16 **Abstract**

17 Solid fuel (SF) combustions, including coal and biomass, are important sources of pollutants in the
18 particle and gas phase and therefore have significant implications for air quality, climate, and human
19 health. In this study, we systematically examined real-time gas-phase emissions using the Vocus proton-
20 transfer-reaction time-of-flight mass spectrometer, from a variety of solid fuels, including beech logs,
21 spruce and pine logs, spruce and pine branches and needles, straw, cow dung, and coal. The average
22 emission factors (EFs) for organic gases ranged from 6.7 to 74.2 g kg⁻¹, depending on the combustion
23 phases and fuel types. Despite slight differences in modified combustion efficiency (MCE) for some
24 experiments, increasing EFs for primary organic gases were observed with lower MCE. The C_xH_yO_z
25 family is the most abundant group, but a greater contribution of nitrogen-containing species and C_xH_y
26 families (related to polycyclic aromatic hydrocarbons) could be found in cow dung burning and coal
27 burning, respectively. Intermediate volatility organic compounds (IVOCs) also constituted a
28 considerable fraction in solid-fuel combustions (from 12.6% to 39.3%), especially for spruce and pine
29 branches and needles (39.3%), and coal (31.1%). Despite the large variability of EFs in the organic gas
30 emissions, the relative contribution of different classes showed large similarities between the
31 combustion phases in beech stove burning. The product from pyrolysis of coniferyl-type lignin and the
32 extract of cedar pine needle were identified as characteristic compounds in the spruce and pine branches
33 and needles open burning (e.g., C₁₀H₁₄O₂, C₁₁H₁₄O₂, C₁₀H₁₀O₂). The characteristic product (C₉H₁₂O)
34 from the pyrolysis of beech lignin was identified as the characteristic compound for beech log stove
35 burning. Many series of nitrogen-containing homologues (e.g., C₁₀H₁₁₋₂₁NO, C₁₂H₁₁₋₂₁N, C₁₁H₁₁₋₂₃NO
36 and C₁₅H₁₅₋₃₁N) and nitrogen-containing species (e.g., acetonitrile, acrylonitrile, propanenitrile,
37 methylpentanenitrile) were specifically identified in cow dung burning emissions. Polycyclic aromatic

38 hydrocarbons (PAHs) with 9-12 carbons were identified with significantly higher abundance from coal
39 burning compared to emissions from other studied fuels. The composition of these characteristic organic
40 vapors reflects the burned fuel types and can help constrain emissions of solid fuel burning in regional
41 models.

42 **Keywords:** Vocus, solid fuel, primary emission, characteristic compounds, combustion phase

43 **1 Introduction**

44 Solid fuels (SFs), including coal and biomass, are a primary source of domestic heating worldwide (Tao
45 et al., 2018; Oberschelp et al., 2019; Wu et al., 2022). In developing regions, such as India, more than
46 80% of rural households use biomass as cooking fuel (Balakrishnan et al., 2011). Firewood is mainly
47 used for rural households, followed by crop residues and cow dung ‘cakes’, which are made of a mixture
48 of dried cow dung and crop residues (Loebel Roson et al., 2021; Chandramouli and General, 2011). In
49 Europe, fireplaces and woodstoves are used for domestic heating in winter, which have considerable
50 impacts on air quality, resulting in intense ‘smog’ events (Kalogridis et al., 2018; Fourtziou et al., 2017;
51 Bailey et al., 2019; Font et al., 2022). China is the largest producer and consumer of coal in the world.
52 In China and some Eastern European countries like Poland, coal is widely used for domestic purposes,
53 such as heating and cooking of households, due to its cost-effectiveness and easy accessibility (Guo et
54 al., 2021; Stala-Szlugaj, 2018). The combustion of these solid fuels has been recognized as the main
55 source of anthropogenic emission of atmospheric pollutants that elicit adverse effects on air quality and
56 human health (Wu et al., 2022; Zhang and Smith, 2007).

57 Wildfires or bushfires have become more frequent in many regions due to heatwaves and drought
58 (Weber and Yadav, 2020; Williams et al., 2012). SF combustion, including wildfires, is a major source
59 of non-methane organic gases (NMOGs) to the atmosphere, emitting hundreds to thousands of different
60 organic gas-phase species (Hatch et al., 2019; Koss et al., 2018; Permar et al., 2021). Once emitted,
61 evaporated vapors or freshly emitted burning NMOGs will oxidize to produce oxygenated organic gases
62 with a broad volatility range. These organic gases with sufficiently low volatility will nucleate or
63 condense onto pre-existing aerosols to form secondary organic aerosols (SOA) (Kumar et al., 2023).

64 The identification of characteristic compounds for each emission source will be highly valuable in
65 evaluating SOA formation potential and ambient source contributions. Liu et al. (2008) identified
66 potential characteristic volatile organic compounds for different emission sources (e.g., biomass
67 burning, mobile sources and painting). Nevertheless, these commonly used characteristic compounds
68 are well-established, yet due to their presence in more than one type of biomass fuel, distinguishing
69 between different biomass-burning sources presents challenges. Since 2009, there have been many
70 advancements in the gas-phase measurements of SF, which include lab studies (Bruns et al., 2017;
71 Bruns et al., 2016; Bhattu et al., 2019) and large field campaigns (e.g., WE-CAN Aircraft Measurements,
72 FIREX-AQ campaign) (Permar et al., 2021; Jin et al., 2023; Majluf et al., 2022). However, efforts
73 toward understanding SOA formation in burning plumes have been hindered by limited identification
74 and quantification of NMOGs emitted by fires, especially intermediate volatility organic compounds
75 (IVOCs) (Akagi et al., 2011). Laboratory and field campaigns suggest that intermediate volatility
76 organic compounds are important precursors of SOA. Grieshop et al. (2009) demonstrated that
77 traditional SOA precursors account for less than 20% of the observed SOA formed from residential

78 wood combustion emissions, while IVOCs can contribute approximately 70% of the formed SOA (Li
79 et al., 2024), which highlights the urgent need for more research on IVOCs from biomass burning
80 emissions.

