

Response to referee #1:

We thank referee #1 for their comments. We welcome the opportunity to clarify the issues they raised. We first summarize the main findings of our paper and then respond to several overarching criticisms offered by referee #1. We then address their specific line-by-line comments.

Our preprint argued that landscapes with slopes that initially tend to be aligned along the regional slope direction across a wide range of spatial scales tend to have lower mean junction angles. We established this based on a new high-resolution dataset for the conterminous U.S.A. that uses methods/codes that we have shared with the community and that we explicitly tested on synthetic branching landscapes to demonstrate their accuracy. We argued that the geomorphic history of alluvial piedmonts (including the specific tectonic and depositional processes that create alluvial piedmonts) lends itself to especially planar initial conditions (i.e., low S_i/S_r values), consistent with the correlation we document between junction angles and the presence/absence of late Cenozoic alluvial deposits (which, prior to fluvial incision, likely tend to have lower S_i/S_r values compared to bedrock/older deposits). As a result, we caution against using junction angles to infer paleoclimate (as was done for Mars by Seybold et al., 2018). Our argument is not based merely on a correlation between junction angles and the tendency of slopes to be aligned along the regional slope direction across a wide range of spatial scales, but instead on how two planes intersect to form a line and the associated equation for how junction angles are partially constrained by the ratio of slopes of the main valley bottom and each tributary valley bottom.

Referee #1 concluded that the essential elements of our study were previously published by Castelltort (2013) (which we take to be Castelltort and Yamato (2013) since no other paper dealing with river networks was published by Castelltort in 2013). However, Castelltort and Yamato (2013) did not study junction angles (they studied the length to width ratio of drainage basins). They did not extract any network. They did not reference Howard, whose geometric model is a critical part of our study. Our work was undoubtedly inspired by, and owes a large intellectual debt to, the work of Castelltort and Yamato (2013). We tried to make that intellectual debt clear in the caption to Figure 2 of our preprint where we wrote “The specific examples in this figure are ours but the concept closely follows Castelltort and Yamato (2013).”

Please also note that the data for real landscapes that we present tell nearly the opposite story to that of the data for real landscapes presented by Castelltort and Yamato (2013) (their Figure 2). Their Figure 2 plots the convergence angle (a measure of the aspect ratio of a drainage basin) versus regional slope, illustrating that higher regional slopes result in more elongate drainage basins. What we demonstrated in our preprint is very different, i.e., that tributary fluvial networks incised into alluvial piedmonts (which tend to have lower regional slopes than tributary fluvial networks incised into bedrock/older deposits) have lower mean junction angles than those incised into bedrock/older deposits. We proposed that this trend exists because, while the regional slope is lower for alluvial piedmonts compared to bedrock landscapes (which, all else being equal and if S_i/S_r values are a control, would result in larger (not smaller) mean junction angles on alluvial

piedmonts), the initial microtopographic slope is far lower still (the distributary Holocene alluvial piedmonts of Fort Irwin that we studied provide a modern analog for the initial conditions of late-Cenozoic alluvial piedmont deposits that are now incised and have tributary fluvial networks developed in them) with the result that alluvial piedmont deposits have lower mean junction angles *despite their lower regional slopes* compared to tributary fluvial networks incised into bedrock/older deposits.

Referee #1 states that slopes must be a result of geomorphic processes that occur during valley incision, including erosion, deposition, and tectonic uplift. We couldn't agree more. That fact does not preclude the geometric model and/or initial flow pathways in the landscape from playing a substantial role in controlling fluvial network junction angles, however. Clearly, tectonic uplift, substrate erodibility, and erosional and depositional processes do control slopes, but it is *the ratio of slopes*, not their absolute values, that is the independent variable (i.e., the variable controlled by other factors) in the geometric model for tributary junction angles (the dependent variable in the geometric model). As such, the geometric model for junction angles is not inconsistent with any proposed control on slopes. The conceptual model we are proposing includes geomorphic processes explicitly, albeit potentially different ones than reviewer #1 believes control junction angles. One example: lines 68-75, in which we described the specific tectonic and depositional processes that create alluvial piedmonts and their tendency for slopes to align, across a wide range of scales, with the regional slope. Referee #1 rejects our argument that alluvial piedmont deposition creates low-relief landforms, a point that we have worked hard to address (see response to L40 comment below).

How might a more parallel initial drainage architecture tend to be preserved as valleys incise? One possibility is that more parallel and elongate initial valleys have relatively similar contributing areas (relative to the power-law distribution of contributing areas typically observed in drainage networks with a more dendritic architecture, e.g., Veitzer et al., 2003), leading to relatively similar incision rates among neighboring drainage basins, thus tending to maintain the parallel nature of the landscape by minimizing the tendency for one or a few drainage networks to incise faster than others. We will include new numerical modeling work (see new text in the response to referee #2) designed to show how both the initial condition and geomorphic processes of incision combine to control junction angles.

We respectfully disagree with the referee that the correlations documented in our paper are "spurious." In documenting a correlation between mean junction angles and the presence/absence of late Cenozoic alluvial piedmont deposits, we have taken the analysis as far as it will go because the initial S_i/S_r value of a now-incised landscape cannot possibly be measured. In such cases, the best one can do is establish a correlation with a quantity or characteristic (i.e., the presence/absence of late Cenozoic alluvial piedmont deposits) that is related to the property that cannot be measured (i.e., the initial S_i/S_r value of a now-incised landscape) and then make a process-based association between that quantity/characteristic and the property that cannot be measured. That is what we have done.

We regret that our writing came across as non-inclusive. We intended to propose that the ratio of the initial microtopographic slope to the regional slope, S_i/S_r , is a constraint (not the only constraint) on junction angles. The preprint contained a paragraph emphasizing that S_i/S_r was one of many controlling factors (lines 630-640). Since the preprint did not convey this message as intended, we have rewritten the introduction and discussion to further clarify that many processes and factors likely control junction angles. These proposed changes are all detailed in on pages

Line-by-line comments and responses:

“While the paper makes some interesting points on how topographic features and geology may be expressed in a channel network's branching geometry, several points need to be clarified and some miss-perceptions of previous studies need to be resolved. First, the fact that vertical features of topography like slope correlate with horizontal geometric properties of landscapes such as branching angles should be surprising. Ultimately, Earth's surface evolves as a result of erosion and uplift and valley networks are simply characteristic features embedded in this three-dimensional topography. More important than correlations between different topographic features is the understanding of how the underlying processes, namely erosion, deposition, and tectonic uplift are expressed in the network's branching structure. Quoting from Howard's 1990 paper on the geometric model: , "[this geometric model] was only sketchily related to the assumed channel processes ...". This point actually prompted Howard in 1990, to explore additional hydrological arguments to constrain the angle-slope relation found on more process-based descriptions of how the flow in a channel may modify its bed, even if the particular expression may result in a slightly lower r-square, than the predictions of the geometric model. Also note, that much of the theoretical basis of Howard 1990 was mostly done 20 years earlier in [Howard 1971b, 1971c] as referenced in the 1990 paper. Similarly, Hooshyar 2017 and Seybold 2017 try to relate branching angles to channel-forming processes, namely overland flow v.s. debris flow in the first and seepage flow v.s. overland flow in the latter, while the optimality models of Strong & Mudd e.g. use hydrological conservation arguments at the junction, similar to the arguments in Howard 1990. I would like to note here, that while the authors promote the impression that the observed slope-angle relation contradicts the above-mentioned interpretations, however, these conceptual frameworks are more complementary as they simply provide different aspects for explaining how landscapes evolve. Consequently, the authors may consider a more "inclusive tone" in their argumentation, particularly because the author's own explanations remain rather vague on process understanding giving too much focus on the trivial angle-slope relations of the geometric model.”

Response: The referee is correct that Howard (1990) did not find the geometric model to be compelling as a process-based understanding of junction angles. That does not preclude others from arguing that the geometric model and/or initial flow pathways exert some control on the junction angles of tributary fluvial valley networks. We regret that we did not use a more inclusive tone. Pages 20-57 detail the many changes to the introduction and discussion sections we propose to make to be more inclusive.

“An interesting point in the manuscript which I was initially excited to read about was the alleged finding that incisions into alluvial piedmonts exhibit different structural controls on branching angles than channel networks incised into bedrock. Here, the role of geology is an important point for channel erosion and has not been addressed adequately in previous work, including the recent papers cited by the authors. However, the more I was disappointed when reading through the text to find out that the narrowing of branching angles in alluvial piedmonts is fully explained by the fact that piedmonts are (usually) preferentially sloped while bedrock valley networks do not display a preferential slope. Thus, what is thought to be a structural effect is simply the higher prevalence of regional gradients that narrow the branching angle statistics. This effect of regional slope and microtopography has been already demonstrated by Castelltort in 2013 through numerical simulations and also observed in multiple previous studies over the last decade.”

Response: Thank you for this comment. As noted above, Castelltort in 2013 did not study junction angles nor any other aspect of the network (they studied the aspect ratio of drainage basins).

“L.5: Ignoring some degenerated special cases, three planes, one for each upstream tributary and one for the downstream channel can intersect at any angle and slope and thus does not provide a geometric constraint for branched valley networks. What actually constraints the argument of Horton /Howard is the presence of fixed a general slope (for all three basins) aligned with the downstream channel, while the side valley is additionally inclined with respect to this dominant direction.”

Response: Thank you for this comment. The geometric model for tributary fluvial network junction angles does not involve three planes (intersecting or otherwise). The geometric model of Howard (1990) posits that two planes (approximating the topography of the tributary valley bottoms and the topography upslope from and surrounding those tributary valley bottoms) *intersect to form a line* that constrains the orientation of the main/downstream valley bottom.

“L 9-10: Landscapes evolve through erosion/deposition and uplift creating sloped valley networks. Thus I firmly object to the implications that the geometric "model" actually contradicts the process-based explanation by Hooshyar et al. or Seybold et al. as well as the optimality principles proposed by Rinaldo, Strong & Mudd, and many others. Earth's surface is shaped by processes and not geometric features.”

Response: Thank you for the opportunity to clarify our thoughts on this aspect of our work. We concluded that the initial condition prior to incision is one “constraint” (the title of the paper, line 26, and elsewhere) on junction angles. Also note that, as discussed above, the ratio of slopes can be viewed as the independent variable in the geometric model, hence that ratio can be controlled by any process with no contradiction with the geometric model for tributary junction angles. No text in our preprint precluded other processes from being important controls on junction angles. We acknowledge that included a sentence proposing that the geometric model be used as a null hypothesis to be disproven before other hypotheses are accepted. We have removed that sentence

from our paper so as not to send the intended impression that we believe that any of our work contradicts other proposed models for junction angles.

L. 11-12: "Junction angles are consistent with the geometric model..." It would be good to have a 1:1 plot between prediction vs measurement and a quantification of the spread and uncertainty of the model prediction. Also, it would be favorable to see how the "classical geometric model" compares to the "modified geometric model" in such a comparison.

Response: Thank you for this comment. We have modified Figure 8 of our preprint to plot the observed versus predicted junction angles (see revised Figure 8c&8d below). The classical geometric model of Horton (1932) is counterfactual because it assumes that the larger of the two tributaries is precisely the same orientation as the main (downstream) valley. It was superseded 52 years ago by a more realistic model, and it will not be considered in this study.

Revised Figure 8. Plots illustrating the relationships of junction angles to the ratios of slopes downslope and upslope of the junctions for the portion of southern Arizona illustrated in Figure 5. (a) Plot of junction angles measured using BA properties as a function of the ratio of slopes downslope and upslope. (b) Plot of junction angles measured using AVB properties as a function of the ratio of slopes downslope and upslope. (c)&(d) Plots of observed junction angles versus those predicted by the MGM using the data of (a)&(b), respectively. (e) Plots of junction angles measured both AVB (using three different values of the elevation change over which slopes and orientations are computed) and BA properties.

