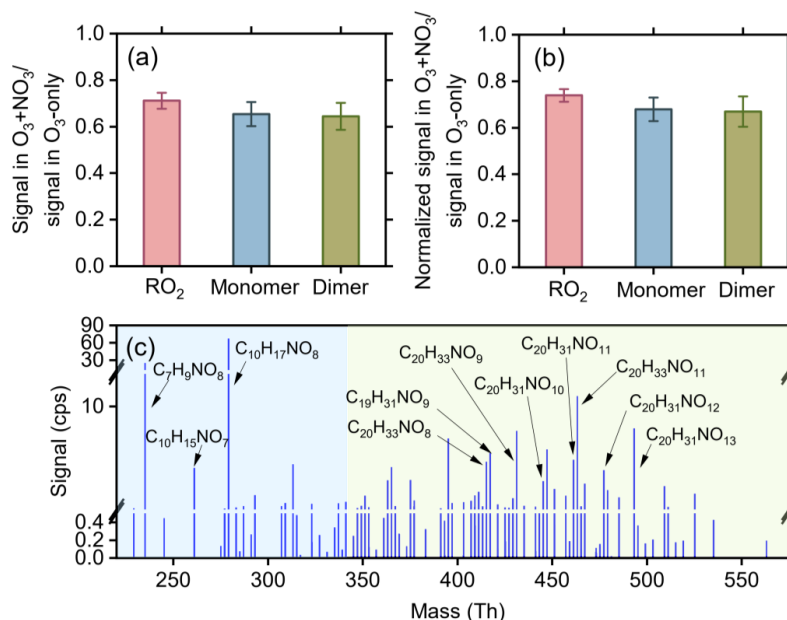

174 **3. Results and Discussion**

175 **3.1 Molecular distribution of RO₂ and HOMs in the synergistic oxidation regime**

176 The relative changes in the abundance of gas-phase RO₂ species and C_xH_yO_z-HOMs in the
177 synergistic O₃ + NO₃ oxidation of α-pinene vs. the O₃-only regime are shown in Figure 1. The
178 signals of C_xH_yO_z-HOMs significantly decrease by 29 – 36% in the synergistic O₃ + NO₃ regime
179 compared to those in the O₃-only regime (Figure 1a). Note that the initial concentrations of α-pinene
180 and O₃ in the two oxidation regimes were the same. In addition, model simulations show that in the
181 synergistic oxidation regime, over 97% of OH radicals react with α-pinene and the depletion of OH
182 by NO₂ is minor (0.2 – 1.3%). Also, NO₃ radicals almost entirely (over 98.5%) react with α-pinene
183 and their reaction with RO₂ has negligible influence on the fate of RO₂. Therefore, the strong
184 reduction in HOM formation in the synergistic oxidation regime vs. the O₃-only regime is likely due
185 to the following two reasons. The first one is the fast competitive consumption of α-pinene by NO₃
186 radicals, which results in a reduction in the reacted α-pinene by O₃ ($\Delta[\alpha\text{-pinene}]_{\text{O}_3}$, Figure S2) and
187 thereby the formation of C_xH_yO_z-HOMs. The second reason is associated with the reactions of
188 ^{NO₃}RO₂ with ^{Cl}RO₂ or ^{OH}RO₂ from α-pinene, which suppresses the autoxidation and self/cross-
189 reactions of ^{Cl}RO₂ and ^{OH}RO₂ to form C_xH_yO_z-HOMs.

190 To quantify the contribution of the synergistic RO₂ chemistry to the suppression of C_xH_yO_z-HOM
191 formation in the O₃ + NO₃ oxidation regime, the C_xH_yO_z-HOM signal ratios in Figure 1a are further
192 normalized to the ratio of $\Delta[\alpha\text{-pinene}]_{\text{O}_3}$ in the synergistic oxidation regime vs. the O₃-only regime
193 (see Figure 1b). Notably, after excluding the influence of reduced $\Delta[\alpha\text{-pinene}]_{\text{O}_3}$, the C_xH_yO_z-HOMs
194 signals still drop by 24 – 32% in the O₃ + NO₃ regime compared to those in the O₃-only regime,
195 indicating a significant contribution of the coupled reactions between ^{NO₃}RO₂ and ^{Cl}RO₂ or ^{OH}RO₂
196 to suppressed C_xH_yO_z-HOM formation.