81 Adding an IVOC emission inventory to an air quality model can significantly narrow the gap between
82 the estimated and measured SOA concentrations (Li et al., 2024; Hodzic et al., 2010; Zhao et al., 2016;
83 Robinson et al., 2007).

84 Offline sampling methods such as canisters and adsorption-thermal desorption (ATD) cartridges, along
85 with gas chromatography (GC) analysis, have limitations related to their low time resolution,
86 susceptibility to sampling artifacts, and a limited range of measurable compounds (Hatch et al., 2018;
87 Hatch et al., 2017). In addition to offline techniques, proton-transfer-reaction mass spectrometry (PTR-
88 MS) has been widely used for the online measurement of volatile organic compounds (VOCs) in the
89 atmosphere (Yuan et al., 2017). However, IVOCs still suffer from high losses in the sampling lines and
90 PTR-MS drift tubes. Furthermore, most studies have focused on either primary or aged emissions, with
91 very few examining the real-time influence of combustion conditions on the composition of emitted
92 organic gases (Bruns et al., 2016; Akherati et al., 2020; Tkacik et al., 2017). The recently developed
93 Vocus PTR time-of-flight mass spectrometer (hereafter Vocus) has greatly enhanced sensitivity due to
94 a newly designed chemical ionization source (Krechmer et al., 2018), and it can detect a broader
95 spectrum of VOCs, IVOCs, and their oxygenated products (up to six to eight oxygen atoms for
96 monoterpene oxidation products) (Li et al., 2020; Wang et al., 2021; Riva et al., 2019). With a novel
97 design and chemical ionization source, the Vocus PTR-TOF allows for real-time characterization of
98 gas-phase emissions during various burning phases (e.g., flaming and non-flaming phases) and
99 identifies the characteristic compounds for a wide range of fuels.

100 The present study compares real-time emissions from different combustion fuels. We systematically
101 characterize the primary organic gas composition using Vocus from a variety of burning fuels from
102 both residential stoves (beech logs, pine and spruce logs, and coal) and open combustion (spruce and
103 pine branches and needles, straw, cow dung). We investigate the characteristics of compounds and
104 emission factors for different combustibles and explore the dependence of individual NMOGs emission
105 intensity, variability, and chemical composition on combustion conditions (open or stove) and
106 combustion phases. We also discuss characteristic compounds for the burning fuels examined in this
107 study. The differences in EFs and profiles between different combustibles can be considerable, and
108 these results illustrate the importance of considering these emission sources individually. Measurements
109 capable of identifying and quantifying rarely measured and presently unidentified emissions of NMOGs,
110 particularly chemically complex low volatility fraction, are vital for advancing the current
111 understanding of the impact of solid fuel combustion on air quality and climate.

112 **2 Materials and methods**

113 **2.1 Fuel and burning setup**

114 The experiments were conducted at the Paul Scherrer Institute (PSI) in Villigen, Switzerland and the
115 burning facility that is part of the PSI Atmospheric Chemistry Simulation Chambers (PACS). Real-time
116 characterization of the primary gas and particle phase emissions was carried out during 28 test burns.
117 Six fuels were studied (beech, spruce, pine, straw, cow dung, and coal briquettes) with three to six

118 replicate burns. Material in the beech, spruce, and pine fuels (e.g., logs and needles) was sourced from
119 a local forestry company in Würenlingen, Switzerland. Cow dung cakes (a mixture of cow dung and
120 straw) were collected from Goyla Dairy in Delhi, India. Coal briquettes were purchased from Gansu,
121 China (Ni et al., 2021; Klein et al., 2018). These fuels are classified into four categories, representing
122 different types of burning scenarios in real life: 1) residential wood burning, 2) agricultural burning, 3)
123 forest fires, and 4) traditional heating and cooking in two regions. Residential wood burning included
124 beech and spruce/pine logs burned separately in a stove, consistent with the materials used in two
125 previous articles (Bertrand et al., 2017; Bhattu et al., 2019). Combustion of agricultural waste, straw,
126 and a mixture of fresh spruce and pine branches and needles were in an open stainless-steel cylinder
127 measuring 65 cm in diameter and 35 cm in height. Forest fires were simulated by burning a mixture of
128 spruce and pine branches and needles. Traditional cooking and heating practices in regions like India
129 are represented by burning cow dung cakes using half-open stoves (Loebel Roson et al., 2021).
130 Traditional cooking and heating practices in rural regions of developing countries are represented by
131 burning coal in a portable cast iron stove purchased from the local market (Liu et al., 2017).

132 **2.2 Instrumentation and sampling**

133 The experimental design is shown in Figure S1. In summary, it is made up of a burner and a set of
134 diluters with heated lines. Before each burn, a continuous stream of pure air was passed through the gas
135 lines overnight to avoid cross-contamination between burns and to ensure a low background of VOCs.
136 From the various combustibles, once a burn is initiated, emissions are sampled from the chimney
137 through a heated line (473 K) and diluted by two dekati diluters by a factor of ~ 100 (473 K, DI-1000,
138 Dekati Ltd.). Note that wood-burning combustion cycles consist of a first cycle referred to as the ‘first
139 load’ and subsequent cycles, referred to as ‘reloads’. The first load consisted of a cold start, flaming,
140 smoldering, and burn-out phase, and the reloads were comprised of a warm start, flaming, smoldering,
141 and burn-out phase. NMOG emissions of solid fuel combustion are released within 10–30 min after
142 loading. We define the time until full ignition duration for burning encompasses 80% of the entire
143 process, starting from loading the fuels to burnout.