To put the scatter in the revised Figures 8c&8d into context and to mitigate concerns that we are using a new junction-angle dataset, Figure R1a below plots the relationship between the measured sum of junction angles $\theta = \theta_1 + \theta_2$ from the classic NHDPlusV2 dataset and the predictions of the geometric model using the supplementary data of Getraer and Maloof (2021) (<https://hydroshare.org/resource/0b93e7c659fe4fc59bf6a202c269313c/>) and the relationship between the measured sum of the junction angles and the logarithm of the aridity index using the supplementary data of Seybold et al. (2017) (grl55580-sup-0001-supinfo.csv). A key point of Figure R1 is that there is substantial scatter when plotting individual (unaveraged) junction angles regardless of the data source used and the model or controlling variable being proposed (geometric vs. aridity-based).

Figure R1.

“L.17-25: How does the type of geology (alluvial vs bedrock) relate to the sloping of the topography? The tilting effect on branching angles and basin shapes observed in the modeling procedures of Casteltort 2013) which the authors draw to explain their findings makes absolutely no assumption on the ground surface material. Neither piedmonts nor bedrock is part of Casteltort's model. Consequently, I see nothing new in the interpretation besides the finding that alluvial piedmonts at mountain fronts often display a general sloping tilt and thus have narrower branching angles on average. However, this has been known for over 10 years (Casteltort 2013) and also observed in multiple network studies.”

Response: Thank you for this comment. Casteltort and Yamato (2013) did not study junction angles.

“L. 27: "demonstrates independent[ce] of climate and optimality principles": How can the authors ensure that the generation of slopes in landscape evolution is not the effect of climate-driven erosion/deposition processes (rainfall leads to discharge and channel incision as a consequence) which follow optimization rules of landscape evolution?”

Response: Thank you for this comment. We did not intend to suggest that the generation of slopes in landscape evolution is not the effect of climate-driven erosion/deposition processes. Line 27 merely stated that the geometric principle that we argue is a constraint on fluvial network junction angles is independent of climate. *It is the geometric principle that it is independent of climate, not landscapes themselves.* In any case, we removed this sentence.

“L 35: parallel and sub-parallel networks in piedmonts v.s. dendritic and rectangular basins incised in bedrock: Is this a geological effect (alluvium vs bedrock) or simply an effect that the piedmont has a dominant regional slope?”

Response: This is an effect of the low S_i/S_r of the initial piedmont landscape following a phase of aggradation. See the response to the next comment for additional information.

“L. 40: Piedmont deposition: I don't buy the claim that the deposition cycles created initially unincised low-relief landforms because the timescales for deposition are rather similar to the timescales of valley incision. Thus one can hardly separate the two processes as they occur simultaneously. Here the authors need to provide some additional arguments which support their claim.”

Response: Thank you for this comment. We welcome the opportunity to clarify this important point.

There is abundant evidence from the Basin and Range province of the U.S.A. (which has more alluvial piedmonts than any other region in the U.S.A.) that deposition and erosion take place in separate phases on alluvial piedmonts, such that alluvial piedmont deposits are emplaced during a

depositional phase that culminates in a low-relief landscape, followed by an erosional phase during which tributary fluvial drainage networks develop.

First, it is important to note that alluvial piedmont deposits have a range of ages but deposits that pre-date the mid-Holocene period are the most common on many piedmonts. To see this, one can examine any geologic map of the Basin and Range province that recognizes multiple surficial geologic map alluvial units (as opposed to lumping them all into a single Tertiary and/or Quaternary alluvial map unit). A good example of such a map is Workman et al. (2002) (<https://pubs.usgs.gov/mf/2002/mf-2381/mf-2381-a/mf-2381-a.pdf>). All of the alluvial map units (labeled with a small “a”) other than Qay are mid-Holocene or older in age. Note that such map units are the vast majority of the total area of the alluvial piedmonts in this map. These ages represent the time since substantial alluvial deposition last took place at each location.

Christensen and Purcell (1985) documented that alluvial piedmont deposits that are Pleistocene in age or older are undergoing a phase of erosion and have had sufficient time for the distributary drainage networks characteristic of active/late Holocene portions of the piedmont to be converted (via fan-head entrenchment and abandonment of the surface as a zone of widespread deposition to one of fluvial incision) into tributary fluvial networks. The finding that Holocene deposits tend to have distributary drainage networks while Pleistocene and older deposits have tributary drainage networks has been corroborated by many studies, the best known of which to us are the many papers of the Arizona Geological Survey that have mapped alluvial piedmonts in southern Arizona and have used the distributary versus tributary nature of the drainage architecture as an age indicator (along with many other criteria including absolute dating methods). Geomorphologists working in the Basin and Range province have long used soil development as an age indicator because soil development requires a stable surface (neither widespread or substantial fluvial erosion or deposition on the surface). For example, Dempsey et al. (1993) state: “If an alluvial surface has been stable for thousands of years or more, soil fabric obscures the original sedimentary fabric... Significant soil development requires that a surface be quite stable and not subject to frequent flooding.” Soil development would not be an accurate age indicator if, as the referee concludes, alluvial piedmont deposits undergo fluvial erosion and deposition simultaneously.

We ask the editors to advise us on how to proceed in addressing this comment. We believe that the work of Bull (1991) adequately details the concepts we have briefly summarized in the last two paragraphs, hence our referencing of Bull (1991) in the preprint on the cyclic nature of deposition and fluvial incision on alluvial piedmonts is adequate. We are, however, open to expanding our discussion of this point if it is deemed necessary.

“L.56-58: If this is true, then the narrow branching angles in piedmonts are not the result of the underlying geology but a spurious effect of the gently sloping terrain. This effect has been very clearly demonstrated by Castelltort using landscape evolution models which are completely independent of the underlying geology.”

Response: Thank you for this comment. We respectfully propose that it is inaccurate to characterize this portion of our analysis as a spurious correlation and we note again that Castelltort did not study junction angles. We are using the presence/absence of late Cenozoic alluvial deposits as a proxy for the tendency of the slopes of alluvial piedmont deposits to be aligned, across a wide range of spatial scales, with the regional slope direction. As stated earlier, we have carried the data as far as they will go because the initial S_i/S_r value of a now-incised landscape cannot possibly be measured. It is common in geomorphology that some important factor of the initial landscape cannot be measured because e.g., the rocks or sediments have been removed or the landscape has otherwise evolved from some past condition that is hypothesized to control the present morphology. In such cases, the best one can do is to establish a correlation with a quantity or characteristic that is related to the property that cannot be measured and then make a process-based association between that quantity/characteristic and the property that cannot be measured. That is what we have done.

L63: “The authors fail to demonstrate that tortuosity is indeed the driver for wider junction angles compared to the arguments of Howard 1990. “may promote narrower junction angles ...” is simply not enough for a central result in a scientific publication.

Response: Thank you for this comment.

It is difficult to respond to this comment because we don’t know where the referee believes that our analysis falls short. We showed that along-valley tributary junction angles approach that of the predictions of the geometric model as the horizontal distance over which the slopes and orientations of the valley bottoms were computed is increased. Smaller horizontal distances will be more affected by tortuosity/local variations in valley-bottom orientation and that larger horizontal distances will be less affected by tortuosity/local variations in valley-bottom orientation. Referee 2 agrees with our point that Lazarus and Constantine (2009) proved that increasing values of S_i/S_r increase valley tortuosity. Figure 12a-c of the preprint demonstrates visually that greater tortuosity is associated with larger junction angles.

“L 104: the importance of piedmont deposits: As the authors have already explained in a previous paragraph, it is not the piedmont deposit (geology) that narrows the branching angle but the gentle regional slope that often comes with the depositional landscape at mountain fronts. Consequently, any sloped geology e.g. volcanic bedrock in Hawaii would also lead to the same effect.”

Response: Thank you for this comment. The piedmont nature of the landscape does matter in that piedmont deposition leads to a relatively planar, tilted initial surface, partly as a result of processes that are specific to piedmonts, i.e., the topographic diffusion associated with aggradation (Pizzuto, 1987) and the tendency of avulsions to fill in low spots on the piedmont. These processes are very different from those present in Hawaiian bedrock volcanoes (the S_i/S_r values of which we did not study and don’t feel qualified to comment on).

“L. 133: How do the authors define the basin averaged slope in the case of n-th order junctions with $n > 1$? Do they follow the longest upstream tributary up to its source, or do they average the slope of the whole upstream network tree? This point needs to be clarified.”

Response: Thank you for this comment. Clarified: “When computing BA properties, the algorithm computes the average orientation and slope of every pixel whose outlet is that junction, using every pixel upslope along directions 1, 2, and 3 (the latter being the total area comprising drainage basins 1 and 2).”

“L 190: Same as above. Do the authors use the pixel-by-pixel slope of the DEM and then average over all pixels of the upstream basin? What is the upslope along directions? These points need to be clarified.”

Response: Thank you for this comment. Clarified. We use the pixel-by-pixel slope of the DEM and then average over all pixels of the drainage basin.

“L. 229-231: “... suggests that junction angles may be systematically lower, on average, in fluvial networks incised into late-Cenozoic alluvial piedmont deposits than those incised into adjacent areas of bedrock/older deposits.” The authors need to show that the structural control on junction angle is not a spurious slope bias in gently sloped depositional landscapes such as piedmonts.”

Response: Thank you for this comment. The referee’s insistence that we identify a “structural” control on junction angles may stem, in part, from their rejection (see their L40 comment above) of our argument that deposition and erosion take place in separate phases on alluvial piedmonts. We hope that the additional justification we have offered (see above response to their L40 comment) is compelling.

“L. 316: comparison with NHD: Comparing USGS’s medium-resolution blue lines with a fixed flow accumulation threshold extracted channel network is not a fair comparison, particularly as one can obtain any drainage density by adjusting the drainage area threshold. NHDPlus (and its higher resolution companion NHDPlusHR have been extensively ground-checked). For example, I was unable to identify many of the fine channel networks from Fig. 6b/d around 32.3N/110.9W on aerial images on Google Maps.”

Response: Thank you for this comment.

We have eliminated all criticism of the NHDPlusV2 dataset. The revised version of Figure 6 is

Revised Figure 6. Comparison of the tributary fluvial valley bottom networks for the larger Tucson region. (a) Shaded-relief image of the 30 m pixel⁻¹ National Elevation Dataset (NED). Fluvial valley-bottom networks obtained in this study using (b) 30 m pixel⁻¹ NED data and (c) using 50 m pixel⁻¹ NED data.

The referee refers throughout their review to the “channel” network. The referee’s statement that they cannot find channel networks in our dataset might be explained by the fact that we are studying a different landform than the one they are looking for. Channels are defined as zones of localized water flow *with banks*. As stated throughout our preprint, we are studying valley bottoms, i.e., zones of localized water flow with or without banks. Our preprint used the word “channel” in only one context, i.e., in reference to the large (contributing areas of $> 10^4$ km²) valley-bottom channels where piedmonts of opposing orientation intersect. Otherwise, we were careful to state that we are studying valley-bottom networks, i.e., the entire fluvial network up to the point where hillslopes become convergent and transition into valley bottoms (with or without banks). If one confines oneself to the channel network only, many of the smaller valley bottoms in the fluvial system will be missed.