197

198 Figure 1. Distributions of RO₂ and HOMs in the synergistic O₃ + NO₃ regime. (a) Relative changes
199 in the signals of C_xH_yO_z-RO₂ radicals, HOM monomers, and HOM dimers in the O₃ + NO₃ regime
200 compared to those in the O₃-only regime (Exps 1-10). (b) Similar to (a), but with ion signals
201 normalized to Δ[α-pinene]_{O₃} in each oxidation regime. (c) HOM nitrates measured in the O₃ + NO₃
202 regime.

203 Figure 1c shows the signals of closed-shell monomeric and dimeric HOM nitrates (HOM-ONs) that
204 were only observed in the synergistic O₃ + NO₃ regime. Their specific formulas are listed in Table
205 S2. These HOM-ONs mainly consist of C₁₀ monomers and C₂₀ dimers that only contain one nitrogen
206 atom. The C₂₀ HOM-ONs are believed to be formed from the cross-reactions of ^{Cl}RO₂ and ^{OH}RO₂
207 with ^{NO₃}RO₂. The substantial formation of these dimeric ONs provides direct evidence for the
208 synergistic RO₂ chemistry in the O₃ + NO₃ regime. It should be noted that although several closed-
209 shell monomeric HOM-ONs have been observed, only a few of them exhibit relatively high signals.
210 In addition, no obvious signals of highly oxygenated ^{NO₃}RO₂ (C₁₀H₁₆NO_x, x ≥ 6) were observed by
211 nitrate-CIMS in the synergistic O₃ + NO₃ oxidation system. Previous studies revealed that the
212 primary ^{NO₃}RO₂ radicals (i.e., C₁₀H₁₆NO₅-RO₂) in the α-pinene + NO₃ system mainly react to form
213 pinonaldehyde (Kurtén et al., 2017; Perraud et al., 2010). Therefore, it is likely that only a very
214 small amount of ^{NO₃}RO₂ can undergo autoxidation to form highly oxygenated ^{NO₃}RO₂. In addition,
215 the overlapping of the ^{NO₃}RO₂ peaks with strong C_xH_yO_z-HOMs peaks also hinders the observation

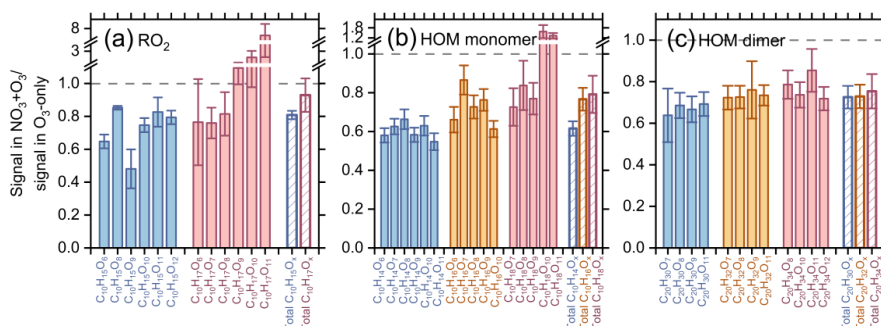

216 of highly oxygenated NO_3RO_2 signals in this study (Table S3). However, we note that although the
217 primary $\text{C}_{10}\text{H}_{16}\text{NO}_5\text{-RO}_2$ species arising from NO_3 oxidation may not undergo fast autoxidation,
218 they tend to efficiently terminate ClRO_2 and/or OHRO_2 and suppress the formation of $\text{C}_x\text{H}_y\text{O}_z\text{-HOMs}$.