144 Numerous instruments were connected after the second dekati diluter for the characterization of both
145 the particulate and gaseous phases. A Scanning Mobility Particle Sizer (SMPS, CPC 3022, TSI, and
146 custom-built DMA) provided particle number size distribution information. The non-refractory particle
147 composition was monitored by a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-
148 AMS, Aerodyne Research Inc.). AMS data were processed using SQUIRREL (SeQUential Igor data
149 RetRiEvaL v. 1.63; D. Sueper, University of Colorado, Boulder, CO, USA) and PIKA (Peak Integration
150 and Key Analysis v. 1.23) to obtain mass spectra of identified ions in the m/z range of 12 to 120. Black
151 carbon was measured with an Aethalometer (Magee Scientific Aethalometer model AE33) (Drinovec
152 et al., 2015) with a time resolution of 1 minute. A LI-7000 CO₂ analyzer (LI-COR) provided continuous
153 measurements of carbon dioxide (CO₂). The concentrations of total hydrocarbons (THC) and methane
154 (CH₄) were monitored using a flame ionization detector monitor (THC monitor Horiba APHA-370).

155 We deployed a Vocus to measure organic vapors with a wider range of volatilities. A detailed
156 description of the Vocus is provided elsewhere (Huang et al., 2021; Krechmer et al., 2018). For this
157 study, the Vocus was operated with H₃O⁺ as the reagent ion. The sample air was drawn in through a 1
158 m long polytetrafluoroethylene (PTFE) tube (6 mm o.d.) using a total sample flow of 4.3 L/min, which

159 helped reduce the losses in the inlet wall and the sampling delay. Of the total sample flow, only 100-
160 150 cm³/min went to Vocus, and the rest was exhausted. The Vocus was calibrated before and after
161 measurements every day using a multi-component standard cylinder (Tofwerk AG). Standard gases
162 were diluted by the injection of zero air, producing mixing ratios of VOCs of around 20 ppbv. The
163 calibration components were methanol, acetaldehyde, acetonitrile, acetone, acrylonitrile, isoprene,
164 methyl ethyl ketone, benzene, toluene, m-xylene, α -pinene and 1,2,4-trimethylbenzene. The
165 background measurements were performed using dry zero air every day. Data were recorded with a
166 time resolution of 1 s. The raw data were processed using Tofware v3.2.3 software (TOFWERK,
167 Aerodyne, Inc.). The standard non-targeted analysis workflow developed by Tofwerk was adopted for
168 mass calibration and peak fitting. The mass transmission function and the ratios between the measured
169 and calculated sensitivities for a series of ions were used to quantify the data and convert the ion counts
170 to ppbv. To calculate the mixing ratio for compounds not present in the calibration mixture, the slope
171 of the linear fit was multiplied by the proton transfer rate constants (k_{PTR}) which have been provided in
172 Supplement Table.

173 2.3 Data analysis

174 Modified combustion efficiency (MCE, Equation 1) is an estimate of the relative amount of flaming
175 and smoldering and is equal to

$$MCE = \frac{\Delta CO_2}{\Delta CO + \Delta CO_2} \quad \text{Equation (1)}$$

176 Where ΔCO , ΔCO_2 are the excess mixing ratios of CO or CO₂, respectively (Ward and Radke, 1993).
177 Generally, a higher MCE (> 0.9) suggests dominated flaming combustion, whereas a lower MCE (<
178 0.9) is mostly associated with smoldering combustion (Zhao et al., 2021; Zhang et al., 2022).

179 Primary emission factors (EFs, g kg⁻¹) of conventional gases (CO₂, CO, and CH₄), NMOGs (Vocus)
180 and particle phase species were calculated, following a carbon-mass balance approach (Andreae and
181 Merlet, 2001)

$$EF_i = \frac{m_i}{\Delta CO + \Delta CO_2 + \Delta CH_4 + \Delta NMOGs + \Delta OC + \Delta BC} \times W_C \quad \text{Equation (2)}$$

182 Here m_i refers to the mass concentration of species i . ΔCO , ΔCO_2 , ΔCH_4 , $\Delta NMOGs$, ΔOC , and ΔBC
183 are the background-corrected carbon mass concentrations of carbon-containing species in the flue gas.
184 OC is derived from the OM / OC ratio determined with high-resolution AMS analysis (Canagaratna et
185 al., 2015). W_C is the carbon mass fraction of the burning fuel. The W_C in the fuel a constant average
186 value of 0.46 for wood (Bertrand et al., 2017), 0.45 for straw (Li et al., 2007), 0.45 for cow dung (Font-
187 Palma, 2019), and 0.49 for coal (Zhang et al., 2000) was assumed. Changes of W_C over the burning
188 cycle are expected to be small compared to the variability of pollutant emissions.

189 2.4 Volatility calculation of gaseous organic compounds

190 The volatility (i.e. the saturation mass concentration, C^*) for individual organic compounds was
191 calculated based on the number of oxygen, carbon, and nitrogen atoms in the compound using the
192 approach by Li et al. (2016):

193
$$\log_{10}^* = (n_C^0 - n_C^i)b_C - n_O^i b_O - 2 \frac{n_C^i n_O^i}{n_C^i + n_O^i} b_{CO} - n_N^i b_N$$
 Equation (3)

194 where n_C^0 is the reference carbon number; n_C^i , n_O^i and n_N^i denote the numbers of carbon, oxygen, and
 195 nitrogen, respectively, in the compound. b_C , b_O and b_N are the contributions of each atom to \log_{10}^* ,
 196 respectively; and b_{CO} is the carbon-oxygen nonideality. The parameters used in this analysis are
 197 presented in Table S1. Most notably, the empirical approach used by Li et al. (2016) was derived with
 198 only a limited number of organonitrates, which could potentially introduce bias in estimating vapor
 199 pressure (Isaacman-Vanwertz and Aumont, 2021). To mitigate this bias, we modified the nitrogen
 200 coefficient for CHON formulas that can be forced to equal twice the negative of the oxygen atom ($b_N =$
 201 $-2b_O$).

