## Abstract

Highly reactive volatile organic compounds (HRVOCs) from mobile and petrochemical sources are important players in atmospheric photochemistry that contribute to the formation of ozone (O<sub>3</sub>). In a typical elevated O<sub>3</sub> episode, we applied a high-resolution large eddy simulation (LES), coupled with the Weather Research and Forecasting model with chemistry (WRF-LES-Chem) to understand the mechanism of high O<sub>3</sub> production over the Houston area. Our modeling was constrained and evaluated using field measurements from the NASA Tracking Aerosol Convection Interactions Experiment – Air Quality (TRACER-AQ) project, Texas Commission on Environmental Quality (TCEQ), and vertical column density observations from Pandora spectrometers. The modeling results show enhanced performance in the LES domain, compared to the mesoscale models in simulating key chemicals. O<sub>3</sub> sensitivity in the Houston urban area demonstrates a nearly homogenous early morning VOC-limited regime and transits to a noontime NO<sub>x</sub>-limited regime. As the day progresses into the afternoon, the atmospheric oxidative capacity (AOC) increases with major contribution from hydroxyl (OH) radical (90 %). High concentrations of alkenes also increased O<sub>3</sub> (8-10 %) contribution to AOC in the late afternoon. The OH reactivity (K<sub>OH</sub>) is dominated by isoprene (35.76 %), carbon monoxide (CO; 12.98 %), formaldehyde (HCHO; 12.21 %), and alkanes with C > 3 (6.29 %), thus accelerating the production of hydroperoxyl (HO<sub>2</sub>) and peroxy (RO<sub>2</sub>) radicals. The concentrations of short-lived VOCs such as HCHO and acetaldehyde from the oxidation of HRVOCs, increased in the afternoon, which elevated O<sub>3</sub> production rates under a NO<sub>x</sub>-limited regime. The oxidation of isoprene also accelerated the production of HCHO and contributed to the production of HO<sub>2</sub> radicals, thus leading to a high O<sub>3</sub> production rate. This study suggests the possible impacts of NO<sub>x</sub>-O<sub>3</sub>-VOC sensitivity on O<sub>3</sub> production rates in polluted urban areas with high emission of HRVOCs, and also provides insights on radical chemistry that drives the photochemical processes of O<sub>3</sub> formation. Ultimately, the study underlines the need to control

anthropogenic emissions such as alkenes and HCHO and also highlights the role of naturally emitted isoprene species in elevated urban O<sub>3</sub> levels.

## 1. Introduction

35 The Houston metropolitan area is home to approximately 7.3 million people and represents a heavily-polluted urban atmosphere due to the presence of complex industrial emissions. Like many polluted urban cities in the United States, Houston is identified as an ozone (O<sub>3</sub>) nonattainment area by the U.S. Environmental Protection Agency (US EPA) due to its summertime exceedances of the National Ambient Air Quality Standards (NAAQS) (Shahriar et al., 2015; Botlaguduru et al., 2018), which cause severe human health concerns (Blanchard et al., 2008; Rammah et al., 2020). In 2015, the EPA lowered  
40 the 8 h O<sub>3</sub> NAAQS to 70 ppb with projected national attainment by 2025; however, this does not appear realistic over Houston, as evident from the observed O<sub>3</sub> concentrations from the TRacking Aerosol Convection ExpeRiment – Air Quality (TRACER-AQ) 2021 summertime campaign. Generally, O<sub>3</sub> exceedances are highly dependent on the source of primary emissions, chemical reaction rates of primary and secondary oxidants, and meteorological processes (Spiridonov et al., 2019). However, the sensitivity of O<sub>3</sub> to precursors' regimes may also undermine or enhance its production in the atmosphere (Zhou et al., 2014;  
45 Ye et al., 2016). Additionally, boundary layer dynamics that affect nonlinear chemistry-turbulence interactions are not well-resolved in mesoscale models with coarse resolutions, yet these processes are essential to understand chemical behaviors in polluted environments (Wang et al., 2023). Thus, this study is aimed to understand the complex pathways of O<sub>3</sub> production and changes in O<sub>3</sub> formation regime in the Houston urban atmosphere using a high-resolution modeling approach.

The O<sub>3</sub> problem in Houston, unlike other large metropolitan cities in the U.S., is a combined product of (i) highly reactive  
50 volatile organic compounds (HRVOCs) and nitrogen oxides (NO<sub>x</sub> = NO<sub>2</sub> + NO) emissions from automobile and industrial sources along the Houston Ship Channel (Souri et al., 2016b; Botlaguduru and Kommalapati, 2020), (ii) variability in the along-shore sea breeze and the planetary boundary layer (PBL) depth (Banta et al., 2011), (iii) the midday reversals of flow patterns or clustering of weak easterly and northeasterly winds (Darby, 2005; Souri et al., 2016a), (iv) potential transport of pollutants from regional and long-range sources (Morris et al., 2006; Berlin et al., 2013), and (v) complex photochemistry  
55 under the hot and humid Houston environment (Perring et al., 2013). Because of the heterogeneous automobile emission sources and the presence of multiple oil and natural gas industries in Houston, anthropogenic emissions play an important role in O<sub>3</sub> formation. Primarily, the photochemical processes of ethylene, propylene and 1,3-butadiene from the alkene group are identified as the major anthropogenic VOC contributors to enhanced O<sub>3</sub> formation over Houston (Nam et al., 2006; Kim et al., 2011; Czader and Rappenglück, 2015; Sadeghi et al., 2022). Additionally, the photochemical reactivities of isoprene and  
60 monoterpenes from biogenic sources are also major contributors to O<sub>3</sub> formation (Leong et al., 2017; Ma et al., 2022).