219 3.2 Synergistic reaction efficiencies of different RO_2 species

220 In the $\text{O}_3 + \text{NO}_3$ regime, synergistic reactions are likely to occur between ClRO_2 , OHRO_2 and NO_3RO_2 .
221 Figure 2 shows the $\Delta[\alpha\text{-pinene}]_{\text{O}_3}$ -normalized signal ratios of specific C_{10} RO_2 as well as their
222 related $\text{C}_x\text{H}_y\text{O}_z\text{-HOM}$ monomers and dimers in the synergistic $\text{O}_3 + \text{NO}_3$ regime vs. the O_3 -only
223 regime. Model simulations show that the H-abstraction of α -pinene by OH radicals contributes less
224 than 2% to the formation of $\text{C}_{10}\text{H}_{15}\text{O}_x\text{-RO}_2$ and related HOMs under different experimental
225 conditions (Figure S3). Therefore, $\text{C}_{10}\text{H}_{15}\text{O}_x\text{-RO}_2$ observed in this study are primarily ClRO_2 .
226 Notably, the ClRO_2 ($\text{C}_{10}\text{H}_{15}\text{O}_x$) and related $\text{C}_{10}\text{H}_{14}\text{O}_x\text{-HOMs}$ decrease by ~30 – 60% in the $\text{O}_3 + \text{NO}_3$
227 regime (Figures 2 a, b), while the decreasing extent of OHRO_2 ($\text{C}_{10}\text{H}_{17}\text{O}_x$) and related $\text{C}_{10}\text{H}_{18}\text{O}_x\text{-}$
228 HOMs are significantly smaller (0 – 40%). In particular, some of the most oxygenated $\text{C}_{10}\text{H}_{17}\text{O}_x\text{-}$
229 RO_2 and $\text{C}_{10}\text{H}_{18}\text{O}_x\text{-HOMs}$ ($x \geq 9$) even increase unexpectedly in the synergistic oxidation regime.
230 For the $\text{C}_{10}\text{H}_{16}\text{O}_x\text{-HOMs}$ that can be derived from the termination reactions of both ClRO_2 and
231 OHRO_2 , their reductions are at a medium level. The significantly larger decrease in signals of ClRO_2
232 and related HOMs as compared to the OH-derived ones indicates that in the synergistic $\text{O}_3 + \text{NO}_3$
233 regime, the NO_3RO_2 species have a strong termination effect on ClRO_2 than on OHRO_2 (especially for
234 the most oxygenated OHRO_2). Because a large amount of ClRO_2 is terminated by NO_3RO_2 , fewer
235 ClRO_2 are available to terminate OHRO_2 . As a result, more OHRO_2 can undergo autoxidation to form
236 highly oxygenated $\text{C}_{10}\text{H}_{17}\text{O}_x\text{-RO}_2$ and $\text{C}_{10}\text{H}_{18}\text{O}_x\text{-HOMs}$ ($x \geq 9$), leading to an increase in signals of
237 these species. Consistently, the signals of C_{20} HOM dimers decrease by 20 – 40% in the $\text{O}_3 + \text{NO}_3$
238 regime compared to that in O_3 -only regime, and the signal reduction of dimers ($\text{C}_{20}\text{H}_{30}\text{O}_x$) formed
239 by ClRO_2 is slightly larger than that of the dimers ($\text{C}_{20}\text{H}_{34}\text{O}_x$) arising from OHRO_2 (Figure 2c). Note
240 that the highly oxygenated $\text{C}_{20}\text{H}_{34}\text{O}_x$ dimers ($x \geq 13$) that can be formed from self/cross-reactions
241 of $\text{C}_{10}\text{H}_{17}\text{O}_x\text{-RO}_2$ ($x \geq 9$) are not observed in this study, likely due to their low abundance and the
242 limitation of instrument sensitivity.

243

244
 245 Figure 2. Normalized signal ratios of (a) specific and total $C_{10}H_{15,17}O_x$ -RO₂ radicals, as well as their
 246 related (b) C_{10} HOM monomers and (c) C_{20} HOM dimers in the O₃ + NO₃ regime vs. the O₃-only
 247 regime (Exps 1-10). Ion signals observed in each oxidation regime are normalized to $\Delta[\alpha\text{-pinene}]_{O_3}$.

248 To gain quantitative constraints on the relative reaction efficiency of $^{NO_3}RO_2 + ^{Cl}RO_2$ vs. $^{NO_3}RO_2 +$
 249 $^{OH}RO_2$ (i.e., k_{NO_3+Cl}/k_{NO_3+OH}), the signal ratios of C_{10} - $^{Cl}RO_2$ and $^{OH}RO_2$ as well as their related C_{10}
 250 HOMs in the synergistic oxidation regime vs. the O₃-only regime were predicted using a kinetic
 251 model (see Section 2.3) with different k_{NO_3+Cl}/k_{NO_3+OH} ratios. Figure 3 shows a measurement-model
 252 comparison of those signal ratios. When the ratio of k_{NO_3+Cl}/k_{NO_3+OH} is smaller than or equal to 1,
 253 the simulated signal ratios of many RO₂ and HOMs differ significantly from the measured ratios,
 254 especially for some $C_{10}H_{17}O_x$ -RO₂ and $C_{10}H_{18}O_x$ -HOMs. When the ratio of k_{NO_3+Cl}/k_{NO_3+OH} is 10
 255 – 100, there is a good measurement-model agreement for most of RO₂ and HOMs. Therefore, we
 256 conclude that the cross-reactions of $^{NO_3}RO_2 + ^{Cl}RO_2$ are on average 10 – 100 times more efficient
 257 than $^{NO_3}RO_2 + ^{OH}RO_2$.