202 **2.5 Identification of characteristic compounds**

203 In this study, the mixing ratio relative contribution for more than 1500 species from six different fuels
 204 for all 28 test burns was quantified by using Vocus. To identify the characteristic compounds of
 205 emissions from different fuels, we implemented the Mann-Whitney U test (Mann and Whitney, 1947;
 206 Wilcoxon, 1945) in MATLAB®, which has been applied in the selection of aerosol markers (Zhang et
 207 al., 2023). It is a nonparametric test and is used for between-group comparisons when the dependent
 208 variable is ordinal or continuous and not assumed to follow a normal distribution.

209 This test takes two data samples as parameters, uses the ranks as a measure of central tendency, and
 210 then returns the test results with a p -value to indicate the statistical significance. When the p -value is
 211 lower than the significance level of 0.1 (a commonly used p -value to study statistical significance in
 212 atmospheric research), the median of the tested sample is significantly high or low in the two-tailed test.
 213 However, due to the similarity in fuel types between burning spruce and pine logs, as well as spruce
 214 and pine branches and needles, they were categorized as separate fuel sources for this test and not
 215 compared with each other but were only compared with the other four types of fuels. Similarly, due to
 216 the composition of cow dung "cakes," which comprise a mixture of dried cow dung and crop residues
 217 and a relatively high correlation between cow dung and straw (Figure 1), the Mann-Whitney U test was
 218 carried out without accounting for the presence of the other fuels.

219 The molecules from a specific class of fuel that satisfy the pairwise comparison test between one fuel,
 220 referred to as fuel j , and other types of fuel, were determined to be significantly high- or low-fraction
 221 ions in fuel j . These ions have the potential to serve as characteristic compounds for fuel j . We have
 222 calculated in addition the fold change (FC) of ion i in fuel j was calculated using Equation 4,

$$FC_{i,j} = \frac{f_{i,j}}{f_{i,other}}$$
 Equation (4)

223 Where $f_{i,j}$ represents the fraction of ion i in the mass spectra profiles of fuel j , and $f_{i,other}$ represents
 224 the average fraction of ion i in the mass spectra from the other fuels.

225 **3 Results and discussion**

226 **3.1 Emission factors from solid-fuel combustion**

227 The average EFs of CO, CO₂, NMOGs and PM in g/kg as well as the MCE values calculated for the 6
228 types of fuels, are shown in Table 1. Detailed EFs and MCE values for each experiment can be found
229 in Table S2.

230 The average MCE values depend on the fuel types and combustion phases (flaming and smoldering).
231 The lowest MCE values, 0.90, were observed during the smoldering phase of the stove-burning of beech
232 logs, while the highest values, at 0.99 ± 0.02 , were recorded during the flaming phase of the spruce and
233 pine branches and needles open burning. In all experiments, the highest EFs for a single gas-phase
234 species correspond to CO₂ (1136.2-1711.7 g/kg). Coal burning has the highest average CO EFs ($40.6 \pm$
235 12.6 g kg^{-1}) and CO₂ EFs ($1680.2 \pm 32.7 \text{ g kg}^{-1}$)

236 Total NMOG EFs reported in Table 1 refer to species quantified using the Vocus. The average EFs of
237 primary organic gases (in the range of 6.7 to 74.2 g kg^{-1}) and the standard deviation are calculated based
238 on the average EFs for the repeatable experiments, which depend on the combustion phases and fuel
239 types. Generally, lower MCE values correspond to higher NMOGs EFs within a given class of burning
240 fuel (Figure S2a). For instance, smoldering beech logs resulted in significantly higher average NMOGs
241 EFs (74.2 ± 42.9) compared to burning pine and spruce logs. Pine and spruce stove and open burning,
242 dominated by the flaming phase (average MCE > 0.95), exhibited average NMOGs EFs of 44.9 ± 17.5
243 and 39.8 ± 11.4 , respectively. The slightly higher EFs for pine and spruce wood burning can be
244 attributed to the more extensive analysis of NMOGs in our study compared to previous research (37.3
245 g/kg) (Hatch et al., 2017). Despite the slight difference in MCE for some experiments, the increasing
246 EFs for NMOGs with at least six carbon atoms per molecule ($\geq \text{C}_6$) as proxy SOA precursors were
247 observed with lower MCE (Figure S2b) (Bruns et al., 2016). Moreover, the EFs of these SOA
248 precursors are much higher than the primary biomass-burning organic aerosol (BBOA), which suggests
249 a higher potential for SOA formation. Notably, the emission of NMOGs from cow dung and coal was
250 relatively low, at 6.7 ± 2.1 and $11.5 \pm 2.6 \text{ g kg}^{-1}$, respectively. Our emission factors align well with
251 previously reported volatile organic compound emission factors from bituminous coal combustion
252 under similar conditions (range of 1.5 to 14.1 g/kg) reported by (Klein et al., 2018).