The referee makes a good point by noting that another dataset (NHDPlusHR, first available in a non-beta-version on July 7, 2022) became available after our work was finished. Our choice not to use the NHDPlusHR dataset was partly an issue of timing: the dataset did not exist as an official

release when we completed our work in Spring, 2020 semester (the study was performed as part of a class project during the Spring 2020 semester at the University of Arizona, although it took another four years to finalize the wording of the preprint). In addition, the NHDPlusHR dataset is relatively impractical to use for a nationwide analysis because it is distributed as many files with a total size of 952Gb. In contrast, our nationwide network was distributed as a single image with size of 216Mb. Finally, NHDPlusHR vastly undermaps the valley network (much less so than NHDPlus, but still by a lot) relative to our dataset in some areas and on alluvial piedmonts especially. Figure R2 below shows a shaded-relief image of a typical study area comprised of late-Cenozoic alluvial piedmont deposits and a portion of the adjacent mountain range (in this case the northwest side of the Tortolita Mountains near Tucson) (Fig. R2a) along with the network maps extracted using our methods (Fig. R2b) and those of NHDPlusHR (Fig. R2c). The corner coordinates are in UTM zone 12. Both our dataset and NHDPlusHR vastly undermap the many thousands of fluvial valley bottom segments that are visually apparent in the shaded-relief map (the undermapping partly results from the fact that the shaded-relief map was made from 1 m/pixel lidar-based DEMs while lower-resolution DEMs were used input for the valley-network extraction for both our dataset and NHDPlusHR). Although both our dataset and NHDPlusHR undermap the valley-bottom network in this example area, our dataset does a significantly better job at capturing the smaller valley bottoms.

We acknowledge that Figure R2 is based on only one example area. Figure R2 does not prove that our dataset is superior to NHDPlusHR generally in its resolution of small valley bottoms, let alone other metrics. That said, the example area depicted in Figure R2 is representative of the general tendency of our dataset to capture more small fluvial valley bottoms on alluvial piedmonts.

490000E, 3596000N

Figure R2.

“L. 579: I agree with the AI~elevation argument which should be easy to test. (correlation elevation~AI and correlation angle~elevation”

Response: Thank you for this comment.

We added the Spearman correlation coefficient and the statistical significance of the relationships between elevation and aridity (significant) and between elevation and the presence/absence of late Cenozoic alluvial piedmont deposits (very significant).

We did not find a statistically significant correlation between junction angles and elevation for southern Arizona. We attribute this to two possibilities: 1) the fact that the low-elevation Santa Cruz and similar valley-bottom channels of the region have junction angles close to 90° may preclude a simple correlation between mean junction angles and elevation, and 2) the fact that, while the elevation of alluvial piedmonts is always low relative to their adjacent mountain ranges, the elevation of piedmonts varies substantially from one basin to another (alluvial piedmonts exist at elevations ranging from 600 to 1500 m a.s.l. even in the relatively small southern Arizona study site). Any correlation between elevation and junction angles, therefore, would have to exist despite the potentially offsetting effects of higher mean junction angles in low-elevation portions of some bedrock mountain ranges (e.g., 700 m a.s.l.) and the lower mean junction angles in some relatively high elevation (e.g., 1500 m a.s.l.) alluvial piedmonts.

New text: “Both aridity and deposition depend on elevation (the Spearman correlation coefficient between elevation and aridity in the southern Arizona study area is $\rho = 0.034$ and $p = \sim 10^{-5}$ and between elevation and the presence/absence of late Cenozoic alluvial piedmont deposits is $\rho = -0.40$ and $p < 10^{-100}$) with lower elevation areas being more likely to be both arid (e.g., Basist et al., 1994) and depositional.”

“L 615: I agree with the author's similarity arguments between minimum power and MGM, but while MGM only relates different aspects of Earth's tomography with each other, the optimal branching models seek to explain WHY the slopes are as they are from a physical mechanistic perspective of landscape evolution in general and channel erosion in particular. Here, the topographic slope itself is only a feedback variable for flow accumulation in the erosional term of the landscape evolution equation.”

Response: Thank you for this comment.

As noted above, the ratio of slopes can be viewed as the independent variable in the geometric model, hence the geometric model is not inconsistent with any proposed control on slopes. This is also true of optimality principles: slopes can be viewed as the input to those models and junction angles are the output.

While it is not central to this rebuttal, we respectfully state that we do not believe that optimality principles are inherently superior to the geometric model because they are more process-based. The intersection of two planes is also a process, one that should not be dismissed just because it

does not explicitly relate to sediment transport, bank retreat, or some other fluvial geomorphic process. We are not aware of any paper based on optimality principles that explains why geomorphic systems should evolve to minimize stream power, momentum balance, etc. We accept that fluvial systems may evolve to minimize *gradients* of stream power as part of a maximum-entropy thermodynamics principle (e.g., Schneider and Sagan, 2005), but our understanding is that published studies of optimality principles applied to the fluvial system do not rely on such principles but instead assume that fluvial systems evolve to states of minimum power, momentum balance, etc. rather than demonstrating how or why they evolve to such states. The unanswered question is whether power minimization is a causal explanation for junction angles or a coincidental consequence of some other controlling process or principle.

The key point for this response is that we did not intend for our text to imply that optimality principles are ruled out by anything we have done. We still believe that the geometric model is an appropriate null hypothesis to consider, but we have removed the sentence that advocated consideration of the geometric model as a null hypothesis so as not to state or imply that the geometric model should be in any way favored over alternative explanations for junction angles.

Response to referee #2:

“I’ve read the paper with much interest and found it extremely well-written and fascinating. Only sometimes did I find myself a bit lost in the lengthy technical discussions, but this might be entirely my fault, as I am not an expert on the topic discussed here. Also, I appreciate that the literature and scientific debate on junction angles in tributary fluvial networks are extensive, so previous arguments need to be discussed in detail.

Being not an expert, I’ll refrain from delving into the debate regarding what drives the distribution of junction angles and how this study copes with or does not cope with earlier literature. The pros and cons of the approach are discussed in sufficient detail, and results are put into perspective with previous literature in a way that allows even a non-expert reader to navigate through the discussion, although it is very technical.

Still, I’d like to raise two possibly minor comments, one being purely terminological and the other perhaps more fundamental.

First, I’d suggest the authors avoid using the term “meandering” to describe sinuous valley patterns. Meandering refers to landforms that grow orderly rather than randomly. The fact that sinuous patterns can arise even from unordered growth, and that at low sinuosity random versus ordered shapes are not distinguishable (Limaye et al. 2021).”

Response: Thank you for this comment. We agree that the word meandering is potentially misleading in this context and have removed it.

“Second, and more importantly, the major limitation I see in the idea behind the paper is that valley sinuosity is assumed to remain fixed once their shape and sinuosity have been determined by the initial microtopography (in the way Lazarus & Constantine's idea illustrates).

Kwang et al. (2021) have demonstrated how lateral erosion/incision of rivers into bedrock is fundamental for the development of dendritic drainage networks, to the point that without lateral erosion, landscape evolution models cannot turn non-optimal, non-dendritic networks into optimal dendritic ones such as those observed in nature.

For the point being made in this paper (that valley tortuosity matters when it comes to junction angles) I think lateral erosion should be considered/discussed because it has the potential to:

Alter river valley tortuosity over time, thereby impacting junction angles.

Cause the system to lose memory of initial conditions (inducing persistent reorganization in dynamic steady-state network shape), thus critically diminishing (if not completely erasing) the effect of initial microtopography on which the authors anchor all their analyses and results.

In short, assuming that river networks evolve from initial conditions to a frozen state with no further modifications poses a strong limitations to the new perspective the authroes bring abotu regarding the drivers of junction angles in fluvial tributary networks. Later network modification by lateral river erosion into valleys, which can induce major drainage reorganization and long transience in landscape shape, should be discussed more thoroughly because it's potentially tied to how tributary channels intersect each others.

Response: Thank you for this comment.

We have included new landscape evolution modeling aimed at demonstrating how geomorphic processes may be affected by initial conditions such that both initial conditions and geomorphic processes may exert control on fluvial tributary network junction angles (we use the word “may” because any landscape evolution model is a gross approximation to the complex dynamics of real landscapes). Our LEM includes lateral migration of both ridges and valleys in that the diffusive term representing hillslopes processes will drive lateral migration in any asymmetric valley or ridge. That said, we accept Kwang et al.'s point that lateral migration driven by fluvial processes may be dominant sources of lateral migration in bedrock landscapes, and may be underestimated by our model because fluvial in our LEM is assumed to occur vertically.

New text:

“2.3.3 Landscape evolution model results with planar tilted landscapes as initial conditions

The tilted planar landscapes with random microtopography described in Section 2.3.2 were input into a standard coupled hillslope-fluvial detachment-limited landscape evolution model described by Pelletier (2013) to study junction angles on landscapes with and without geomorphic evolution (results presented in Sections 3.2.4 and 3.2.3, respectively). The hillslope diffusivity D was prescribed to be $10 \text{ m}^2 \text{ kyr}^{-1}$ and the bedrock erodibility K was chosen

to be 0.001 kyr^{-1} because these values result in landscapes with a reasonable drainage density ($\sim 0.01 \text{ m}^{-1}$). K values that are too low relative to D can fail to develop fluvial channels and those that are too high can result in landscapes with fluvial valleys that extend to every pixel in the model domain. The models were subjected to uniform uplift of 0.1 m kyr^{-1} relative to the base level at the lowest side of the square domain for 5-10 Myr, i.e., sufficient time for the landscape to reach an approximate topographic steady-state condition.”

and

“3.2.4. Results of junction-angle extraction for uniformly uplifted landscapes at steady state

Figure 13 illustrates the steady-state topography output by a landscape evolution model with initial topography corresponding to landscapes whose fluvial networks are illustrated in Figures 12a-12c.

Figure 13d illustrates that, for the lowest value of S_t/S_r illustrated in Figure 13a, the junction angle distribution is bimodal. Deep incision of the major valleys that are aligned parallel to the large-scale/regional slope triggers the development of steep low-order tributary valleys that join with the main valleys at junction angles close to 90° . Larger values of S_t/S_r have sufficient small-scale roughness that major slope-parallel valleys do not form and the junction-angle distributions are unimodal. As in the results obtained for flow over tilted planar landscapes with random microtopography in Figure 12, mean junction angles increase with increasing S_t/S_r (dashed vertical lines in Fig. 13d).

Figure 13: Results of landscape evolution models using the landscapes whose fluvial networks are illustrated in Figs. 12a-12c as initial topographies. (a)-(c) Color maps of steady-state landscapes. (d) Plot of histograms of junction angles extracted from the landscapes in (a)-(c).

Below we have detailed all of the changes we have promised to make and where those changes are to be made. We look forward to addressing any additional comments provided by the referees and editors. Thank you all for your time and interest in our work.