The self-cleaning response of the atmosphere to emissions, defined as atmospheric oxidative capacity (AOC), determines the rate of removal of primary pollutants (e.g., CO, NO<sub>x</sub>, and VOCs) by oxidizing chemical reactions with O<sub>3</sub>, OH, and nitrate radicals (NO<sub>3</sub>) (Geyer et al., 2003; Chen et al., 2020). AOC is an important driving force in understanding atmospheric

chemistry, as it determines the removal rate of primary pollutants and the production rate of secondary pollutants (Mao et al.,  
65 2010). The total sum of the oxidation rates of these pollutant species is thus used to estimate AOC (Li et al., 2021). Several  
studies have been carried out to quantify atmospheric oxidation processes and have shown that AOC is dominated by pollutant  
oxidation from OH radicals, especially in heavily polluted environments (Xue et al., 2016; Li et al., 2018; Zhu et al., 2020). In  
such environments, the average daytime AOC may range from  $6.7 \times 10^7$  molecules  $\text{cm}^{-3} \text{s}^{-1}$  to  $3.2 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$  (Liu  
et al., 2022). In contrast,  $\text{NO}_3$  is insignificant during daytime photochemistry but principally contributes to nighttime AOC  
70 (Brown et al., 2011; Chen et al., 2019). However, experimental results from the TexasAQ-2000 campaign suggested that  $\text{NO}_3$   
contributes significantly to the daytime oxidation of monoterpenes and phenol in Houston (Geyer et al., 2003). Still, there is a  
very limited understanding of the daytime AOC over the Houston region, as compared to some other major urban polluted  
regions (Tan et al., 2019; Liu et al., 2022).

$\text{O}_3$  formation is driven by directly emitted precursors,  $\text{NO}_x$  and VOCs, yet the  $\text{O}_3$ - $\text{NO}_x$ -VOCs photochemistry is nonlinear,  
75 and two regimes with different  $\text{O}_3$ - $\text{NO}_x$ -VOC sensitivity have been identified (Sillman et al., 2003). Understanding the  
photochemical responses of  $\text{O}_3$  to reductions in emissions of  $\text{NO}_x$  and VOCs is crucial to developing an effective  $\text{O}_3$  control  
strategy. In a VOC-limited regime, for example, an incremental increase in VOCs promotes the chemical production of peroxy  
( $\text{RO}_2$ ) and hydroperoxy ( $\text{HO}_2$ ) radicals, which increases  $\text{NO}_x$  cycling and ultimately increases ambient  $\text{O}_3$  (Ye et al., 2016).  
By contrast, in a  $\text{NO}_x$ -limited regime, increased emissions of  $\text{NO}_x$  enhance the photolysis of  $\text{NO}_2$ , thus producing free reactive  
80 oxygen atoms, and ultimately reacting with  $\text{O}_2$  to produce  $\text{O}_3$ , resulting in increased  $\text{O}_3$  concentrations (Jin and Holloway,  
2015). Here,  $\text{O}_3$  is produced when the  $\text{HO}_2$  and  $\text{RO}_2$  radicals convert  $\text{NO}$  to  $\text{NO}_2$  without the consumption of  $\text{O}_3$ . Previous air  
quality campaigns over Houston have focused extensively on understanding  $\text{O}_3$  photochemistry to  $\text{NO}_x$ - and VOC-limited  
regimes. For instance, the TexAQS-2006 campaign (conducted from September to October 2006) showed that the rapid  
production of  $\text{O}_3$  was associated with a VOC-limited regime and a slow production was characterized by a  $\text{NO}_x$ -limited regime  
85 (Zhou et al., 2014). Evidence from the SHARP (April – May 2009) and DISCOVER-AQ (September – October 2013)  
campaigns also show that  $\text{O}_3$  production was more VOC-limited in the morning hours and  $\text{NO}_x$ -limited in the afternoon hours  
(Ren et al., 2013; Mazzuca et al., 2016). Despite evidence from the TexAQS-2006 campaign that reducing  $\text{NO}_x$  emissions  
from power plants led to reduced  $\text{O}_3$  concentrations (Cowling et al., 2007; Parrish et al., 2009), high  $\text{O}_3$  concentrations up to  
120 ppb were observed during the TRACER-AQ campaign. Nevertheless, this sensitivity regime is poorly understood over  
90 the Houston region and may be exacerbated by the complex interactions in the region. The exact dependence of  $\text{O}_3$  on  $\text{NO}_x$ -  
and VOC-limited regimes varies greatly on assumptions and different conditions, hence, threshold criteria for transition  
regimes are likely to change depending on changes in emission rates and patterns (Zhang et al., 2023), which may create a  
shift in  $\text{O}_3$  regimes. Thus, we need an accurate modeling interpretation of chemical and physical processes to more accurately  
determine  $\text{O}_3$ - $\text{NO}_x$ -VOCs sensitivity.