258 As a competitive reaction pathway, the autoxidation rates of RO₂ can affect the extent to which RO₂
 259 cross-reactions influence the RO₂ fate and HOM formation. Therefore, sensitivity analyses of the
 260 autoxidation rate of RO₂ were conducted to evaluate its influence on the changes of RO₂ and related
 261 HOM concentrations in the synergistic O₃ + NO₃ regime vs. the O₃-only regime (Figure S4). In
 262 these analyses, a k_{NO_3+Cl}/k_{NO_3+OH} ratio of 10 was used according to the above discussions. As the
 263 autoxidation rate of $^{OH}RO_2$ increases from 0.28 to 10 s⁻¹, corresponding to the rate range reported in
 264 previous studies (Berndt et al., 2016; Zhao et al., 2018; Xu et al., 2019), the simulated reduction of
 265 highly oxygenated $^{OH}RO_2$ and related $C_{10}H_{18}O_x$ -HOMs in the synergistic O₃ + NO₃ regime exhibits
 266 a slight decrease (< 7%) but still agrees reasonably well with the measured value (Figures S4 a-d).
 267 Considering that the autoxidation rates of $^{Cl}RO_2$ used in the model approach their upper limits

268 reported in the literature, i.e., $\sim 1 \text{ s}^{-1}$ for the butyl ring-opened $\text{C}_{10}\text{H}_{15}\text{O}_4\text{-RO}_2$ (Iyer et al., 2021) and
 269 relatively smaller rates for ring-retained $\text{C}_{10}\text{H}_{15}\text{O}_4\text{-RO}_2$ ($0.02 - 0.29 \text{ s}^{-1}$, see Scheme S1) (Zhao et
 270 al., 2021), we also lowered the autoxidation rate constants of $^{\text{Cl}}\text{RO}_2$ by a factor of 10 to see its
 271 influence on RO_2 and HOM distribution in the $\text{O}_3 + \text{NO}_3$ regime. The simulated reduction of $^{\text{Cl}}\text{RO}_2$
 272 and $\text{C}_{10}\text{H}_{14}\text{O}_x\text{-HOMs}$ in this case decreases by 11 – 18% (Figures S4 e-h), while that of $\text{C}_{10}\text{H}_{16}\text{O}_x\text{-}$
 273 HOMs increases by up to 30% (Figures S4 i, j). However, the simulated results are still close to the
 274 measured values. These sensitivity analyses suggest that the uncertainty in the autoxidation rates of
 275 $^{\text{OH}}\text{RO}_2$ and $^{\text{Cl}}\text{RO}_2$ could slightly affect the simulated distribution of RO_2 and HOMs across different
 276 oxidation regimes but not significantly change the $k_{\text{NO}_3+\text{Cl}}/k_{\text{NO}_3+\text{OH}}$ ratio obtained in this study.