253 **3.2 Chemical composition of primary organic vapors**

254 **3.2.1 Overview of the measurements**

255 To assess the feasibility of distinguishing differences between combustion fuel sources based on the
256 measured species, we evaluated the similarity of the mass spectra obtained from each experiment using
257 the correlation coefficient (r), as shown in Figure 1. Primary NMOGs from the same burning fuel are
258 strongly correlated (0.82-0.99), indicating the general repeatability of the experiments. Furthermore,
259 we observed a weak intra-fuel correlation between coal and other biomass sources (0.44-0.78),
260 suggesting significant differences in chemical composition. By contrast, the separation between
261 different biomass samples is not stark and all possess a correlation between 0.6-0.98. We also note the
262 slight difference in composition between smoldering and flaming beech wood.

263 Figure 1 also shows the average mixing ratio contribution of full ignition duration from m/z 40 to 300
264 for each experiment, and is categorized into C_xH_y , $C_xH_yO_z$, C_xH_yN and $C_xH_yO_zN$ families based on their
265 elemental composition. In all primary NMOGs, the $C_xH_yO_z$ family is the most abundant group, making
266 the largest contribution to beech logs (88.6%), pine and spruces logs (82.1%) and straw (81.7%). These
267 percentages are higher than those for coal (63.1%) and cow dung (68.9%). Coal burning results in
268 considerably higher contributions in the C_xH_y families (33.7%) than beech logs (9.3%), consistent with
269 the bulk chemical composition of the fuels.

270 Figure 2 separates emitted compounds based on their carbon (x-axis) numbers. The dominant signals
271 in primary organic gases for all fuels are attributed to C3-6 compounds, while more species with higher
272 carbon numbers ($\#C > 10$) are observed in pine and spruce branches and needles open burning. The
273 bin containing H/C ratios between 1.2 and 1.5 has the largest contribution in all fuels except the straw,
274 ranging from 27% to 31.2%. O/C ratios less than 0.15 contribute significantly to coal burning (42%),
275 which corresponds to the high proportion of C_xH_y families (Figure 1). Wood and straw burning emitted
276 more oxygenated organic vapors than coal and cow dung burning with more contribution of higher O/C
277 species ($O/C > 0.5$). The results show similarities to the comparison between burning wood and cow
278 dung in the particle phase. Specifically, cow dung exhibits a slightly lower fraction of high O/C
279 compared to other fuels studied. (Zhang et al., 2023).

280 Generally, the total fraction of nitrogen-containing species (C_xH_yN and $C_xH_yO_zN$) is significantly higher
281 in the primary NMOGs emitted from open burning of cow dung (18.8%) compared to the other fuels
282 (2.1% to 7.3%). This trend is consistent with both our results from aerosol composition measurement
283 and previous literature (Stewart et al., 2021b; Zhang et al., 2023; Loebel Roson et al., 2021). Generally,
284 nitrogen containing compounds in cow dung consist mainly of one nitrogen atom and have a wide range
285 of carbon numbers between 2 and 7 (Figure 2). Stewart et al. (2021a) also reported that cow dung was
286 the largest emitter of nitrogen-containing NMOGs than other fuelwood and crops in India, releasing
287 large amounts of acetonitrile and nitriles. These nitrogen-containing organic gases are likely formed
288 from the volatilization and decomposition of nitrogen-containing compounds within the cow dung cake,
289 such as free amino acids, pyrroline, pyridine, and chlorophyll (Ren and Zhao, 2015; Burling et al., 2010).

290 We categorized NMOGs by functional groups into 10 classes, including alcohols, carbonyls (including
291 acid), hydrocarbons, furans, N-containing compounds, O-containing < 6 (where the number of carbon
292 atoms is less than 6), O-containing ≥ 6 (where the number of carbon atoms is equal or greater than 6),
293 oxygenated aromatics, polycyclic aromatic hydrocarbons (PAHs), single-ring aromatics (SRA) (Bhattu
294 et al., 2019). Figure S3 and Figure S4 show a comparison of the organic gas composition observed from
295 different fuel types. The measured emissions exhibit significantly different compositions, reflecting the
296 variability of organic components produced from different fuel types. The emissions of all solid fuels
297 are overwhelmingly dominated by carbonyls in the range of 23.1% (coal) to 45.1% (straw). For all
298 emissions, furans represent the second largest group, which account for more than 14% of the emissions.
299 Comparatively, aromatic compounds are less significant in biomass burning: 5.9% - 12% for
300 oxygenated aromatics, 0.5% - 2.1% for PAHs, and 2.1% - 5.8% for SRA. In contrast, aromatic
301 emissions are relatively larger in coal burning emissions (13.6%, 8.1%, and 13.8%, respectively).

302 **3.2.2 Volatility of organic compounds**

303 Based on the $\log_{10}C^*$ values of all organic compounds parameterized with the modified approach of Li
304 et al. (2016) described in Sect. 2.4, the gaseous organic compounds were grouped into a 14-bin volatility
305 basis set (Donahue et al., 2006) (Figure 3). We choose to classify the volatility in four main classes with
306 units of $\mu\text{g m}^{-3}$: VOCs as $\log_{10}(C^*) > 6.5$, IVOCs as $\log_{10}(C^*)$ between 6.5 to 2.5, semi-VOCs (SVOCs)
307 as $\log_{10}(C^*)$ between 2.5 to - 0.5 and low-VOCs (LVOCs) as $\log_{10}(C^*) < - 0.5$.

308 Comparison and compilation of gaseous biomass burning emissions sorted by volatility and functional
309 group are shown in Figure 3, and the distribution of average EFs as a function of binned saturation
310 vapor concentration is shown. The VOC class was found to be the most abundant, ranging from 58.7%
311 to 87% (Figure S5). For all burns, carbonyls, furans, and SRA families are overwhelmingly dominant
312 in VOCs, accounting for more than 60% of the VOC emissions. The high fraction of oxygenated VOCs
313 like carbonyls in biomass burning emissions is in stark contrast to VOCs emitted from coal combustion,
314 which is dominated by aromatic hydrocarbon emissions, particularly PAHs. This difference may be
315 attributed to the condensed structure of coal. PAHs are a group of organic matter compounds containing
316 multiple aromatic rings that mainly result from incomplete combustion (Mastral and Callen, 2000).