95 Since  $\text{O}_3$ - $\text{NO}_x$ -VOCs sensitivity is mostly determined from photochemical air quality models (Sillman et al., 2003; Song et  
al., 2010; Li et al., 2011; Goldberg et al., 2016; Du et al., 2022), accurate modeling representations of chemical and physical  
processes are crucial to better determine  $\text{O}_3$  formation regime, thus more effectively supporting ozone mitigation strategies in

Houston. However, previous model-based studies are subject to large uncertainties from simulated O<sub>3</sub> concentration and its precursors. The diurnal evolution of the PBL can significantly influence the mixing, transport, and chemistry of pollutants (Miao et al., 2019; Xiang et al., 2019), and thus must be accurately resolved in modeling. Based on previous studies, turbulence results in reductions of chemical reaction rates in the boundary layer, as a result of negatively correlated concentrations and vertical velocities (Li et al., 2016). Stockwell (1995) showed turbulence causes a non-uniform mixing of gas-phase trace species, thus limiting the accuracy of chemical models. This is particularly true if the model resolution is too coarse to resolve heterogeneous urban emissions and wind flows (Chen et al., 2009; Uebel and Bott, 2018). Also, these chemical models cannot adequately resolve the concentration and transport of O<sub>3</sub> pollutants in convective, unstable atmospheres due to a misrepresentation of boundary layer evolution (Li et al., 2016; Cuchiara et al., 2014). In a recent study, Wang et al. (2023) showed an improved modeling-observation agreement of the spatial and vertical distributions of key chemical species (e.g., O<sub>3</sub>, NO and NO<sub>2</sub>) from large eddy simulation (LES) compared with mesoscale simulations, indicating LES is an effective tool to resolve turbulence effects on chemical reactions. WRF-LES-Chem is advantageous due to its potential to improve the physical and chemical processes of pollutants at different scales.

In this work, we perform high-resolution simulations using WRF-LES-Chem over an O<sub>3</sub> exceedance period in September 2021 during the TRACER-AQ experiment, aiming to provide a comprehensive understanding of photochemical and physical processes involved in O<sub>3</sub> formation over Houston. Recent modeling studies have investigated ozone episodes during the TRACER-AQ campaign (Soleimanian et al., 2023; Li et al., 2023; Liu et al., 2023). This work expands upon those efforts by applying higher resolution LES simulations on the particular case day of September 8, 2021. Model results are comprehensively validated utilizing long-term ground-based observations from the TCEQ monitoring stations, measurements from the TRACER-AQ campaign, and observations from ground-based Pandora spectrometers to ensure modeling accuracy. This study also assesses spatial and temporal variability of the O<sub>3</sub> formation regime and investigates AOC, which can provide useful information to environmental managers to better control O<sub>3</sub> pollution over Houston.

## 2. Methodology

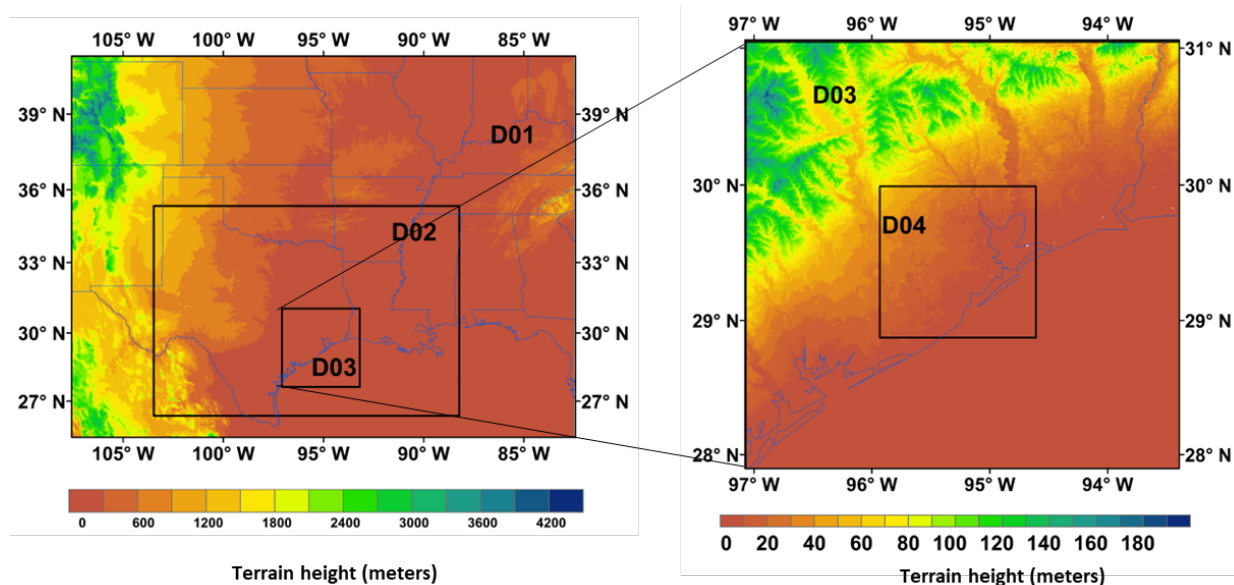

### 2.1 Model description and set-up

#### 2.1.1 Dynamic settings

We use the WRF-Chem model (Grell et al., 2005; Fast et al., 2006) version 4.4 with the integrated rate reactions capability that allows for the investigation of specific chemical pathways. Since LES is better suited to represent the PBL evolution and the transport of large eddies, we use a WRF-LES-Chem approach to simulate the concentration and transport of O<sub>3</sub> pollutants in convective, unstable atmospheres evolution (Li et al., 2016; Wang et al., 2023). Our modeling consists of four domains (D01 – D04) with horizontal grid resolutions of 8.1 km, 2.7 km, 900 m, and 300 m from outermost to innermost domains on a Lambert conformal projection (Fig. 1). The first three domains (D01 – D03) represent mesoscale setups while the innermost