Abstract. The intersection of two non-parallel planes is a line. Howard (1990), following Horton (1932), proposed that the orientation and slope of a fluvial valley bottom within a tributary network are geometrically constrained by the orientation and slope of the line formed by the intersection of planar approximations to the topography upslope from the tributary junction along the two tributary directions. Previously published analyses of junction-angle data support this geometric model, yet junction angles have also been proposed to be controlled by climate and/or optimality principles (e.g., minimum-power expenditure). In this paper, we document a test of the Howard (1990) model using $\sim 10^7$ fluvial network junctions in the conterminous U.S. and a portion of the Loess Plateau, China. Junction angles are consistent with the predictions of the Howard (1990) model when the orientations and slopes are computed using drainage basins rather than in the traditional way using valley-bottom segments near tributary junctions. When computed in the traditional way, junction angles are a function of slope ratios (as the Howard (1990) model predicts), but data deviate systematically from the Howard (1990) model in a manner that we propose is the result of valley-bottom meandering/tortuosity. We map the mean junction angles computed along valley bottoms within each 2.5 km x 2.5 km pixel of the conterminous U.S.A. and document lower mean junction angles in incised late-Cenozoic alluvial piedmont deposits compared to those of incised bedrock/older deposits. To understand how this finding relates to the geometric model of Howard (1990), we demonstrate using numerical modeling that, for an idealized model of an initially unincised landform, i.e., a tilted plane with random microtopography, lower ratios of the mean microtopographic slope-small-scale roughness of the initial, pre-incision surface to the large-scale/regional slope/tilt are associated with lower mean junction angles compared to landforms with higher such ratios both before and after fluvial incision. Using modern analogs, we demonstrate that late-Cenozoic alluvial piedmonts likely had ratios of mean microtopographic slope to large-scale slope/tilt that were lower (i.e., ~ 1) prior to tributary drainage network development than the same ratios of bedrock/older deposits ($\gg 1$). This finding provides a means of understanding how the geometric model of Howard (1990) results in incised late Cenozoic alluvial piedmont deposits with lower mean tributary fluvial network junction angles, on average, compared to those of incised bedrock/older deposits. This work demonstrates that the topography of a landscape prior to fluvial incision exerts may exert a key constraint on tributary fluvial network junction angles via a fundamental geometric principle that is independent. This work adds to the list of any possible controls on fluvial network junction angles, including climate- and optimality-based principle models for junction angles that have been the primary focus of research during the past decade.

1 Introduction

Many tributary fluvial networks located on alluvial piedmonts of the Basin and Range province of the U.S.A. are parallel or subparallel (Fig. 1). The dashed curve in Figure 1b delineates the bedrock-alluvial contact of the Santa Catalina Mountains near Tucson, Arizona. South and west of this dashed curve, tributary fluvial valleys incised into late-Cenozoic alluvial piedmont deposits of the Santa Catalina Mountains (Dickinson, 1992) are predominantly parallel and sub-parallel. North and east of this curve, tributary fluvial valleys incised into the bedrock of the Santa Catalina Mountains are predominantly dendritic and rectangular. Basins and ranges of this region are separated by normal faults that juxtapose predominantly metamorphic rocks in the ranges with predominantly unconsolidated alluvium near the surface in the piedmonts/basins. In southern Arizona, normal faulting ceased c. 10 Ma (Davis, 1980) and piedmonts have since undergone several cycles of aggradation and incision driven by late-Cenozoic climatic changes and episodic incisions of valley-floor channels that act as the base level for adjacent alluvial piedmont deposits (Bull, 1991; Waters and Haynes, 2001). These cycles have resulted in alluvial piedmont deposits that, immediately post-deposition, were unincised, low-relief landforms sloping gently from the mountain front to the valley-floor channel that have since experienced incision and tributary fluvial network development.

Figure 1: Shaded relief and fluvial valley network maps of two piedmont regions characterized by predominantly parallel, subparallel, and/or pinnate fluvial networks. (a)&(b) Santa Catalina Mountains and adjacent piedmont comprised of incised late-Cenozoic alluvial deposits; (c)&(d) a portion of the late-Cenozoic alluvial Ogallala Formation in the central Great Plains of southern Nebraska and northern Kansas.

The piedmont of the Rocky Mountains, i.e., the depozone of the Miocene-to-Pliocene Ogallala Formation of the U.S.A. (Darton, 1899), feature predominantly parallel, subparallel, and pinnate drainage networks (Figs. 1c&1d) (see

Zernitz (1932) for a classification of drainage patterns that includes pinnate). As such, both regions illustrated in Figure 1 include incised late-Cenozoic alluvial piedmont deposits with what appear to be relatively low mean tributary fluvial network junction angles.

How might tributary fluvial network junction angles of incised late-Cenozoic alluvial piedmont deposits tend to be lower compared to those of adjacent bedrock/older deposits? In this paper, we test the hypothesis that the lower mean junction angles of late-Cenozoic alluvial piedmont deposits are a consequence of the tendency of their initial, unincised landforms to have lower ratios of mean microtopographic slope to large-scale slope/tilt (Fig. 2). The orientation of a fluvial valley is initially constrained by the pathways of water flow upslope of the valley, which, for networks dominated by surface runoff, must be a function of the upslope topography. Increasing microtopographic amplitudes, quantified by the root-mean-squared variation in local slope, S_l , promotes greater valley tortuosity (Lazarus and Constantine, 2013), which, in turn, may promote larger tributary fluvial network junction angles. Conversely, steeper large-scale slopes/tilts, S_r , may promote lower junction angles via the tendency of water flow pathways to be more aligned with the tilt direction as the tilt increases relative to the mean microtopographic slope that drives local variations in drainage orientations. As such, we hypothesize that S_l/S_r of an initially unincised landform may partly control tributary fluvial network junction angles.

Incised alluvial piedmont deposits are characterized by one or more cycles of aggradation and incision (Bull, 1991). At the end of an aggradational phase, alluvial piedmont deposits tend to be relatively planar, partly as a result of the topographic diffusion associated with aggradation (Pizzuto, 1987) and the tendency of avulsions to fill in low spots on the piedmont that, according to the control of junction angles by S_l/S_r tested here, may be associated with more subparallel-to-parallel surface-water-flow pathways. Quantitatively, the relief of alluvial piedmonts undergoing active transport and deposition over geologic time scales (i.e., those with predominantly Holocene deposits) is dominated by bar-and-swale topography with amplitudes of ~1 m over spatial scales of ~100 m (Frankel and Dolan, 2007) while large-scale slopes/tilts are typically on the order of one to several percent. As such, if alluvial piedmonts with Holocene deposits are adequate modern analogs for the initially unincised late-Cenozoic alluvial piedmonts that have since experienced base-level drop and tributary fluvial drainage network development, the initial S_l/S_r values for late-Cenozoic alluvial piedmonts are likely to be less than or equal to ~1. Bedrock landforms, in contrast, are generally influenced by complex patterns of faulting and folding that often preclude any substantial degree of large-scale planarity. That is, S_l/S_r is likely $\gg 1$ at all stages of the development of fluvial valleys incised into bedrock/older deposits.

Castelltort et al. (2008) and Castelltort and Yamato (2013) demonstrated the importance of S_l/S_r on the length-to-width ratio of drainage basins using digital topographic analysis and numerical modeling. In this paper we test the applicability of this concept to tributary fluvial network junction angles.

Seybold et al. (2017) and Hooshyar et al. (2017) documented mean tributary fluvial network junction angles between approximately 45° and 72° (in Seybold et al., 2017) and 49.5° and 75.0° (in Hooshyar et al., 2017). Seybold et al. (2017; 2018) attributed the variation between 45° and 72° primarily to climate (with lower mean junction angles in more arid regions). Hooshyar et al. (2017) attributed the variation in mean junction angles to process dominance (with lower mean junction angles in areas where incision is driven predominantly by debris flows). Getraer and Maloof (2021) demonstrated that a higher correlation exists between mean junction angles and the ratio of the slopes of the main and tributary valleys than between mean junction angles and the aridity index (defined as the ratio of mean annual precipitation to potential evapotranspiration, such that higher values of the aridity index are less arid), underscoring the likely importance of upslope topography on tributary fluvial network junction angles. Li et al. (2023) argued that tectonic tilting can overprint the role of climate in controlling junction angles on the steep margin of the eastern Tibetan Plateau. Further clarifying and quantifying the roles of initial topography, climate, and tectonic forcing in controlling junction angles is necessary to better understand this fundamental aspect of fluvial topography and to improve our ability to assess the extent to which junction angles may record information about climate and/or tectonics.

We begin by reviewing the geometric model for junction angles proposed by Howard (1990), following Horton (1932). This model provides a basis for quantifying how upslope topography, including the S_i/S_r of the initially unincised landform, may partly control tributary fluvial network junction angles. We then propose a novel drainage network extraction algorithm that enables the construction of a dataset of $\sim 10^7$ junction angles for the conterminous U.S.A. We document the importance of the presence/absence of incised late-Cenozoic alluvial piedmont deposits on junction angles, using southern Arizona and the conterminous U.S.A. as examples. We also consider whether late-Cenozoic aeolian deposits exhibit junction angles similar to those of late-Cenozoic alluvial piedmont deposits, using a portion of the Loess Plateau, China as an example. We then systematically evaluate the relationship between mean junction angles and S_i/S_r on tilted planar surfaces with random microtopography to test whether the signatures of the geometric model of Howard (1990) are present even in the drainage pathways that exist before any fluvial incision takes place before and after geomorphic evolution using numerical modeling.

Figure 2: Conceptual illustration of how differences in the ratio of microtopographic amplitude (quantified by the root-mean-squared variation in local slope, S_l) to the large-scale or regional slope, S_r , may control fluvial network junction angles. The landforms illustrated in both (a) and (b) have small-scale random microtopography superimposed on a planar tilted slope. The flow patterns defined by contributing area were determined by hydrologic correction and the steepest-descent routing algorithm. Landforms with a lower S_l/S_r (shown in a) result in more parallel fluvial valleys compared to landforms with a higher value of S_l/S_r (shown in b). The specific examples in this figure are ours but the concept closely follows Castellort and Yamato (2013).

2 Methods

2.1 The modified-geometric model and junction-angle extraction from Digital Elevation Models (DEMs)

2.1.1. The modified-geometric model (MGM) for junction angles

Horton (1932) proposed that the junction angle between a tributary valley bottom and a main valley bottom is determined by the intersection of the paths of steepest descent of planar approximations to the topography upslope from each tributary junction. Horton's geometric model was limited in that it assumed that the main valley had the same orientation upstream and downstream of the tributary. Howard (1990) rectified this limitation by modifying the model of Horton (1932) to include two tributaries joining together to make a larger main valley with an orientation downstream of the tributary junction that is distinct from that of either of the two valleys upstream from the tributary junction. In this paper we refer to Howard's modification of Horton's geometric model as the modified-geometric model (MGM).

In the MGM, the orientation and slope of a main valley bottom is defined by the intersection of two planes, each an approximation to the topography upslope of the tributary junction along the two directions of largest upslope contributing area. In this paper we test two versions of the MGM: one in which the topography upslope along each of

the tributary directions is the entire drainage basin (denoted as BA for basin-averaged) and another (i.e., the traditional approach) in which the topography upslope along each of the tributary directions is limited to valley bottom segments in the vicinity of the tributary junction (denoted as AVB for along-valley bottom) (Fig. 3).

The vector defining the intersection of any two planes is the cross product of the normal vectors of the planes. Howard (1990) demonstrated that the MGM predicts that the cosine of each tributary junction angle is equal to the ratio of the slopes of the main (labeled as 3) and tributary (labeled as 1 and 2) valley bottoms (Fig. 3):

$$\theta_1 \approx \cos^{-1} \left(\frac{S_3}{S_1} \right), \theta_2 \approx \cos^{-1} \left(\frac{S_3}{S_2} \right) \quad (1)$$

Equation (1) states that, as the slope between the tributary and main valley become more similar, so must their planform orientations. This is not a trivial or obvious relationship, in part because the slope is a function solely of steepness and orientation is a function solely of planform characteristics (i.e., it does not depend on any vertical aspect of the landform). The approximate signs in equation (1) reflect the fact that equation (1) is an approximation to the cross product of the normal vectors of the planes. This approximation is nearly exact for all slopes that are smaller than $\approx 60^\circ$ (i.e., essentially all fluvial valleys).