317 IVOCs also constituted a considerable fraction in solid-fuel combustions (from 12.6% to 39.3%),
318 particularly in spruce and pine branches and needles (39.3%), cow dung (24.3%) and coal (31.1%)
319 (Figure S5). Significant differences in the bulk volatility of organic compounds were observed among
320 different types of wood burning. In general, spruce and pine branches and needles open burning released
321 a higher proportion of IVOCs (39.3%) into the gas phase compared to stove logs burning (12.6% and
322 23.9%). Pallozzi et al. (2018) also reported a similar result, showing that needle/leaf combustion
323 released a greater amount of volatile organic compounds into the atmosphere than branch combustion.
324 This difference may be attributed to a lower percentage of terpenes in woody tissues compared to
325 needle/leaf tissues (Greenberg et al., 2006). In addition, open burning provides more oxygen than stove
326 burning, which enhances the formation of partially oxidized organic compounds. Within the open
327 burning experiments, the oxygenated molecules (both aromatics and $C \geq 6$) are enhanced relative to the
328 other experiments and result in the largest emission factors of IVOCs. In addition to the burning
329 conditions, the fuel properties are also an important factor affecting the IVOC component. Notably,
330 cow dung comprised a higher fraction of N-containing species within their IVOC emissions compared
331 to other fuels. The emission in volatility bins in this study is important for the modeling of organics
332 with the VBS scheme.

333 **3.3 Comparison between flaming and smoldering of wood burning**

334 Figure 4a shows a typical burning cycle during beech log wood experiments with distinct emission
335 characteristics between flaming and smoldering phases. In the top panel, the MCE is used to indicate
336 the flaming stage with a significant CO_2 enhancement, while the smoldering stage exhibits high levels
337 of CO. The flaming phase shows considerable BC emission, while the smoldering phase is dominated
338 by OA emissions without visible flame. The AAE during the smoldering phase is approximately twice
339 that of the flaming phase, possibly due to the presence of "brown carbon" in organic aerosols. f_{60}
340 represents the prevalence of primary combustion products such as levoglucosan and is used as an
341 indicator for fresh BB emissions (Schneider et al., 2006; Alfara et al., 2007). During the
342 starting/flaming phase, when the temperature is higher, f_{60} increases, whereas for lower temperatures

343 in the smoldering phase, f_{60} decreases (Weimer et al., 2008). The mixing ratio of most of the
344 compounds correlates negatively with the MCE as expected with a significant increase in the
345 smoldering phase (Figure 4a and Figure S6). However, some compounds like benzene have different
346 enhancement rates from flaming to smoldering, which is similar to previous studies (Warneke et al.,
347 2011).

348 Figure 4b illustrates the measured emission factors for flaming and smoldering wood fire stages. On
349 average, emission factors for organic gases in the flaming stage are approximately four times lower
350 (31.4 g/kg) than those in the smoldering stage fires (121.9 g/kg). Despite significant variability in
351 organic gas emission strengths, the relative contribution of different classes showed large similarities
352 among combustion phases (Figure S7). Hardwood (beech) is a fibrous substance primarily composed
353 of three chemical elements: carbon, hydrogen, and oxygen and these basic elements are incorporated
354 into several organic compounds, i.e. cellulose, hemicellulose, lignin, and extractives formed into a
355 cellular structure (Asif, 2009). The flaming stage is associated with more complete oxidation with a
356 relatively higher contribution of OVOCs (e.g., furan, oxygenated aromatics, O-containing, Figure S8).
357 Conversely, during the smoldering stage, more CO and organic gases are emitted relative to the flaming
358 stage (Figure 4a). OVOCs, such as carbonyl, furan, oxygenated aromatics, and O-containing species,
359 form the major fraction (> 88%) of emissions in both flaming and smoldering fires. They are followed
360 by the sum of C_xH_y , and SRA (5-10%). As shown in Figure S9, the volatility distribution of beech log
361 stove burning between the flaming phase and smoldering phase is also similar, only with a relatively
362 higher contribution of carbonyls and C_xH_y in the smoldering phase than flaming phase. This suggests
363 that the emission factor plays a more important role than the chemical composition in differentiating
364 between flaming and smoldering fires.

365 **3.4 Common compounds emission for biomass-burning combustion and identification of** 366 **characteristic compounds for different fuels**

367 **3.4.1 Common compounds for biomass burning**

368 To conduct a comprehensive analysis aimed at identifying characteristic compounds among emissions,
369 the Mann-Whitney U test (refer to Sect. 2.5) was performed on the relative contribution of primary
370 organic gases derived from various fuels as measured by Vocus. The results of the pairwise Mann-
371 Whitney test are presented in Figure S10, illustrating the average $-\log_{10}$ of the p -value as a function of
372 the \log_2 of the fold change (FC). Species that yield p -values lower than 0.1 in the two-tailed test for all
373 pairwise comparisons are deemed significantly more abundant or scarce in a particular fuel type
374 compared to all other fuels. These species are indicated as colored circles in Figure 5. In cases where
375 species do not meet this criterion once or multiple times, they are represented as gray circles, even if
376 their average p -value falls below 0.1. A higher $-\log_{10}(p\text{-value})$ signifies a reduced likelihood that the
377 fractional medians of two species are equivalent. Simultaneously, a greater FC (as per Equation 4)
378 indicates an increased presence of the species' fractional contribution in the tested fuel in comparison
379 to the average contribution across all other fuels. This suggests a higher degree of exclusivity for this
380 species in the given context. The selected characteristic compounds, p -values, fold changes, and
381 threshold results are listed in the Supplement Table.