domain (D04) is the LES domain. While the ideal LES resolution may range from 100 m and below, we select a 300 m  
 130 resolution due to the computational feasibility of our study that aims to better account for both boundary layer dynamics and  
 detailed atmospheric chemistry, as used in other literature (e.g., Wang et al., 2023). At this resolution, we aim to reach a  
 compromise between model computational efficiency and model resolution, since LES at finer scale resolutions are otherwise  
 too computationally expensive, especially given the size of our innermost domain that aims to focus on most of the Houston  
 area. The LES domain extends over the Houston urban area, including all TRACER-AQ measurement stations and Houston  
 135 Ship Channel, and includes 427 x 415 grid cells horizontally. A two-way nesting approach (the inner domain provides feedback  
 to the outer domain) is set up between the domains. We perform two simulations where a two-way nesting between domains  
 D01 and D02 is used to drive another two-way nested simulation between domains D03 and D04. The simulations are  
 performed at a time step integration of 24 seconds and 1.8 seconds, respectively. The vertical layers comprise of 61 levels  
 across all domains with the lowest layer within ~20 m near the surface, and include 25 layers located within the PBL to resolve  
 140 boundary layer processes (~1.5 km). The vertical grid spacing gradually increases up to the top of the model at 50 hPa.

**Figure 1: The four-layer domain setup with the background contour showing average topography.**

To better examine chemical processes in a complex, dynamic urban atmosphere like Houston, a more accurate meteorological  
 145 product is needed to drive the simulations. We therefore examine model sensitivity to meteorological initial and boundary (IC  
 & BC) conditions from the High-Resolution Rapid Refresh (HRRR; Dowell et al., 2022) and the Final Operational Global  
 Analysis (NCEP-FNL; NCEP, 2000) data, with these two meteorological products widely used in previous studies (Jiménez  
 et al., 2022; Pinto et al., 2021; Gholami et al., 2021) (Fig. S1). NCEP-FNL has a spatial resolution of 1° x 1° and is provided  
 at a 6 h interval. HRRR is provided at a horizontal grid spacing of 3 km and available every 1 h up to 48 h forecasts. We  
 150 perform a two-way nested simulation using domains D01 and D02 without chemistry to test the performance of both FNL and

HRRR as IC & BC. The simulation extends from September 6, 2021 (00:00 UTC; September 5, 19:00 CDT) to September 9, 2021 (00:00 UTC, September 8, 19:00 CDT). Our model results, driven by the two datasets show similar spatial distributions of the surface heat budget (Fig. S1). We also show a wind rose diagram which gives a succinct view of how wind speed and direction are typically distributed at a particular location. Here, a prevailing north-westerly wind based on the TCEQ in-situ observations is observed. The model results driven by the NCEP-FNL more closely matches the TCEQ observed north-westerly wind than HRRR.. Wind fields are key parameters to determine the transport and mixing of pollutants. Hence, although HRRR has a much higher spatial resolution, we select the NCEP-FNL meteorological product to provide a more realistic dynamic field in our simulations.

Key physical parameterizations in our modeling include: the Rapid Radiative Transfer Model for GCMs (RRTMG) scheme for longwave and shortwave radiation (Iacono et al., 2008), Morrison double moment scheme for cloud microphysics (Morrison et al., 2009), the Noah land surface model (Chen and Dudhia, 2001), and the revised MM5 Monin-Obukhov for the surface layer scheme (Jiménez et al., 2012). The Grell 3D scheme (Grell and Dévényi, 2002) is used for cumulus parameterization to resolve sub-grid cloud processes for coarser resolution (D01 and D02), while it is turned off for D03 and the LES (D04) domain. We use the Yonsei University PBL scheme (YSU; Hong et al., 2006) to parameterize the sub-grid scale turbulent fluxes within the PBL for the mesoscale domains. YSU represents a non-local and first-order closure scheme to estimate turbulent diffusion, where vertical diffusion is expressed as a function of a non-local gradient adjustment term. This PBL option is turned off for the LES domain to resolve large eddies directly, however, finer-scale eddies are resolved by the three-dimensional 1.5 order turbulent kinetic energy (TKE) closure (Deardorff, 1970).

Simulations for the mesoscale domains (D01 – D02) cover the period from September 6, 2021 (00:00 UTC) to September 9, 2021 (00:00 UTC), which corresponds to Houston’s local time from September 5, 2021 (19:00 Central Daylight Time, CDT) to September 8, 2021 (19:00 CDT), with the first 20 hours as the spin-up time. The output was used to drive parallel simulations for D03 and the LES domain and cover the period from 11:00 to 21:00 UTC (06:00 – 16:00 CDT) on September 8, 2021.