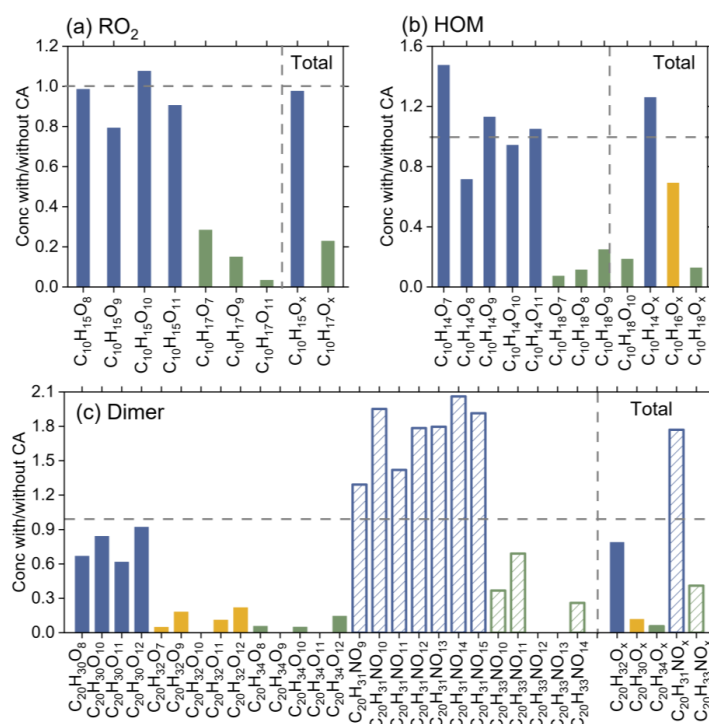

277

278 Figure 3. Measurement-model comparisons of the signal ratios of different C_{10} RO_2 and HOMs in
 279 the synergistic $\text{O}_3 + \text{NO}_3$ regime vs. the O_3 -only regime. The cross-reaction rate of $^{\text{NO}_3}\text{RO}_2 + ^{\text{Cl}}\text{RO}_2$
 280 was set to $1 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and the rate of $^{\text{NO}_3}\text{RO}_2 + ^{\text{OH}}\text{RO}_2$ was varied from $1 \times 10^{-11} \text{ cm}^3$
 281 $\text{molecule}^{-1} \text{ s}^{-1}$ to $1 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ in the model.

282 Cyclohexane was added in some experiments as an OH scavenger to elucidate the role of $^{\text{OH}}\text{RO}_2$
 283 chemistry in HOM formation in the $\text{O}_3 + \text{NO}_3$ regime. In the presence of cyclohexane, $^{\text{OH}}\text{RO}_2$
 284 ($\text{C}_{10}\text{H}_{17}\text{O}_x$) and related HOM monomers ($\text{C}_{10}\text{H}_{18}\text{O}_x$) and dimers ($\text{C}_{20}\text{H}_{32}\text{O}_x$ and $\text{C}_{20}\text{H}_{34}\text{O}_x$) decrease
 285 by more than 80% (Figure 4), while $^{\text{Cl}}\text{RO}_2$ ($\text{C}_{10}\text{H}_{15}\text{O}_x$) and related HOM monomers ($\text{C}_{10}\text{H}_{14}\text{O}_x$) and
 286 dimers ($\text{C}_{20}\text{H}_{30}\text{O}_x$) only decrease slightly ($< 30\%$), in a good agreement with previous measurements
 287 (Zhao et al., 2018; Zang et al., 2023). The $\text{C}_{10}\text{H}_{16}\text{O}_x$ species, which can arise from both $^{\text{Cl}}\text{RO}_2$ and
 288 $^{\text{OH}}\text{RO}_2$, exhibit a medium reduction (Figure 4b). It is interesting to note that with the addition of
 289 cyclohexane, there is a significant increase in $\text{C}_{20}\text{H}_{31}\text{NO}_x$, which are formed from the cross-reactions

290 of $^{\text{Cl}}\text{RO}_2$ with $^{\text{NO}_3}\text{RO}_2$. Such an enhanced production of $\text{C}_{20}\text{H}_{31}\text{NO}_x$ as compared to the slightly
 291 decreased formation of $\text{C}_{20}\text{H}_{30}\text{O}_x$ indicates that the cross-reaction of $^{\text{Cl}}\text{RO}_2 + ^{\text{NO}_3}\text{RO}_2$ is fast compared
 292 to that of $^{\text{Cl}}\text{RO}_2 + ^{\text{Cl}}\text{RO}_2$ and $^{\text{Cl}}\text{RO}_2 + ^{\text{OH}}\text{RO}_2$. As a result, when the $^{\text{OH}}\text{RO}_2$ are depleted, the $^{\text{Cl}}\text{RO}_2$
 293 that are supposed to react with $^{\text{OH}}\text{RO}_2$, efficiently react with $^{\text{NO}_3}\text{RO}_2$ to form $\text{C}_{20}\text{H}_{31}\text{NO}_x$, leading to
 294 the increase in $\text{C}_{20}\text{H}_{31}\text{NO}_x$ signals.