Recent analyses of junction angles (e.g., Seybold et al., 2017; 2018; Hooshyar et al., 2017; Getraer and Maloof, 2021) have considered the sum of the two tributary junction angles defined by Howard (1990), i.e., $\theta_1 + \theta_2$. Measuring θ_1 and θ_2 separately provides more complete information about the geometry of the junction (i.e., $\theta_1 + \theta_2$ quantifies how the two tributary orientations relate to one another but not how either tributary orientation relates to the main valley orientation downstream of the junction) and is necessary for testing the MGM.

The blue curves in Figure 3 illustrate the AVB flow pathways along each of the three directions emanating from the tributary junction. Thin white lines illustrate how the orientations, θ , and slopes, S , along the three directions are calculated as linear approximations to what may be tortuous AVB flow pathways. Salmon-colored shaded areas in Figure 3 illustrate the two drainage basins upslope from the tributary junction that are used to compute BA properties along the upslope directions 1 and 2. The BA properties defined along direction 3 are computed using the total area of drainage basins 1 and 2.

Figure 3: Schematic diagram illustrating the AVB junction angles θ_{avb1} and θ_{avb2} and their relationships to the steepest-descent pathways in the direction downslope from the tributary junction (labeled 3) and the directions upslope in the direction of the largest contributing area (direction 1) and the second largest contributing area (direction 2). Also illustrated are the basins 1 and 2 used to compute BA junction angles θ_{ba1} and θ_{ba2} . Inset diagram illustrating the AVB junction angles in map-view is from Howard (1990).

2.1.2. Drainage network extraction and junction angle measurement

We developed a novel algorithm for junction-angle extraction from a DEM. This Development of this algorithm was motivated by a desire to extract junction angles throughout the valley network, including those associated with relatively small valley segments that flow ephemerally and may not be identified by the types of algorithms employed by NHD and NHDPlusV2 (Benstead and Leigh, 2012; Fritz et al., 2013; Benda et al., 2016). Our algorithm identifies tributary junctions in four steps. First, all areas of internal drainage that are less than a threshold maximum depth (10 m is used here) are assumed to be areas that are noise/errors in the DEM, areas of anthropogenic infrastructure/disturbance, etc., that are best treated by hydrologic correction (the recursive fill-and-spill procedure of Pelletier (2008) is used here). Areas of internal drainage with depths larger than the prescribed threshold maximum value are assumed to be true depressions and are not filled, resulting in disconnections in the fluvial network at the downstream spill points of those areas of internal drainage. Second, contributing areas are computed for each pixel in the DEM using steepest-descent flow routing. Third, a user-prescribed threshold contributing area (0.1 km^2 is used here but the sensitivity of the results to this value was determined by repeating the analyses with 0.3 km^2) is used to

define valley heads. Fourth, for each valley bottom pixel (i,j) downslope from each valley head, we compute the ratio of the sum of the two largest contributing areas of the nearest neighbors (including diagonals) to the contributing area of pixel (i,j). If this ratio is larger than or equal to a specified threshold (0.99 is used here), the pixel is treated as a tributary junction. The ratio 0.99 means that the total contributing area from pixels other than the two largest tributaries is less than 1% of the total contributing area in pixel (i,j).

For every tributary junction thus defined, the algorithm identifies the direction of steepest descent (direction 3 in Fig. 3) and the directions of the largest (direction 1) and second-largest (direction 2) contributing areas among the nearest-neighbor pixels upslope. To compute the AVB junction angles and slopes, the algorithm searches along each of the three steepest-descent pathways (one downslope and two upslope) until the elevation change between the tributary junction and the location along each search direction is larger than a threshold value (10 m is used here but the sensitivity of the results to this value was evaluated by repeating the analyses with 5 m and 30 m). The default value of 10 m of elevation change was chosen to be sufficiently small that local orientations and slopes are being calculated but large enough that the method is not substantially biased by elevation errors/noise in the DEM. When computing BA properties, the algorithm computes the average orientation and slope of ~~the entire drainage basin~~ every pixel whose outlet is that junction, using every pixel upslope along directions 1, 2, and 3 (the latter being the total area comprising drainage basins 1 and 2).

2.2 Analyses performed on natural landforms

The analyses of this paper include both natural and synthetic landforms. The natural landforms include: Holocene alluvial piedmonts of the Ft. Irwin region of California, a portion of the Basin and Range Province of southern Arizona, a portion of the Loess Plateau in China, and the conterminous U.S.A. (CONUS).

2.2.1 Holocene alluvial piedmonts of the Ft. Irwin region

Random variations in initial topography, in addition to spatial variations in erodibility and tectonic forcing, result in tortuosity in fluvial valley bottoms that we hypothesize partly control junction angles. To investigate the potential impact of the microtopography of the initially unincised landform on fluvial network junction angles using numerical modeling, we must quantify the statistical nature of that microtopography so that we can create synthetic realizations for hypothesis testing.

We posit that Holocene alluvial piedmont deposits are an appropriate analog for the initially unincised state of late-Cenozoic alluvial piedmont deposits that have experienced tributary fluvial network development. Areas of Holocene deposits include active channels and adjacent areas that may be flood-prone during extreme flow events. They are distributary in nature, while Plio-Pleistocene deposits are typically tributary in nature due to climate-change-driven base-level changes associated with valley-floor-channel incision downstream and the fact that sufficient time has elapsed for tributary fluvial network development to occur on these deposits (Christensen and Purcell, 1985).

Formatted: Font: (Default) Times New Roman, 10 pt, Font color: Red, English (United Kingdom), Ligatures: None

In this section, we quantify the microtopography of Holocene alluvial piedmonts of the Ft. Irwin region of California because the piedmont deposits of that area are nearly all Holocene in age (Miller et al., 2013). In contrast, alluvial piedmont deposits in other portions of the Basin and Range province of California tend to be predominantly Plio-Pleistocene in age (e.g., Death Valley; Workman et al., 2002). We focused on the Basin and Range Province in California for this analysis because surficial geologic maps that distinguish Holocene and Plio-Pleistocene deposits tend to be more widely available for this region compared to other parts of the Basin and Range.

The simplest model of microtopography is one in which the elevation of adjacent pixels is uncorrelated (i.e., white noise). White-noise microtopography is not a realistic model for the microtopography of natural landforms, however, because spectral analyses of natural landforms demonstrate a generally inverse relationship between power-spectral amplitude and wavenumber (e.g., García-Serrana et al., 2018, Luo et al., 2021). In this study, we performed power-spectral analyses of along-strike transects of the microtopography of Holocene surfaces of the Ft. Irwin region using a 1 m pixel⁻¹ DEM derived from airborne-lidar data obtained from the natural resources staff of Ft. Irwin. The power-spectral behavior of microtopography thus constrained, we generated synthetic microtopography with statistical properties identical those of the Holocene alluvial piedmonts of the Ft. Irwin region for use in the junction angle analyses of tilted planar landscapes with microtopography (Section 2.3.2).

2.2.2 Southern Arizona

The motivating example in Figures 1a&1b suggests that junction angles may be systematically lower, on average, in fluvial networks incised into late-Cenozoic alluvial piedmont deposits than those incised into adjacent areas of bedrock/older deposits. We analyzed a portion of southern Arizona that includes several mountain ranges and their intervening piedmonts/basins to determine whether the lower mean junction angles of piedmonts comprised of incised late-Cenozoic alluvial deposits suggested by Figures 1a&1b can be confirmed quantitatively and over a larger region. We used the data from the National Elevation Dataset (Gesch et al., 2002) for this purpose, projected to a UTM coordinate system at 30 m pixel⁻¹ resolution.

2.2.3 Loess Plateau

We included an analysis of the tributary fluvial network junction angles of a portion of the Loess Plateau, China, in this study for two reasons. First, this region allows us to test the MGM in fluvial networks incised into an unusually homogeneous substrate (i.e., a well-sorted silt-sand deposit). Second, as an aeolian deposit, results from the Loess Plateau enable us to test whether the MGM is applicable to fluvial network development into both aeolian and fluvial deposits. We used 90 m pixel⁻¹ DEM data from the Shuttle Radar Topographic Mission (Farr et al., 2007) for this purpose.

Landform evolution in the Loess Plateau is characterized by a competition between fluvial erosion and aeolian deposition from approximately 3 Ma to the present. The Loess Plateau was a low-relief bedrock landform c. 3 Ma (Xiong et al., 2014) when climatic changes associated with the development of Northern Hemispheric ice sheets

increased the rate of dust deposition (Nie et al., 2015). Since then, fluvial valleys in the Loess Plateau region with relatively large contributing areas have been able to keep pace with aeolian deposition (large rivers such as the Ji follow the contact between the loess and the underlying Cretaceous bedrock closely, see Section 3.1.4) while hillslopes and fluvial valleys with relatively small contributing areas have not kept pace with aeolian deposition, resulting in loess aggradation.

2.2.4 Conterminous U.S.A. (CONUS)

The input DEM for junction-angle extraction for CONUS was created by downloading and merging individual tiles from the National Elevation Dataset (Gesch et al., 2002). We projected the merged DEM to the Lambert Conformal Conic (LCC) projection at 50 m pixel⁻¹ resolution. The LCC projection was chosen because it is optimally angle-preserving for large regions (Seybold et al., 2017; 2018).

2.3 Synthetic landforms

2.3.1 Idealized branching network landform

We validated the drainage-network-extraction algorithm of this paper on an idealized branching network with known junction angles. The idealized branching network used for this purpose was constructed by first digitally drawing a tributary network of known junction angles using the graphics program Canvas. That digital image file, with valley-bottom pixels assigned a value of 1 and non-valley-bottom pixels assigned a value of 0, was then used as input to a simple landform evolution model built from components described in Pelletier (2008) that include topographic diffusion and a uniform and constant vertical uplift rate in all non-valley-bottom pixels (Fig. 4).

Figure 4: Images of the idealized branching network used to test the junction-angle-extraction algorithm. (a) network, illustrating examples of the three types of junction angles present in the network. (b) Color map of the topography of the synthetic landform.

2.3.2 Planar tilted landforms with random microtopography

The second type of synthetic landform considered in this paper is random microtopography of a prescribed Gaussian distribution with root-mean-squared variation in local slope, S_l , superimposed on a plane tilted to a prescribed large-scale slope/tilt S_r . Hydrologic correction is performed on these and all other landforms analyzed in this paper, with the difference in the case of these synthetic landforms being that all depressions of any size are filled in. The junction angles of the steepest-descent pathways of such tilted planar landscapes with microtopography and hydrologic correction are instructive to consider because they have not experienced any geomorphic evolution, hence any drainage patterns they exhibit can be associated with fundamental, non-geomorphic principles.

We used the Fourier-filtering method (e.g., Malamud and Turcotte, 1999) to generate microtopography that matches the observed power-spectral form of Holocene alluvial piedmonts documented in Section 3.1.1. This method uses a pseudo-random-number generator to produce white-noise microtopography with a Gaussian distribution of values, transforms the data into wavenumber space using a 2D Fast Fourier Transform, multiplies each Fourier coefficient by

the square root of the wavenumber-dependent square root of the power spectrum, and then inverse-transforms the data back to real space.

2.3.3 Landscape evolution model results with planar tilted landscapes as initial conditions

The tilted planar landscapes with random microtopography described in Section 2.3.2 were input into a standard coupled hillslope-fluvial detachment-limited landscape evolution model described by Pelletier (2013) to study junction angles on landscapes with and without geomorphic evolution (results presented in Sections 3.2.4 and 3.2.3, respectively). The hillslope diffusivity D was prescribed to be $10 \text{ m}^2 \text{ kyr}^{-1}$ and the bedrock erodibility K was chosen to be 0.001 kyr^{-1} because these values result in landscapes with a reasonable drainage density ($\sim 0.01 \text{ m}^{-1}$). K values that are too low relative to D can fail to develop fluvial channels and those that are too high can result in landscapes with fluvial valleys that extend to every pixel in the model domain. The models were subjected to uniform uplift of 0.1 m kyr^{-1} relative to the base level at the lowest side of the square domain for 5-10 Myr, i.e., sufficient time for the landscape to reach an approximate topographic steady-state condition.