### 2.1.2 Chemistry settings

Our study adopts the recent MOZART (Model of Ozone and Related Chemical Tracers) tropospheric chemistry scheme (T1; Emmons et al., 2020) to represent the gas-phase chemistry. MOZART-T1 is a more comprehensive chemistry scheme compared with previous versions. It includes 151 gas-phase chemical species, 65 photolysis reactions and 287 kinetic reactions. Compared to previous versions of the MOZART scheme, specific modifications are made to the oxidation of isoprene and terpenes in MOZART-T1, as well as the speciation of aromatic and organic nitrate to improve the representation of O<sub>3</sub> and secondary organic aerosol (SOA) precursors (Emmons et al., 2020). The Tropospheric Ultraviolet-Visible (TUV; Tie et al., 2003) transfer scheme is used for the estimation of photolysis rates. We also use output from the Community Earth System Model - Whole Atmosphere Community Climate Model (CESM2-WACCM; Liang et al., 2022; Gettelman et al., 2019) as the IC and BC of chemical species in our simulations. Initial conditions and boundary conditions for each nested domain are generated from the parent domains, which are produced by the 8.1 km simulation. The Model of Emissions of Gases and

Aerosols from Nature (MEGAN; Guenther et al., 2006) and the 2017 US EPA National Emissions Inventory (NEI; Reff et al.,  
185 2020) are used as biogenic and anthropogenic emissions, respectively, while the recent release of the Fire Inventory from  
NCAR (FINNv2.5; Wiedinmyer and Emmons, 2022) is used to provide fire emissions and biomass burning. NEI emissions  
data consists of point and non-point sources at a 12-km resolution and are downscaled to respective model resolutions for inner  
domains through WRF nesting. Emissions from MEGAN and FINN are available at a base resolution of 1 km, and all emission  
inventories are mapped to the same resolution for each of the domains. Our simulation results with the 2017 NEI show  
190 overestimated NO<sub>x</sub> concentrations, as found in previous urban studies (Choi and Souri, 2015; Souri et al., 2016a; Silvern et  
al., 2019; Herrmann and Gutheil, 2022). To more accurately represent emissions during the high ozone episode in Houston,  
we compare simulated concentrations of NO and NO<sub>2</sub> with their observations from TRACER-AQ and develop scaling factors  
of 0.3 and 0.2, respectively, to adjust NEI emissions of NO and NO<sub>2</sub>. The total NO<sub>2</sub> emission over Houston accounts for 11.32  
% of the total emitted NO<sub>x</sub> based on the NEI over the study period. On average, the diurnal pattern of the rescaled NO<sub>x</sub>  
195 emission is characterized by high early morning emissions at ~0.65 mol km<sup>-2</sup> h<sup>-1</sup> and then peaks in the late afternoon at ~0.74  
mol km<sup>-2</sup> h<sup>-1</sup>. The results we show in this study are based on simulations with the scaled NO<sub>x</sub> emissions. While existing studies  
show large uncertainties in previous versions of FINN which may result from the coarse resolution of the active fire product  
(Faulstich et al., 2022; Liu et al., 2020), the improved spatial resolution of the VIRS product in the FINNv2.5 provides more  
sensitive detection of fires at local and regional scales to minimize the estimated emission uncertainties (Wiedinmyer et al.,  
200 2023).

## 2.2 Observational data

### 2.2.1 TRACER-AQ airborne observations

The NASA TRACER-AQ experiment aimed to provide a robust understanding of how pollutants vary spatially, vertically and  
temporally over the Houston region. A wide range of instruments were operated during TRACER-AQ, which generated large  
205 measurement datasets from airborne, ship-based, mobile and stationary ground platforms (Knapp and Boyer, 2022; Griggs et  
al., 2024). Continuous atmospheric profile measurements from Sondes and Lidar provide unique and valuable data to  
understand the variability of pollutant profile and column concentrations (Gronoff et al., 2019). We use measured vertical  
distributions of temperature, relative humidity, wind speed, potential temperature, and ozone from field ozonesondes, which  
were launched from Galveston Bay and La Porte stations (see Fig. 2) on 8 September 2021 at 12:47 CDT and 13:07 CDT,  
210 respectively. Since the balloon drifts during its ascent in response to background winds, we use the nearest model grids along  
the sounding trajectory for accurate comparison.