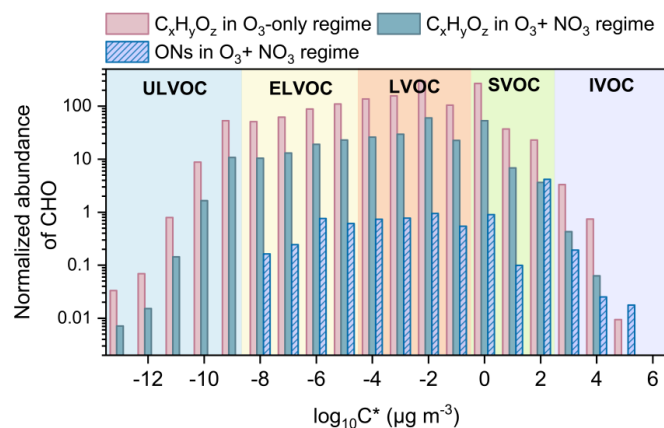

295
 296 Figure 4. Relative changes in signals of (a) C_{10} RO_2 , (b) C_{10} HOMs, and (c) C_{20} dimers due to the
 297 addition of 100 ppm cyclohexane as an OH scavenger derived in the synergistic $\text{O}_3 + \text{NO}_3$ regime
 298 (Exps 6 and 12).

299 3.3 Influence of synergistic oxidation on low-volatility organics and particle formation

300 Compared to the O_3 -only regime, there is a remarkable reduction in $\text{C}_x\text{H}_y\text{O}_z$ -HOMs and a strong
 301 formation of HOM-ONs due to the termination reactions between $^{\text{NO}_3}\text{RO}_2$ and $^{\text{Cl}}\text{RO}_2$ or $^{\text{OH}}\text{RO}_2$ in
 302 the synergistic oxidation regime. This significant change in HOM composition and abundance
 303 would alter the volatility distribution of HOMs and influence the formation of particles. The
 304 volatilities of HOMs formed in the two oxidation regimes are estimated using a modified
 305 composition-activity method (see Section 2.2) and shown in Figure 5. The abundance of $\text{C}_x\text{H}_y\text{O}_z$ -

306 HOMs characterized as ULVOCs and ELVOCs decreases considerably in the synergistic O₃ + NO₃
 307 regime compared to the O₃-only regime (Figure 5a), in agreement with the very recent observations
 308 by Li et al. (2024) who found that the presence of NO₃ radicals during α-pinene ozonolysis
 309 significantly reduced the abundance of ULVOCs. Although substantial amounts of HOM-ONs are
 310 formed in the O₃ + NO₃ regime, they generally have higher volatilities (i.e., characterized as
 311 ELVOCs to IVOCs) (Figure 5b). In addition, the total abundance of newly formed HOM-ONs
 312 characterized as ELVOCs in the synergistic O₃ + NO₃ regime is significantly lower than the reduced
 313 formation of ultra- and extremely low-volatility C_xH_yO_z-HOMs. Therefore, the synergistic O₃ + NO₃
 314 oxidation of α-pinene significantly reduces the formation of ULVOCs and ELVOCs and increases
 315 the overall volatility of total HOMs.

316

317 Figure 5. Volatility distribution of C_xH_yO_z-HOMs and HOM-ONs formed in the O₃ + NO₃ regime
 318 and O₃-only regime (Exps 1, 6). Ion signals in each oxidation regime are normalized to the
 319 corresponding total reacted α-pinene.

320 Figure 6 shows the particle number and mass concentrations formed in the two oxidation regimes
 321 in SOA formation experiments (Table S1, Exps 13, 14). The particle number concentration decreases
 322 by more than 50% whereas the particle mass concentration increases by a factor of 2 in the
 323 synergistic O₃ + NO₃ regime, compared to that in the O₃-only regime. The reduced particle number
 324 concentration in the O₃ + NO₃ regime is ascribed to the suppressed formation of ULVOCs, which
 325 are the key species driving the particle nucleation (Simon et al., 2020; Schervish and Donahue,
 326 2020). However, although the newly formed HOM-ONs with relatively higher volatilities are

327 inefficient in initiating particle nucleation, they are able to partition into the formed particles and
 328 contribute significantly to the particle mass growth. This result is consistent with a recent chamber
 329 study which found that the SOA mass concentration is much higher during α -pinene oxidation by
 330 $O_3 + NO_3$ than during ozonolysis (Bates et al., 2022).

331

332 Figure 6. Number and mass concentrations of particles formed from the ozonolysis and synergistic
 333 $O_3 + NO_3$ oxidation of α -pinene (Exps 13-14).