382 As shown in Figure 1, biomass fuels (wood, straw and cow dung) are different fuels from coal in this
383 study. To address this, we characterized the common compounds from varied biomass fuels by

384 establishing a threshold (relative mixing ratio contribution $\geq 0.1\%$) for compounds that are not specific
385 characteristic compounds of biomass burning, which allowed for the identification of compounds that
386 are more readily detectable in intricate environments. As shown in Figure S11, the gas-phase analysis
387 revealed several dominant species: $C_5H_4O_2$ (furfural, 2.2-10.1%), $C_2H_4O_2$ (acetic acid, 2.1-5.8%),
388 $C_3H_6O_2$ (methyl acetate, 1.7-4.6%), and C_2H_4O (acetaldehyde, 1.3-3.9%), which were also reported
389 prior studies on biomass burning (Bruns et al., 2017; Stockwell et al., 2015; Christian, 2004; Sarkar et
390 al., 2016). Furthermore, the category of common compounds represents the primary set of compounds
391 associated with biomass burning, contributing from 46% to 69% of the emissions (Figure S12). Carter
392 et al. (2022) expand the representation of fire NMOGs in a global chemical transport model, GEOS-
393 Chem, which contributes substantially to atmospheric reactivity, both locally and globally. Our results
394 could provide more input information for global or regional chemistry transport models.

395 **3.4.2 Characteristic compounds for solid-fuel combustion**

396 Mass defect plots of characteristic compounds are visualized in Figure 5, for each burning source,
397 respectively. Many characteristic compounds are identified for each unique type of burning
398 (Supplement Table). As shown in Figure 5, characteristic compounds of all wood burning are mainly
399 composed of compounds from the C_xH_y and $C_xH_yO_z$ -family. However, the selected characteristic
400 compounds for spruce and pine branches and needles have higher molecular weights and are more
401 oxidized, which aligns with their characteristics of the mass spectrum. In contrast, compounds from
402 open burning of straw and cow dung contribute considerably more to nitrogen-containing families but
403 less to oxygen-containing species, consistent with their bulk chemical composition characteristics.
404 Additionally, characteristic compounds for coal consist mainly of compounds from C_xH_y -family, which
405 also aligns with its bulk chemical composition and relatively higher H/C ratios (Figure 2).

406 For all softwood (i.e., spruce and pine logs and spruce and pine branches and needles in this study),
407 monoterpenes ($C_{10}H_{16}$) are a characteristic compound along with the fragment at m/z 81.07 (C_6H_8).
408 However, monoterpenes cannot exclusively be related to biomass burning given their abundance in the
409 atmosphere. Monoterpenes are also the biogenic volatile organic compounds (BVOCs) emitted from
410 natural trees and other vegetation (Hellén et al., 2012). However, the emission rates of terpenes vary
411 with season, with a higher rate in spring and summer and a lower rate in autumn and winter (He et al.,
412 2000; Noe et al., 2012). In winter, monoterpenes could be a characteristic compound for softwood
413 burning due to minor natural emissions from spruce, but in summer, terpene emissions from natural
414 trees would dominate the contribution making it a non-characteristic compound. P-cumenol ($C_9H_{12}O$),
415 as one of the characteristic compounds for beech logs, was discovered to be one of the prominent
416 products of beech wood pyrolysis of lignins (Sengpiel et al., 2019; Keller et al., 2020). Homologues of
417 $C_{10}H_{8-18}O_2$ are determined for spruce and pine branches and needles, with $C_{10}H_{10}O_2$ being β -
418 phenylacrylic acid, which is one of the main chemical compositions of the extract of the cedar pine
419 needle. $C_{10}H_{14}O_2$ could be 1-guaiacylpropane, which is proposed as a characteristic compound for
420 coniferyl-type lignin pyrolysis products from pine (Simoneit et al., 1993; Liu et al., 2021). Homologues
421 of $C_{11}H_{8-18}O_2$ are also seen, for example, $C_{11}H_{14}O_2$, likely 1-(3,4-dimethoxy-phenyl)-1-propene, which
422 is stated as a representative compound found in lignin (Alves et al., 2003; Hill Bembenc, 2011).

423 Noticeably, cow dung has a significantly different chemical composition. As a result, many
424 characteristic compounds are identified from the burning of cow dung compared to other fuels. These

425 characteristic compounds predominantly contain nitrogen in chemical composition and overlap all
426 characteristic compounds for straw, owing to the mixture of dried cow dung and crop residues in "cow
427 dung cakes." Many nitrogen-containing characteristic compounds are found in straw and cow dung,
428 such as C_4H_5N , C_5H_5N , C_5H_7N , and C_6H_7N , which could likely be assigned to pyrrole, pyridine,
429 methylpyrrole and methyl pyridines respectively. Pyrolysis of the constituents in the crop residue is a
430 probable pathway for these compounds (Ma and Hays, 2008). Acetonitrile (C_2H_3N), acrylonitrile
431 (C_3H_3N), propanenitrile (C_3H_5NO), and 4-methylpentanenitrile ($C_6H_{11}N$) were found as characteristics
432 compounds for cow dung with generally higher FC and higher relative contribution. Additionally,
433 several series of nitrogen-containing homologues are found, such as $C_{10}H_{11-21}NO$, $C_{12}H_{11-21}N$, $C_{11}H_{11-}$
434 $_{23}NO$ and $C_{15}H_{15-31}N$. These nitrogen-containing gases have also been detected, especially in emissions
435 from cow dung cake in India compared to fuelwood and are likely formed from the volatilization and
436 decomposition of nitrogen-containing compounds within the cow dung cake. These compounds
437 originate primarily from free amino acids but can also arise from pyrroline, pyridine, and chlorophyll
438 (Stewart et al., 2021a).