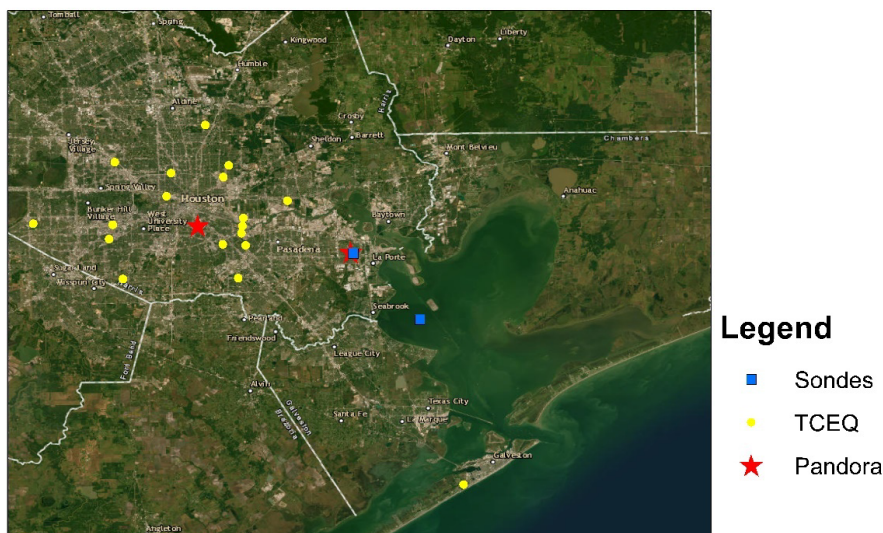

### 2.2.2 TCEQ and Pandora ground station measurements

In-situ measurements from 18 Texas Commission on Environmental Quality (TCEQ) stations are used to evaluate our  
simulated surface meteorological fields (temperature, wind speed, vertical velocity and water vapor) and pollutant (O<sub>3</sub>, NO<sub>2</sub>)

215 concentrations. Data from 67 stations in Houston are available in the TCEQ Texas Air Monitoring Information System (TAMIS) database at every hour. Data coverage from TCEQ stations is widely used in previous studies for VOCs, hydrocarbon and meteorology monitoring (Schade and Roest, 2018; Vizuete et al., 2022).

We also use level 2 (L2) data products retrieved from the two Pandora spectrometers in La Porte (29.67° N; 95.06° W) and the University of Houston (UH; 29.72° N; 95.34° W), including column concentrations of O<sub>3</sub> as well as surface concentrations of HCHO and NO<sub>2</sub> (Fig. 2). Pandora spectrometers directly use the differential optical absorption spectroscopy (DOAS) method to obtain slant column density from measured solar irradiances, and translated to estimate the tropospheric column of pollutant variables (Platt and Stutz, 2008; Herman et al., 2009, 2018; Thompson et al., 2019). Since light detected by Pandora spectrometer systems can transverse through different paths depending on the observation geometry, it allows the detection of trace gas absorption at various altitudes. Previous studies found good agreements between Pandora measurements and calibrated in-situ measurements as well as between Pandora and satellite retrieved data products (Baek et al., 2017; Martins et al., 2016; Thompson et al., 2019; Spinei et al., 2018). The sky-scanning properties of the Pandora spectrometer are critically sensitive to trace gases absorptions in the lower atmosphere and can be used to measure the tropospheric column of NO<sub>2</sub> and HCHO (~4 km top of atmosphere; TOA), while measurements at large zenith direction provide information on O<sub>3</sub> stratospheric gas absorption properties.

230

### 2.3 O<sub>3</sub> production rate and sensitivity regime

In daytime photochemical reactivity, the O<sub>3</sub> production rate (PO<sub>3</sub>) is primarily dependent on NO<sub>2</sub> production from the reactivity of NO with RO<sub>2</sub> and HO<sub>2</sub> radicals. In contrast, the loss of O<sub>3</sub> depends on the photolysis of O<sub>3</sub>, the formation of nitrate acid from OH and NO<sub>2</sub>, and the ozonolysis of alkenes. Overall, we estimate net PO<sub>3</sub> using Eq. 1 as defined by Mazzuca et al. (2016).

235

$$\begin{aligned}
 \text{Net } P(O_3) = & k_{HO_2+NO}[HO_2][NO] + \sum k_{RO_{2i}+NO}[RO_{2i}][NO] \\
 & - k_{OH+NO_2}[OH][NO_2][M] - P(RONO_2) - k_{HO_2+O_3}[HO_2][O_3] \\
 240 \quad & - k_{OH+O_3}[OH][O_3] - k_{O(1D)+H_2O}[O(1D)][H_2O] - L(O_3 + \textit{alkenes}) \quad (1)
 \end{aligned}$$

Here, the  $k$  terms represent the reaction rate coefficients;  $RO_{2i}$  is the individual organic peroxy radicals. Several indicators are used to determine the response of  $O_3$  production to  $NO_x$  and VOC emissions, thus to determine  $NO_x$ -limited and VOC-limited regimes for  $O_3$  formation. More predominantly used methods include the ratio of the rate of radical loss via  $NO_x$  reaction ( $L_N$ ) to the total primary radical production ( $Q$ ) (Mazucca et al., 2016; Zhou et al., 2014; Yu et al., 2020; Zhang et al., 2023) and HCHO to  $NO_2$  ratio (FNR; Duncan et al., 2010; Jin and Holloway, 2015; Schroeder et al., 2017; Goldberg et al., 2022; Chen et al., 2023). As proposed by Kleinman (2005),  $L_N/Q$  can be calculated by dividing the rate of radical loss via  $NO_x$  reaction ( $L_N = R_4 + R_5 + R_{6a} - R_{6b}$ ) by the total of primary radical productions ( $Q = 2*R_1 + 2*R_2 + R_3$ ). The photodissociation of  $O_3$  and HCHO represent the primary pathways for the production of  $HO_x$  ( $HO_2 + OH$ ) radicals (R1-R3), while radical termination through  $NO_x$  is summarized in R4-R6. A reactivity-weighted threshold of 0.5 indicates the transition between a VOC-limited regime and a  $NO_x$ -limited regime, with  $L_N/Q < 0.5$  representing a  $NO_x$ -limited regime, while  $L_N/Q > 0.5$  indicating a VOC-limited regime (Kleinman et al., 2001; Kleinman, 2005).