334 3.4 Atmospheric relevance of experimental results

335 To evaluate the relevance of our experimental findings to the real atmosphere, we performed
 336 chemical model simulations of HOM formation from nocturnal synergistic $O_3 + NO_3$ oxidation of
 337 α -pinene under typical atmospheric conditions. In these simulations, constant concentrations of α -
 338 pinene (1 ppb), O_3 (30 ppb), NO (5 ppt), NO_2 (1.8 ppb), NO_3 radicals (0.2 or 1 ppt), OH radicals (5
 339 $\times 10^4$ molecules cm^{-3}), HO_2 radicals (4 ppt), as well as a constant RH of 50% and temperature
 340 of 298 K were used as typical nocturnal conditions in the boreal forest according to the field studies
 341 (Stone et al., 2012; Lee et al., 2016; Brown and Stutz, 2012; Geyer et al., 2003b; Kristensen et al.,
 342 2016; Hakola et al., 2012; Liebmann et al., 2018). Considering the rapid deposition of oxidized
 343 biogenic compounds (Nguyen et al., 2015), a typical dilution lifetime of 5 h (i.e., $k_{dil} = 1/5$ h⁻¹) was
 344 assumed in the model. According to the above analysis, the cross-reaction rate constants for NO_3RO_2
 345 + ^{Cl}RO₂ and NO_3RO_2 + ^{OH}RO₂ were set to 1×10^{-12} cm³ molecule⁻¹ s⁻¹ and 1×10^{-13} cm³ molecule⁻¹
 346 s⁻¹ in the model, respectively.

347 As shown in Figure 7a, when a relatively low NO_3 concentration (0.2 ppt) is considered, ozonolysis
 348 is the primary loss pathway of α -pinene (68%), followed by NO_3 (30%) and OH oxidation (2%).
 349 The reactions of $RO_2 + HO_2$, $RO_2 + NO$ and $RO_2 + RO_2$ account for ~49%, ~27% and ~24% of the

350 total RO₂ fate, respectively. Under these conditions, the synergistic O₃ + NO₃ oxidation of α-pinene
351 leads to a reduction of 3% and 13% in the formation of C_xH_yO_z-HOM monomers and dimers,
352 respectively (Figure 7b). Given that the concentrations of α-pinene and oxidants were held constant
353 during the simulation, the consumptions of α-pinene by different oxidants are constant. Therefore,
354 the decreases in the concentrations of C_xH_yO_z-HOM monomers and dimers in the presence of NO₃
355 oxidation are mainly due to the cross-reaction of ^{NO3}RO₂ with other RO₂. When the NO₃
356 concentration is as high as 1 ppt as reported in field studies (Liebmann et al., 2018), NO₃ oxidation
357 contributes to 68% of α-pinene consumption (Figure 7c), and the contribution of RO₂ + RO₂ reaction
358 increases to 33%. As a result, the cross-reactions of ^{NO3}RO₂ with other RO₂ play a more important
359 role in the HOM formation. Under these conditions, the production of C_xH_yO_z-HOM monomers and
360 dimers decreases by 13% and 43%, respectively, due to the presence of NO₃ oxidation (Figure 7d).
361 Considering that there are uncertainties in the dilution rate constant, a sensitivity analysis was
362 performed by varying the *k_{dil}* in the range of 0.04 – 0.2 h⁻¹. It is found that the variation within these
363 rate values does not significantly influence the response of C_xH_yO_z-HOM dimer formation to
364 concurrent NO₃ oxidation (Figure S5).

365 Field observations have shown that NO₃ radicals, O₃, and OH radicals all had important
366 contributions to monoterpene oxidation during the early morning after sunrise and late afternoon
367 before sunset in the southeastern United States (Zhang et al., 2018). In addition, relatively high
368 nighttime OH concentrations of (2 – 10) × 10⁵ molecules cm⁻³ were measured in some areas such
369 as Germany and New York City (Faloona et al., 2001; Geyer et al., 2003a). As a result, model
370 simulations using the same species concentration (NO₃ = 1 ppt) as mentioned above but a 10 times
371 higher OH concentration (5 × 10⁵ molecules cm⁻³) were also conducted. With a higher OH
372 concentration, O₃, NO₃, and OH radicals account for 28%, 62%, and 10% to the total α-pinene
373 consumption, respectively (Figure S6 a). Compared to the results under low OH concentration, the
374 formation of C_xH_yO_z-HOM monomers and dimers are all enhanced under high OH concentration
375 (Figure S6 b). This is mainly due to the promoted self/cross-reactions of ^{OH}RO₂, as well as the
376 promoted formation of C₁₀H₁₅O_x-RO₂ derived from H-abstraction pathway by OH radicals.
377 Nevertheless, the presence of NO₃ oxidation still reduces the formation of C_xH_yO_z-HOM dimers by
378 26% (Figure S6 b).