439 Coal is also a distinct solid fuel compared to other biomass fuels in this study, showing a relatively
440 lower correlation coefficient (Figure 1). Consequently, many series of C_xH_y -family homologues are
441 found. Compounds with 9-12 carbon atoms, as shown in Figure 5 for coal burning, could be PAHs-
442 related, such as C_9H_8 (1-Indene), $C_{10}H_8$ (naphthalene), $C_{10}H_{10}$ (1-methylnaphthalene), $C_{12}H_{10}$
443 (acenaphthene), $C_{12}H_{12}$ (2,6-dimethylnaphthalene). The EFs of the characteristic compounds also show
444 an increasing trend with the decrease of MCE (Figure S13), which suggests EFs of the characteristic
445 compounds are not only dependent upon the type of fuel burnt but also on the burning condition.

446 4 Conclusions

447 In this study, we first investigated the real-time emissions of primary organic gases using Vocus-PTR-
448 TOF during typical solid fuel combustion, including residential burning (beech logs, a mixture of spruce
449 and pine logs, and coal briquettes) and open combustion (spruce and pine branches and needles, straw,
450 and cow dung). Average emission factors of CO, CO₂, primary organic gases and PM were calculated.
451 This work provides a comprehensive laboratory-based analysis of the chemical composition of organic
452 gases emitted from the different combustibles and different combustion phases. We discuss the
453 prominent net combustion emissions from biomass burning and identify new characteristic compounds
454 using the Mann-Whitney U test.

455 The results indicate that wood burning has higher primary organic gas emission factors compared to
456 other fuels. The emissions varied significantly, ranging from 6.7 to 74.2 g kg⁻¹, depending on the
457 combustion phases and fuel types. Despite the slight difference in modified combustion efficiency
458 (MCE) for some experiments, the increasing EFs for primary organic gases were observed with lower
459 MCE. Moreover, the EFs of these SOA precursors are much higher than the primary biomass-burning
460 organic aerosol (BBOA), which suggests a higher potential for SOA formation. The $C_xH_yO_z$ -family is
461 the most abundant group (63.1% to 88.6%) for all solid fuels, followed by C_xH_y (9.3% to 33.7%). A
462 larger contribution of nitrogen-containing species (C_xH_yN and $C_xH_yO_zN$) is found in cow dung burning,
463 while coal burning has a higher contribution from the C_xH_y families. Moreover, the VOC class was
464 found to be the most abundant (58.7% to 87%), followed by the IVOC class (12.6% to 39.3%). Primary
465 semivolatile/intermediate-volatility organic compounds (S/IVOCs) have been proposed as important

466 SOA precursors from biomass burning. Li et al. (2024) found that IVOCs from residential wood burning
467 (~ 13% of total organic gases) can contribute ~70% of the formed SOA. Overall, these data will help
468 update the IVOC emission inventory and improve the estimates of SOA production. Specifically, these
469 results demonstrate that open burning (e.g., wildfire) emissions have enhanced IVOC emission factors,
470 suggesting that the SOA potential from open-burning sources is larger in comparison to their wood
471 stove counterparts.

472 Distinct particulate/gas emissions at different combustion phases are observed for stove burning of
473 beech logs: initial compositions of flaming or smoldering plumes were dominated by BC or OA,
474 respectively, with much higher primary organic gas emission in smoldering. Despite the large
475 variability in organic gas emission strengths, the relative contribution of different classes showed large
476 similarities among combustion phases. Therefore, the enhanced emission factor under smoldering
477 conditions means there is a greater potential for SOA formation when compared to flaming conditions.

478 However, each source generally emits a wide spectrum of organic gas species, leading to considerable
479 overlap between organic gas species from different sources. Based on the Mann-Whitney U, we selected
480 species that were unique in certain emissions as possible characteristic compounds for the
481 characteristic compounds and the common compounds for all biomass fuels. Due to minor natural
482 emissions from spruce in summer, monoterpene ($C_{10}H_{16}$) and its fragment could be characteristic
483 compounds for all softwoods (i.e., pine logs and spruce and pine branches and needles in this study) in
484 winter. More products of the pyrolysis of coniferyl-type lignin and the cedar pine needle extract could
485 be found in spruce and pine branches and needles open burning (e.g., $C_{10}H_{14}O_2$, $C_{11}H_{14}O_2$, $C_{10}H_{10}O_2$).
486 The prominent product ($C_9H_{12}O$) resulting from the pyrolysis of beech lignin is identified as the
487 characteristic compound for beech log stove burning. Many series of nitrogen-containing homologues
488 and nitrogen-containing species (e.g., acetonitrile, acrylonitrile, propanenitrile, methylpentanenitrile)
489 are identified (e.g., $C_{10}H_{11-21}NO$, $C_{12}H_{11-21}N$, $C_{11}H_{11-23}NO$ and $C_{15}H_{15-31}N$), particularly from open
490 burning of cow dung. Coal is a unique solid fuel compared to biomass and more PAHs-related
491 characteristic compounds are identified from coal burning with 9-12 carbon. These characteristic
492 compounds provide important support for future global or regional chemistry transport modeling and
493 source apportionment. Overall, our study provides a comprehensive understanding of the molecular
494 composition and volatility of primary organic compounds, as well as new insights into the identification
495 of characteristic compounds from the burning of solid fuels.