#### Radical Initiation:

#### Radical loss via $NO_x$ :

Research on FNR as an indicator for  $PO_3$  uses HCHO as an estimate of the oxidation of short-lived VOC emissions (Duncan et al., 2010). In their study, HCHO and  $NO_2$  are retrieved from satellite instruments; hence this ratio is introduced as a non-local or regional proxy for the chemical regime (Duncan et al., 2010). Previous studies have adopted varying FNR threshold values to indicate  $NO_x$  or VOC-limited regimes in regions with distinct emission characteristics (Wang et al., 2021; Chen et al., 2023). In a heavily polluted environment from HRVOC emissions, the assumption of HCHO as a proxy for short-lived VOCs may not hold, thus affecting the FNR threshold (Schroeder et al., 2017; Souri et al., 2020). For example, when a large influx of HRVOC emissions is introduced in a heavily polluted atmosphere, radical species and  $NO_x$  partitioning reach new steady state concentrations faster while HCHO may be slower to respond, which temporarily reduces the ability of HCHO to act as a proxy until it reaches a new steady state (Schroeder et al., 2017). Tonnesen and Dennis (2000) used a threshold of 1.0 to estimate the transition of the two regimes over the New York area. Duncan et al. (2010) assumed a VOC-limited regime when  $FNR < 1.0$  and a  $NO_x$ -limited when  $FNR > 2.0$ , which are also adopted in other studies (Tang et al., 2012; Jin and

275 Holloway, 2015; Chen et al., 2023). There is still a high uncertainty relating to the transition threshold between the two regimes for FNR, and peak values of FNR may reach up to ~6 in southeastern US cities (Li et al., 2022). Hence, we apply both the FNR and  $L_N/Q$  methods to examine  $O_3$  formation regimes and use the  $L_N/Q$  to investigate the FNR transition threshold in the Houston area. Calculations are conducted using model results.

## 2.4. Model evaluation metrics

280 To quantitatively evaluate the reliability of the model, we calculate the mean absolute error (MAE) and root mean square error (RMSE) for the comparison of modeled results with TCEQ observations. All comparisons are made on time-paired data for air temperature, wind speed,  $O_3$  and  $NO_2$  across selected stations. MAE and RMSE are calculated using the following equations:

$$MAE = \frac{\sum_{i=1}^n |y_i - x_i|}{n} \quad (2)$$

285

$$RMSE = \sqrt{\frac{\sum_{i=1}^n (y_i - x_i)^2}{n}} \quad (3)$$

where  $y_i$  and  $x_i$  are time-paired model and TCEQ observation values.

## 3. Results

### 3.1 Spatial distributions

Since local production of  $O_3$  is also influenced by temperature and water vapor (Kleinman, 2005; Duncan et al., 2010), it is important to capture the accurate representation of the meteorology. Thus, we first investigate horizontal distributions of simulated key meteorological fields, including temperature, horizontal and vertical wind speed, and water vapor mixing ratio near the surface across in model domains D02 and D04 on September 8, 2021. As we apply an online two-way coupling that allows feedback between the intermediate domain D03 and the LES domain D04, results from the mesoscale D03 are modified by feedback from the LES thus these two domains show similar spatial characteristics. D03 results are therefore not shown nor further discussed. Two time slices, including 09:00 CDT (Fig. S2) and 15:00 CDT (Fig. 3), are selected to represent distinct convective hours. Here, meteorological conditions reveal that warm, moist air prevails in the broad Houston region during the morning, while hot, drier air with prevailing northerly winds dominate the inland Houston during the afternoon. From 09:00 CDT to 15:00 CDT, increasing solar radiation drives a more dynamic boundary layer, with temperature, wind speed and water vapor mixing ratio all demonstrating more heterogeneities in the afternoon. We therefore show maps of the meteorological fields at 15:00 CDT here but keep the 09:00 CDT fields in the Supplementary Materials as a reference. At both times, model generally overestimates (underestimates) temperature (horizontal wind speed), although the results from the LES domain show better agreements with observations from the TCEQ stations than the results from the mesoscale D02 simulation, especially at 15:00 CDT under a more developed PBL condition. The post-sunrise (9:00 CDT) surface temperatures are relatively low and

295

300

exhibit homogeneous distributions both inland and over the sea. As the day progresses into the afternoon, surface temperature  
 305 rises over land due to increased solar radiation, with higher temperatures dominating the Central Houston region due to the  
 impact of the urban heat island (Marsha et al., 2018). Vertical wind speed also indicates enhanced daytime convective updrafts  
 at the surface in the LES domain compared to the mesoscale domains. In addition, both the mesoscale and LES results show  
 warmer biases compared to observations, though the LES domain D04 has lower RMSE of 2.39 °C and 2.74 °C for temperature  
 at the Deer Park and Clinton stations compared to 2.57 °C and 3.53 °C from the mesoscale domain D02 (Table S1). Similarly,  
 310 compared with the observed average wind speed of 4.67 m s<sup>-1</sup>, MAE values show a lower model bias for the LES at 2.42 m s<sup>-1</sup>  
 than 2.91 m s<sup>-1</sup> for the mesoscale domain at the Clinton station. While turbulence may be better resolved at finer LES  
 resolutions (Wang et al., 2023), our LES results with a horizontal spacing of 300 m demonstrate reasonable capacity to resolve  
 PBL dynamics as in Lebo and Morrison (2015) and Grant et al. (2022).