3 Results

3.1 Natural landforms

3.1.1. Power-spectral analysis of Holocene alluvial piedmonts of the Ft. Irwin region of California

Figure 5 plots the average power-spectral density of the along-strike topographic variations of two Holocene alluvial piedmonts in the Ft. Irwin region of eastern California. The Holocene age and alluvial nature of these areas is based on surficial geologic mapping by Miller et al. (2013).

Figure 5b plots the power-spectral density, S_p , averaged across all topographic transects along the N-S direction, as a function of natural wavenumber, v , for spatial scales of approximately 1-1000 m. The power spectra in both cases are similar to a Brownian walk, i.e., $S_p(v) \propto v^{-2}$, with the possible exception of a transition to a constant power-spectral density at the largest spatial scales (i.e., smallest wavenumbers). We allowed for the possibility of such a transition when generating synthetic microtopography by adopting the power-spectral model (termed a Lorentzian function):

$$S_p \propto (v^2 + v_0^2)^{-1} \quad (2)$$

where v_0 is the wavenumber of the transition from constant to Brownian power-spectral behavior and low and high wavenumbers, respectively. We chose to include this transition, despite limited evidence for it in the data of Figure 5, because Brownian walk variability tends to result from avulsions and the along-strike topographic diffusion characteristic of alluvial sedimentary basins (e.g., Pelletier and Turcotte, 1997), but only up to spatial scales associated with the spacing between adjacent drainage basins that source the piedmont or sedimentary basin. Above that spatial scale, the result of fluvial deposition is a bajada or series of coalescing alluvial fans with along-strike topography that can be expected to have reduced variance relative to a Brownian walk at the largest spatial scales. We generated synthetic microtopography with a Lorentzian power-spectrum and a prescribed root-mean-squared variation in local slope, S_l . These synthetic microtopographic examples were each superimposed on planes with a prescribed tilt, S_r .

Figure 5: Quantification of the power-spectral properties of example Holocene alluvial piedmonts in the Ft. Irwin region of eastern California. (a) Shaded relief image of example areas with zoom-in on transects shown on graphs. (b) Elevation, z , versus distance, x , of example transects. (c) Plot of the power spectrum, S_p , as a function of the natural wavenumber, v , for the landforms in (a). Also plotted are the power spectra associated with a Brownian walk and a Lorentzian, i.e., a Brownian walk that transitions to a constant spectrum at low wavenumbers.

3.1.1 Comparison Example of southern Arizona valley networks with NHDPlusV2

Figure 6 compares/illustrates the valley networks resulting from the junction-extraction algorithm of this paper to that of the NHDPlusV2 dataset for the larger Tucson region. Figure 6 illustrates that the algorithm of this paper extracts many more junctions than are mapped in NHDPlusV2. In addition, the algorithm results in a more uniform coverage of valleys compared to NHDPlusV2, which has spatial variations in drainage density that do not correspond to actual variations in drainage density readily identified in shaded-relief images (Fig. 6a). A comparison of Figures 6b&6d6c indicates that the results of the junction extraction algorithm are not sensitive to the resolution of the input DEM data between resolutions of 30 and 50 m pixel⁻¹.

— We used a threshold contributing area of 0.1 km^2 to identify valley heads because it results in fluvial valleys in the Tucson region that are similar to those that we would have identified by visual inspection. To determine whether the results are sensitive to this threshold, we repeated our analyses with an alternative value of the threshold area equal to 0.3 km^2 .

Figure 6: Comparison of the tributary fluvial valley bottom networks for the larger Tucson region. (a) Shaded-relief image of the 30 m pixel⁻¹ National Elevation Dataset (NED). Fluvial valley-bottom networks obtained in this study using (b) 30 m pixel⁻¹ NED data, (c) the NHDPlusV2 data (McKay et al., 2012), and (d) using 50 m pixel⁻¹ DEMNED data.

3.1.2 Dependence of mean junction angle on the presence/absence of Plio-Quaternary alluvial piedmont deposits in southern Arizona

Figure 7 illustrates the results of the junction-angle-extraction algorithm for a portion of southern Arizona. A visual comparison of the map of the geometric mean of all junction angles within each 2.5 m x 2.5 km square (Fig. 7b) to that of the presence/absence of Plio-Quaternary alluvial piedmont deposits indicates that mean junction angles are typically in the range of 15°–25° (red and dark blue in the color map of Figure 7b) in Plio-Quaternary alluvial piedmont deposits of southern Arizona, while mean junction angles in networks incised into bedrock/older deposits are in the range of 35°–45° (medium-to-light blue in Fig. 7b). Note that we are using the term junction angle to refer to angles θ_1 and θ_2 individually to be consistent with Howard (1990), not $\theta_1 + \theta_2$ as other recent studies have done. We use the term Plio-Quaternary to refer to the range of ages of piedmont deposits in southern Arizona and late-Cenozoic to refer to the range of age of pediment deposits in CONUS because piedmont deposits in southern Arizona are almost all

Plio-Quaternary in age, while CONUS include large deposits of Miocene age, including the vast Ogallala Formation of the Great Plains. The highest mean junction angles in southern Arizona are in the range of 60°-90° (yellow to white in the color map of Fig. 7b) and are associated with valley-floor channels where two adjacent piedmonts of opposing orientations intersect; these special cases will be further discussed in Section 3.1.3. Figure 7d plots the aridity index from Trabucco and Zomer (2019). A Spearman correlation analysis (Spearman, 1904) demonstrates that the mean junction angle computed at the 2.5-km scale is more strongly correlated with the presence/absence of Plio-Quaternary alluvial piedmont deposits (Spearman correlation coefficient of $\rho = 0.12$ and p value of $\sim 10^{-43}$) than with the aridity index ($\rho = 0.04$ and $p = \sim 10^{-5}$). The presence of Plio-Quaternary alluvial piedmont deposits was assigned a value of 0 and the absence of Plio-Quaternary alluvial piedmont deposits was assigned a value of 1 for this analysis, hence the positive value of ρ is associated with a lower mean junction angle for fluvial networks incised into Plio-Quaternary deposits than for those incised into bedrock/older deposits. Essentially identical results were obtained analysis when the analysis was repeated on a fluvial valley network extracted using a threshold contributing area of 0.3 km², i.e., the Spearman correlation coefficient is $\rho = 0.11$ and the map of mean junction angles is visually indistinguishable from Figure 7b.

It is important to emphasize that the presence/absence of late-Cenozoic alluvial piedmont deposits is a proxy for what we hypothesize is the primary control on junction angles: initial S/S_r . Lower initial S/S_r values are likely associated with late-Cenozoic alluvial piedmont deposits compared to bedrock/older deposits because such landforms tend to have a relatively low microtopographic amplitude prior to incision as a result of the avulsions and topographic diffusion associated with aggradation, e.g., local variations in elevation of ~ 1 m over spatial scales of ~ 100 m, as discussed conceptually in Section 1 and documented in the example data of Section 3.1.1.

(b) Color map of mean junction angles obtained by averaging the angles of all junctions in each 1 km² subdomain. (c) Map illustrating Plio-Quaternary alluvium and bedrock/older deposits. (d) Color map of the aridity index.

3.1.3 Comparison of southern Arizona valley networks to the predictions of the modified-geometric model -(MGM)

Figures 8a&8b plot junction angles as a function of slope ratios for southern Arizona. [Figures 8c&8d plot junction angles measured versus those predicted by the MGM using the same data as Figures 8a&8b respectively.](#) We use a logarithmic scale for the y axis of Figure 8a not to suggest any particular functional form of trends in the data but merely to spread out the data points that would otherwise cluster in the lower right corner of the graph and therefore be difficult to distinguish. Figures 8a&8b illustrate a generally inverse relationship between junction angles and slope ratios, i.e., when a relatively steep tributary joins with a main valley of much lower slope, the along-valley junction angle tends to be close to 90°. Conversely, when the incoming and outgoing valley bottom to a tributary junction have similar slopes, the junction angle approaches zero. There is substantial scatter in the data. This scatter could reflect

the imperfect nature of planar approximations to drainage basins, the local meandering/tortuosity of valley bottoms, geological heterogeneities that influence landform orientations over a range of spatial scales, etc.

Figure 8e8e plots the mean junction angles for AVB and BA properties, averaged in bins of slope ratio (each is 0.033 wide for a total of 30 bins from a slope ratio of 0 to 1). The plot of mean BA junction angles closely follows the prediction of the MGM (eqn. (1)). This result indicates that when the two upslope tributary drainage basins are approximated as planes, the intersection of those planes defines the slope and orientation of the drainage basin formed by the union of the two tributary drainage basins. The mean junction angle calculated using AVB properties is systematically shifted to the left relative to the curve for BA properties, i.e., for the same value of the slope ratio, AVB junction angles tend to be similar for the end-member cases of slope ratios close to 0 and 1 but are lower than the BA junction angles for cases in which the slope ratios are mid-ranged, i.e., 0.4–0.6. In Section 3.2.5 we will delve more deeply into the possible reasons for this shift and the dependence of the results on the elevation change over which the AVB junction-angle data are computed.

The presence of relatively large mean junction angles along large valley-floor channels in southern Arizona such as the Santa Cruz and San Pedro Rivers (locations in Fig. 7b) is an exception to the tendency of Plio-Quaternary alluvial piedmont deposits in southern Arizona to have lower junction angles. This exception is, however, consistent with the MGM because adjacent valley bottoms within a single piedmont tend to have slopes similar to each other and to the large-scale slope of the piedmont (typically on the order of 10^{-2} m m^{-1}), but when the relatively steep piedmont valleys join with large valley-floor channels such as the Santa Cruz and San Pedro Rivers (which have slopes $\sim 10^{-4}$ to 10^{-3} m m^{-1}), the slope ratios S_{avb3}/S_{abv1} and S_{avb3}/S_{abv2} will typically be ~ 0.01 – 0.1 . The MGM accurately predicts mean junction angles of close to 90° for such junctions involving valley-floor channels.

Figure 8: Plots illustrating the relationships of junction angles to the ratios of slopes downslope and upslope of the junctions for the portion of southern Arizona illustrated in Figure 5. (a) Plot of junction angles measured using BA properties as a function of the ratio of slopes downslope and upslope. (b) Plot of junction angles measured using AVB properties as a function of the ratio of slopes downslope and upslope. (c)&(d) Plots of observed junction angles versus those predicted by the MGM using the data of (a)&(b), respectively. (e) Plots of junction angles measured both AVB (using three different values of the elevation change over which slopes and orientations are computed) and BA properties.

3.1.4 Results for a portion of the Loess Plateau, China

Figure 9 illustrates the results of the junction-extraction algorithm for a portion of the Loess Plateau, China. Figure 9d illustrates the same types of plots for the Loess Plateau as were presented in Figure 8b for the southern Arizona region.

The results are essentially identical, i.e., the relationship between the mean BA junction angles and slope ratios follow the MGM closely while the AVB data are shifted to the left and have a concave-up rather than a concave-down relationship between junction angle and slope ratio.