379 The above model simulations clearly suggest that under typical nocturnal atmospheric conditions,
 380 the synergistic oxidation of α -pinene by O_3 and NO_3 radicals can significantly inhibit the formation
 381 of $C_xH_yO_z$ -HOMs, many of which are characterized as ULVOCs capable of driving particle
 382 nucleation and initial growth. Although HOM-ON dimers are readily produced bycross-reactions
 383 between $^{NO_3}RO_2$ and $^{Cl}RO_2$, they generally have higher volatilities than $C_xH_yO_z$ -HOM dimers and
 384 therefore are less efficient in initiating particle formation. Our results offer mechanistic and
 385 quantitative insights on how the synergistic oxidation of α -pinene by O_3 and NO_3 radicals can
 386 influence the formation of low-volatility organic compounds and hence particle formation and
 387 growth. They also provide a potential explanation for field observations that NPF events frequently
 388 occur in monoterpene-rich regions during daytime but not at nighttime (Mohr et al., 2017; Kulmala
 389 et al., 2001; Junninen et al., 2017).

390

391 Figure 7. Model simulations of α -pinene oxidation and HOM formation under typical nighttime
 392 conditions in the boreal forest. (a, c) Contributions of different loss pathways of α -pinene by
 393 different oxidants at NO_3 concentrations of 0.2 and 1 ppt, respectively; (b, d) Concentrations of
 394 $C_xH_yO_z$ -HOMs and HOM-ONs formed by synergistic $O_3 + NO_3$ oxidation and ozonolysis of α -
 395 pinene under conditions corresponding to (a) and (c). The simulations were run for 4 h after an 8-h
 396 spin-up for intermediates and secondary species.

397 **4. Conclusions**

398 This study provides a comprehensive characterization of the nocturnal synergistic oxidation of α -
399 pinene by O_3 and NO_3 radicals and its influence on the formation of HOMs and low-volatility
400 organic compounds using a combination of flow reactor experiments and detailed kinetic model
401 simulations. It is found that the formation of $C_xH_yO_z$ -HOMs in the $O_3 + NO_3$ regime is significantly
402 suppressed compared to that in the O_3 -only regime, mainly due to the termination of ozonolysis-
403 derived RO_2 (i.e., $^{Cl}RO_2$ and $^{OH}RO_2$) by $^{NO_3}RO_2$. In addition, the decreases in the abundance of
404 $^{Cl}RO_2$ and related HOMs are significantly larger than those of OH-derived ones, indicating that the
405 $^{NO_3}RO_2$ species have a strong termination effect on $^{Cl}RO_2$ than on $^{OH}RO_2$. Detailed measurement-
406 model comparisons for the distribution of a suite of $^{Cl}RO_2$, $^{OH}RO_2$, and associated HOMs across
407 different oxidation regimes further reveal that the terminations reactions between $^{Cl}RO_2$ and $^{NO_3}RO_2$
408 are averagely 10 – 100 times more efficient than those of $^{OH}RO_2$ and $^{NO_3}RO_2$.

409 The suppressed formation of $C_xH_yO_z$ -HOMs in the synergistic $O_3 + NO_3$ regime results in a
410 significant reduction in ULVOCs. Although substantial amounts of HOM-ONs are formed from the
411 cross-reactions between $^{NO_3}RO_2$ and $^{Cl}RO_2$ or $^{OH}RO_2$ in the synergistic oxidation regime, they have
412 higher volatilities and are less likely to participate in the formation and initial growth of new
413 particles. As a result, in our experiment the formation of new particles in the synergistic oxidation
414 regime is substantially inhibited compared to the O_3 -only regime. Chemical model simulations
415 further confirm that the synergistic oxidation of α -pinene by O_3 and NO_3 radicals can significantly
416 inhibit the formation of $C_xH_yO_z$ -HOMs, especially the ultra-low volatility $C_xH_yO_z$ -HOM dimers
417 under typical nighttime atmospheric conditions. Our study sheds lights on the synergistic oxidation
418 mechanism of biogenic emissions and underscores the importance of considering this chemistry for
419 a better depiction of the formation of low-volatility organics and particles in the atmosphere.