Another way of quantifying the dominant role of slope ratio is to plot probability density functions of AVB junction angles for several different ranges of slope ratios (Fig. 9c). For slope ratios less than 0.1, AVB junction angles have a peak in the distribution of values of approximately 80°-90°. For increasing slope ratios, the peaks in the distributions of junction angles systematically decline to lower values. The distributions obtained for portions of CONUS (not shown) are less systematic than those plotted in Figure 9d, consistent with the hypothesis that the relatively straight (low tortuosity) valley bottoms of the Loess Plateau region result in an unusually close correspondence between junction angles and slope ratios. The similarity between results from the Loess Plateau and southern Arizona suggest that the trends we observe are not specific to a particular geographic area or to the processes responsible for the deposition of the substrate (e.g., aeolian versus fluvial) into which fluvial-network development has occurred.

(d) Plot of histograms of AVB junction angles for four ranges of slope ratios. (e) Plot of junction angles as a function of slope ratios for both BA and AVB properties.

3.1.5 Results for the conterminous U.S.A. (CONUS)

Figure 10 illustrates the input data for the analysis of junction angles in CONUS. Figure 10a is a shaded relief image of the NED in LCC projection. The GitHub repository for this paper (Pelletier, 2024) includes an image of the entire

drainage network map of the area extracted by the algorithm along with the positions, angles, and slope ratios of each of the 19,682,591 junctions. Figure 10b is a grayscale map of the surficial geologic map of Soller et al. (2009) simplified to three map units: 1) Plio-Quaternary alluvium and the Miocene-to-Pliocene Ogallala Formation, 2) bedrock and older alluvial deposits, and 3) glacial/aeolian deposits. Our statistical analysis of tributary fluvial network junction angles presented here includes only the areas in white (late-Cenozoic alluvial piedmont deposits) and dark gray (bedrock/older deposits) to avoid the drainage contortions that may be associated with glacial/aeolian deposits.

Figure 10: (a) Shaded relief map of the conterminous U.S.A. in Lambert conformal conic projection. (b) Surficial geologic map of the conterminous U.S.A. (Soller et al., 2009) simplified to three units.

Figure 11a is a color map of the geometric mean of all junction angles within each 2.5 m x 2.5 km square in CONUS. This figure illustrates that mean junction angles are commonly in the range of 35°–45° in large parts of CONUS. Mean junction angles are generally lower, i.e., 15°–25° in areas of late-Cenozoic alluvial piedmont deposits (i.e., the Ogallala Formation (Figs. 11b&11c) and in piedmonts of the western U.S.A. (Figs. 11d&11e)). The change in mean junction angle between relatively low values associated with late-Cenozoic alluvial piedmont deposits and higher values associated with bedrock/older deposits occurs abruptly at bedrock-alluvial contacts, not gradually as would be the case if climate were the primary control on junction angles (given that aridity changes gradually with elevation compared

to the abrupt transition in presence/absence of late-Cenozoic alluvial piedmont deposits that occurs at mountain fronts). Junction angles can be relatively high, i.e., close to 90° , along some of the major rivers of the Great Plains (e.g., the Platte, Republican, Arkansas, and Cimarron Rivers), similar to the pattern observed along the major valley-floor channels of southern Arizona in Figure 8 where two piedmonts of opposing orientation intersect.

Figure 11: Color maps of junction angles averaged for every 2.5 x 2.5 km in the conterminous U.S.A. Junction angles tend to be lower in areas with late-Cenozoic deposits of (b)&(c) the Great Plains and (d)&(e) the Basin and Range province of the southwestern U.S.A.

A Spearman correlation analysis for CONUS demonstrates that the mean junction angle computed at the 2.5 km scale has a correlation coefficient with the presence/absence of late-Cenozoic alluvial piedmont deposits (Spearman correlation coefficient of $\rho = 0.11$ and p value of $<10^{-100}$) that is approximately fifty times higher than for the correlation coefficient with the aridity index ($\rho = 0.002$ and p value of 0.01). This analysis was repeated with drainage networks extracted using a threshold area of 0.3 km². The Spearman correlation coefficient is essentially identical to the one obtained with the threshold contributing area of 0.1 km², and the map of mean junction angle obtained with a threshold contributing area of 0.3 km² is visually indistinguishable from Figures 11b&11d.

3.2 Synthetic landforms

3.2.1. Idealized branching tree test

The idealized branching tree used to test the junction angle extraction algorithm (Fig. 4) has two junctions of 45°, eight junctions of 40°, two junctions of 35°, and fourteen junctions of 30°. The algorithm extracts the two 45° junctions with a mean of 44.7° and a standard deviation of 0.3°, the eight 40° junctions with a mean of 39.3° and a standard deviation of 1.0°, the two 35° junctions with a mean of 36.3° and a standard deviation of 0.8°, and the fourteen 30° junctions with a mean of 29.9° and a standard deviation of 0.9°.

3.2.3. Results of junction angle extraction for flow over tilted planar landforms with random microtopography

The networks defined by steepest-descent directions for flow over tilted planar landforms with random microtopography and hydrologic correction illustrated in Figures 12a-12c transition from lower mean junction angles to higher mean junction angles with increasing S_i/S_r . In Section 1, we estimated that $S_i/S_r \sim 1$ in incised late Cenozoic alluvial piedmont deposits, hence the results in Figure 12a are most applicable to those portions of the landscape. We also estimated that S_i/S_r is likely $\gg 1$ in bedrock and older deposits that have been faulted or folded prior to or coeval with tributary drainage network development. As such, the results in Figure 12b&12c are most applicable to those portions of the landscape. Figure 12d plots the junction-angle histograms associated with the fluvial networks in Figures 12a-12c. Figure 12d demonstrates a systematic increase in mean junction angle (indicated by the vertical dashed lines near the top of the graph) with increasing S_i/S_r . Figure 12e plots the mean junction angle as a function of S_i/S_r for 30 different realizations of these synthetic landforms constructed with a range of values for S_i , S_r , and v_0 . Mean junction angles systematically increase with S_i/S_r and are not sensitive to v_0 . Figure 12f illustrates the equivalent of Figures 8b&8d for flow over tilted planar landforms with random microtopography. These results are similar to those for the landforms of southern Arizona and the Loess Plateau, i.e., junction angles computed using BA properties closely follow the predictions of the MGM while those computed using AVB properties match the predictions of the MGM for slope ratios near 0 and 1 but deviate from the predictions of the MGM for junction angles associated with slope ratios that are mid-ranged.

Figure 12: Results for flow over tilted planar landforms with Lorentzian microtopography. (a)–(c) Fluvial networks obtained with increasing values of S_l/S_r . (d) Plot of histograms of along-valley bottom junction angles for the fluvial networks illustrated in (a)–(c). (e) Plot of mean AVB junction angles as a function of S_l/S_r for a range of values for S_l and S_r . (f) Plots of junction angles as a function of slope ratios for BA and AVB properties.

3.2.4. Results of junction-angle extraction for uniformly uplifted landscapes at steady state

Formatted: Justified, Space After: 0 pt, Line spacing: 1.5 lines

Formatted: Font: (Default) Times New Roman, 10 pt, Not Italic, English (United Kingdom), Ligatures: None

Figure 13 illustrates the steady-state topography output by a landscape evolution model with initial topography corresponding to landscapes whose fluvial networks are illustrated in Figures 12a-12c.

Figure 13d illustrates that, for the lowest value of S_l/S_r illustrated in Figure 13a, the junction angle distribution is bimodal. Deep incision of the major valleys that are aligned parallel to the large-scale/regional slope triggers the development of steep low-order tributary valleys that join with the main valleys at junction angles close to 90° . Larger values of S_l/S_r have sufficient small-scale roughness that major slope-parallel valleys do not form and the junction-angle distributions are unimodal. As in the results obtained for flow over tilted planar landscapes with random microtopography in Figure 12, mean junction angles increase with increasing S_l/S_r (dashed vertical lines in Fig. 13d).

Figure 13: Results of landscape evolution models using the landscapes whose fluvial networks are illustrated in Figs. 12a-12c as initial topographies. (a)-(c) Color maps of steady-state landscapes. (d) Plot of histograms of junction angles extracted from the landscapes in (a)-(c).

3.2.4. Why do junction angles computed using BA properties follow the MGM while those computed using the MGM deviate systematically from the MGM?

Previous sections have documented that the trends in mean junction angle versus slope ratio are different for BA and AVB properties (with data for BA properties consistent with the MGM and data for AVB properties deviating

systematically from the MGM). We posit that AVB properties deviate from the predictions of the MGM in part due to local variations in valley-bottom orientation associated with valley meandering/tortuosity. To test this hypothesis, we varied the scale over which AVB slopes and orientations are computed for southern Arizona using an elevation change over which valley-bottom slopes and orientations are computed of 5 m and 30 for comparison with the results obtained using the default value of 10 m. Figure 8c demonstrates that computing the AVB properties using a larger elevation change results in data that are more consistent with the predictions of the MGM compared to the results obtained using AVB properties computed over a smaller elevation change. BA properties represent the end-member case of computing slopes and orientations using all points in a drainage basin, thus eliminating any BA properties eliminate all randomness/variation due to local valley meandering/-bottom tortuosity. These results support the hypothesis that AVB properties deviate from the predictions of the MGM at least in part due to variations valley-bottom orientations associated with valley meandering/tortuosity.

4 Discussion and Conclusions

4.1 Summary of key findings

Using a novel junction-angle extraction algorithm tested using an idealized branching network with known junction angles, we developed a database of $\sim 10^7$ junction angles for CONUS. Mean junction angles computed using basin-averaged properties are consistent with the MGM while mean local along-valley-bottom orientations and slopes deviate systematically from the MGM, a deviation that we propose is likely the result of variations in slopes and/or orientations associated with valley-bottom meandering/tortuosity. We mapped the spatial distribution of mean junction angles at 2.5-km scale and documented systematically lower mean junction angles in locations of incision into late-Cenozoic alluvial piedmont deposits compared to incision into bedrock/older deposits. We posited that areas of late-Cenozoic alluvial deposition likely have a low initial ratio of mean microtopographic slope to the large-scale slope/tilt because alluvial deposition is associated with avulsion and topographic diffusion that, at analog sites such as the Holocene alluvial piedmonts of Ft. Irwin, are characterized by unusually low microtopography (i.e., ~ 1 m over spatial scales of ~ 100 m). We demonstrated that lower ratios of mean microtopographic slope to the large-scale slope/tilt are associated with lower mean junction angles even before any fluvial incision takes place (Fig. 12).

4.2 ~~Comparison of~~ **Potential limitations associated with the junction-angle dataset of this paper to NHDPlusV2**

~~Several recent junction-angle studies (e.g., Seybold et al., 2017; 2018, Getraer and Maloof, 2021) are based on the NHDPlusV2 dataset (McKay et al., 2012). The NHDPlusV2 dataset has two limitations/drawbacks that motivated our development of the alternative junction-angle dataset for CONUS presented here. First, the NHDPlusV2 does not include many small valleys visually apparent in shaded-relief DEMs of southern Arizona (Fig. 6e versus Fig. 6d). Differences in drainage density are apparent across political (e.g., county) boundaries in the NHDPlusV2 dataset, suggesting that the criteria used to define a valley in that dataset vary in a manner that depends on boundaries that are arbitrary from a geomorphic perspective. Second, the digital topographic analysis used to estimate along-valley-bottom slopes in NHDPlusV2 includes a procedure that reverses negative slopes (McKay et al., 2012, p. 122). The algorithm of this paper obviates the need to enforce such slope reversals by computing the along-valley-bottom slope~~

over a horizontal distance that automatically varies because it is based on a prescribed along-valley-bottom elevation change, hence areas of lower slopes necessarily have their slopes computed over a longer horizontal baseline that guarantees positive slopes.

Our approach of extracting tributary valley networks using a uniform threshold contributing area for identifying valley heads has drawbacks that we want to clearly acknowledge, including the potential for over-mapping valleys in some areas and under-mapping valleys in others. More advanced procedures for valley-network extraction use a threshold contour curvature rather than a threshold contributing area for identifying valley heads (e.g., Pelletier, 2012; Hooshyar et al, 2017). We chose not to use such an approach in this study because drainage network extraction at 1 m pixel⁻¹ resolution for all of CONUS would be computationally difficult. We mitigated potential problems with using a uniform threshold contributing area for valley-head identification by demonstrating that the results are independent of the threshold contributing area value chosen within a reasonable range (0.1 to 0.3 km²).

While we acknowledge the limitation of using a uniform threshold contributing area to identify valley heads, we also wish to note that the use of such a threshold does not result in uniform hillslope lengths because variations in the degree of topographic convergence translate into a range of hillslopes lengths even when a uniform threshold contributing area is used to identify valley heads. To see this, consider the difference in hillslopes lengths between a planar hillslope (oriented along a cardinal direction to simplify the example) with pixel size of 50 m versus a convergent hillslope, square-shaped in planform, formed by the intersection (along the diagonal of the square) of two planes with aspects that differ by 90°. In the case of the planar hillslope valley heads will be identified (using a threshold contributing area of 0.1 km²) at every pixel located 2000 m from the drainage divide because all flow pathways are parallel and 50 m x 2000 m equals the prescribed contributing area threshold of 0.1 km². The convergent hillslope of maximum contributing area of 0.1 km² has a maximum length along the diagonal of 447 m (i.e., the hypotenuse of an isosceles right triangle with legs of length equal to the square root of 0.1 km² or 316 m). As such, the use of a uniform threshold contributing area for identifying valley heads, while simplistic, nevertheless allows hillslope lengths to vary by approximately a factor of 4.

4.3 Comparison of results to prior studies

Slope, aridity, and stream-groundwater interactions have been proposed as primary controls on junction angles (Horton, 1990; Seybold et al., 2017; 2018; Freund et al., 2023). Yi et al. (2018) further related aridity to the drainage basin aspect ratio and Hack exponent. Based on analyses of junction angles derived from NHDPlusV2, Seybold et al. (2017; 2018) demonstrated a correlation between mean junction angles and the aridity index in CONUS that was stronger than the correlation between mean junction angles and slope. Seybold et al. (2017) further demonstrate that junction angles approach 72° as the water table ratio, which quantifies how closely a groundwater aquifer is coupled to surface processes, increases. This is consistent with the theoretical prediction of a 72° junction angle in systems dominated by groundwater-driven erosion (Devauchelle et al., 2012). While the relative dominance of subsurface flow versus surface flow could play an influential role in controlling junction angles, our findings also Yi et al. (2018)

further related aridity to the drainage basin aspect ratio and Hack exponent. We suggest that the correlations ~~that Seybold (2017; 2018) between junction angles and Yi et al. (2018) attributed to aridity may~~ could be more directly related to the presence/absence of late Cenozoic alluvial piedmont deposits, ~~because both. Both~~ aridity and deposition depend on elevation, ~~i.e., lower (the Spearman correlation coefficient between elevation and aridity in the southern Arizona study area is $\rho = 0.034$ and $p \sim 10^{-5}$ and between elevation and the presence/absence of late Cenozoic alluvial piedmont deposits is $\rho = -0.40$ and $p < 10^{-100}$) with lower-elevation areas are~~ being more likely to be both arid (e.g., Basist et al., 1994) and depositional.

~~The correlations between junction angles and their controlling parameters depend on the scale over which junction angles are averaged. Seybold et al. (2017; 2018) averaged all junction angles in each Hydrologic Unit Code 6 drainage basin (average contributing area of $\sim 30,000 \text{ km}^2$) to arrive at a single value of mean junction angle against which aridity was compared. Averaging over such large scales results in junction angles from areas with bedrock/older deposits being lumped together with those of late Cenozoic piedmont alluvial deposits. Some averaging of junction angles is likely necessary when studying the controls on tributary junction angles because averaging is helpful for identifying trends that may otherwise be obscured by the specific pattern of valley-bottom meandering/tortuosity near tributary junctions. We propose, however, that it is necessary~~Correlations between junction angles and their controlling parameters depend on the scale over which junction angles are averaged, though the optimal spatial scale over which to average junction angles ~~over areas that are~~ subjective and is likely made based on the relevant spatial scales for hypothesized controls on junction angles. For example, we average junction angles over 6.25 km^2 since this ~~is~~ sufficiently small to resolve the presence/absence of late Cenozoic alluvial piedmont deposits (~~2.5 km is used here~~). ~~Averaging over larger scales could result in junction angles from areas with bedrock/older deposits being lumped together with those of late Cenozoic piedmont alluvial deposits, which could alter the relative strength of different correlations~~ given the fundamentally different nature of the initial topography in cases of drainage development into late Cenozoic alluvial piedmont deposits compared to drainage development into bedrock/older deposits. Seybold et al. (2017; 2018) averaged all junction angles in each Hydrologic Unit Code 6 drainage basin (average contributing area of $\sim 30,000 \text{ km}^2$) to arrive at a single value of mean junction angle against which aridity was compared. ~~Variations in the relative strength of correlations between mean junction angles, slope, and aridity found here and in past studies could therefore be attributed to differences in the spatial scale over which junction angles are averaged. We suggest that averaging over relatively small spatial scales (e.g. $1\text{-}10 \text{ km}^2$) is beneficial due to the influence of initial topography on junction angles and variations in initial topography due to the presence/absence of late Cenozoic alluvial piedmont deposits.~~

~~The~~Conceptual models and theoretical predictions offer support for a climate-based control on junction angles (e.g. Devauchelle et al., 2012; Seybold et al., 2017). One climate-based model for junction angles is based on a two-step conceptual model in which 1) greater aridity results in less infiltration that, in turn, results in 2) increased erosion by surface water flows that cause fluvial valleys to align more closely with the large-scale slope/tilt (Seybold et al, 2017, p. 2278). Whether or how increased erosion rates cause fluvial valleys to align themselves more closely with the large-

scale slope/tilt is unknown, but more arid regions are not associated with less infiltration relative to precipitation. On a mean-annual basis, Budyko (1974) demonstrated that runoff coefficients are generally lower in more arid areas, indicating more infiltration and/or evapotranspiration relative to precipitation in such climates. On an event basis, which is likely the most relevant time scale for assessing erosional efficiency, runoff coefficients are sufficiently complex (i.e., dependent on the seasonality of precipitation, presence/absence of substantial snowmelt runoff, etc.) that no clear relationship with aridity exists for all of CONUS (Stein et al., 2021). However, any tendency for hillslopes in areas of greater aridity to have higher runoff coefficients due to a prevalence for infiltration-excess overland flow is likely to be counteracted by the tendency of runoff coefficients in such climates to decrease as a result of the spatial variability of precipitation, large channel transmission losses (Simanton et al., 1996), and greater plant water-use efficiency (Troch et al., 2009). The non-monotonic relationship that has been observed between mean annual sediment yield and mean annual precipitation (Langbein and Schumm, 1958) also indicates the presence of complex interactions between vegetation, surface water runoff, and sediment yield that could similarly lead to a non-monotonic relationship between aridity and erosion by surface water runoff. We hypothesize that these factors contribute to the scatter we observe between mean junction angles and aridity.

Seybold et al. (2017) and Hooshyar et al. (2017) documented $\theta_1 + \theta_2$ values in the range between 45° and 72° in Seybold et al. (2017) and 49.5° and 75.0° in Hooshyar et al. (2017). Hooshyar et al. (2017) associated 49.5° with drainage networks incised primarily by debris flows. They inferred debris-flow dominance by assuming that the topographic signature of debris-flow-dominant erosion is a fluvial channel slope-area scaling exponent that is less negative (i.e., closer to zero) in such drainage basins compared to those in drainage basins dominated by fluvial erosion. The results presented here could potentially be reconciled with those of Hooshyar et al. (2017) if tributary fluvial networks incised into late-Cenozoic piedmont alluvial deposits have slope-area scaling exponents with smaller absolute values (again, due to lower initial S_0/S_c) compared to those of incised bedrock/older deposits.

A persistent An important hypothesis in the junction-angle literature is that junction angles evolve toward a state of minimum-power expenditure (Strong and Mudd, 2022 and references therein). Howard (1990) (his Table 1) demonstrated that the predictions of such optimality principles are nearly indistinguishable from those of the MGM. Minimum-power relationships make similar predictions to those of the MGM because slope and contributing area/discharges tend to be inversely correlated in fluvial systems, hence the MGM-based relationship between junction angles and slopes also presents as a relationship between junction angles and contributing areas/discharges (which relate to power expenditure). We view the debate about whether optimality principles or some more fundamental mechanism such as the MGM is the primary control on tributary fluvial network junction angles as analogous to the debate over how to interpret Horton's Laws for such networks. Horton's Laws have been interpreted to be a result of optimality (e.g., Rigon et al., 1993), but Kirchner (1993) proved that they are statistically inevitable given the branching architecture that results from Strahler ordering on a surface that is required to drain an area through a point. Similarly While the agreement between junction angles and those predicted by the MGM does not contradict conceptual frameworks for optimality and climatic controls on junction angles, we propose that the MGM represents

a fundamental/~~inevitable~~ constraint ~~that should be considered as a null hypothesis before less fundamental/inevitable principles are proposed as primary controls on junction angles.~~on junction angles.

4.4 Additional factors that may contribute to the larger junction angles of fluvial networks incised into bedrock

The existence of an initial, pre-incision topography characterized by random microtopography superimposed on a large-scale slope/tilt is reasonable for late-Cenozoic alluvial piedmont deposits but less clearly applicable in cases of fluvial-network development into bedrock/older deposits. Such landforms may be shaped by faulting and folding that occurs over a broad range of spatial and temporal scales as well as by relief production via spatial variations in bedrock erodibility. By focusing our analysis on the flow that occurs on tilted planes with varying degrees of small-scale topographic roughness, we have left out many potential mechanisms, particularly those in bedrock landforms, that may influence junction angles, including preferential erosion along vertically oriented joints (Pelletier et al., 2009), lateral tectonic advection (Hallet and Molnar, 2001), etc. We emphasize the role of initial S_i/S_r in this study because we believe that it is the most relevant factor for understanding the spatial variations in mean junction angles in CONUS, especially the difference between incised late-Cenozoic alluvial deposits and bedrock/older deposits. However, it is far from the only control on fluvial network junction angles.

It is also important to note that relatively low mean junction angles are found in some bedrock landscapes where drainage divides are unusually linear in planform and slopes are especially steep. Figure 13.14, for example, illustrates parallel and subparallel drainage development in bedrock using the Cambrian sedimentary rocks (Wrucke and Corbett, 1990) of the Lost Chance Range of California (Fig. 13a14a) and the granite and schist (Bryan, 1925) of the Mohawk Mountains of Arizona (Fig. 14b) as examples. The relatively low junction angles of such steep bedrock terrains are broadly consistent with the MGM because the relatively linear nature of the drainage divide in planform and the steep nature of the large-scale slope/tilt are likely associated with relatively low initial S_i/S_r values in such cases than is typical in bedrock landscapes.

Figure 1314: Oblique aerial photographs of portions of subparallel drainage networks incised into bedrock in (a) sedimentary rocks of the Lost Chance Range, California, and the granite and schist of the Mohawk Mountains, Arizona.

Code/Data Availability DEM data and codes used to extract junction angles are available at Pelletier (2024).

Author contributions JDP wrote the codes and the paper. RGH compiled the input data for CONUS. RGH, OH, and BF participated in the analysis. JDP benefitted from discussions with LAM on this problem for the past 10+ years.

Competing interests The authors declare they have no competing interest.