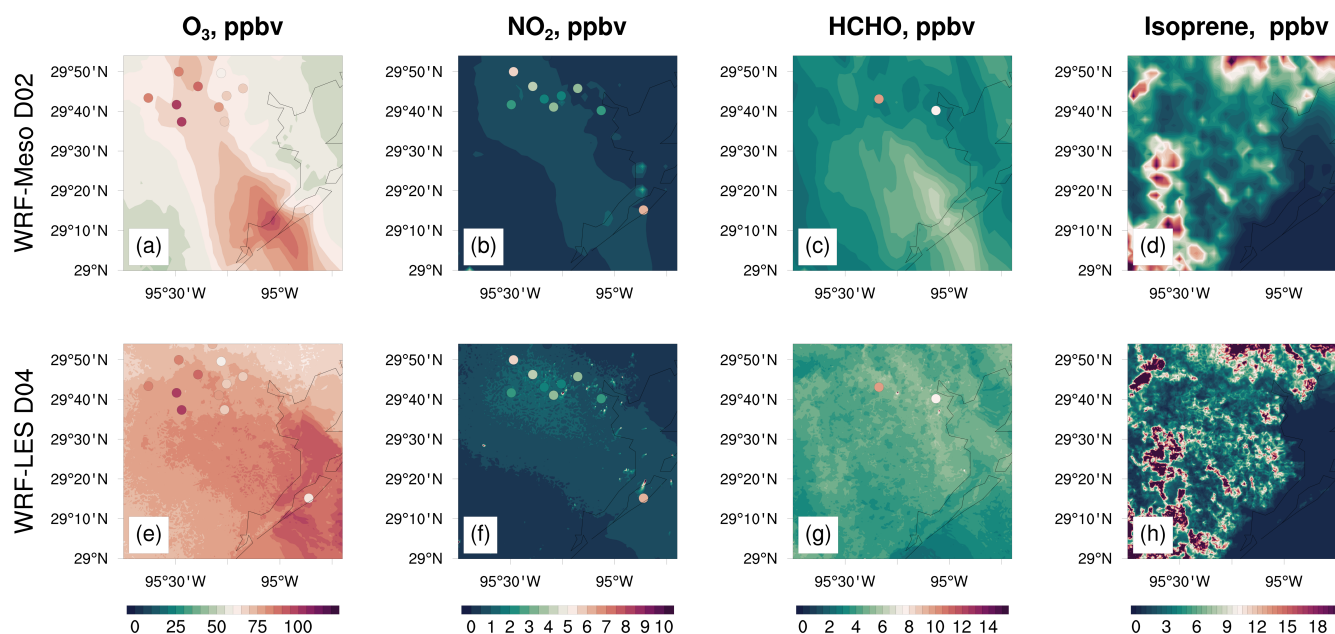

315

**Figure 3: Contour maps are horizontal distributions of simulated temperature (first column), horizontal wind speed (second column), vertical wind speed (third column), water vapor (fourth column), and wind direction (fifth column) near the surface at 15:00 CDT for D02 (first row) and D04 (second row) simulations. Circled dots represent measurements from TCEQ stations.**

320 The near-surface concentrations of modeled O<sub>3</sub>, NO<sub>2</sub>, HCHO and isoprene during the afternoon (15:00 CDT) are shown in  
 Fig. 4. Overall, the model shows slight overestimation of simulated O<sub>3</sub>, NO<sub>2</sub>, and HCHO. However, the model captures well  
 the diurnal variations of these chemical species when compared with observations. In contrast to the LES domain D04, the  
 mesoscale domain D02 shows minimal spatial variation due to its coarse resolution. Like O<sub>3</sub>, the LES domain D04 shows  
 improved model resolving capacity for chemical species as they show the best agreement with observations in the morning  
 325 and afternoon hours. Peak O<sub>3</sub> concentrations occur around 15:00 CDT. While the LES domain (D04) slightly overestimates

observations of O<sub>3</sub> over Galveston Island by up to 10 ppb, our model results in D04 still demonstrate good agreement with observations from the majority of the TCEQ stations, particularly in the Central Houston region with a dense observation network. High NO<sub>2</sub> concentrations are both observed and simulated in the morning hours (Fig. S3), with a maximum surface concentration of 42 ppbv identified in Central Houston, resulting from road traffic emissions during rush hour (Souri et al., 2016b). In the late afternoon, the photolysis of NO<sub>2</sub> is enhanced, thus resulting in reduced NO<sub>2</sub> concentrations. Overall, the model captures NO<sub>2</sub> dominant zones within the Central Houston and the Houston Ship Channel areas, as their presence in the atmosphere is largely dependent on anthropogenic emissions. The statistical comparison of both the mesoscale and LES domains with TCEQ observations (Table S1) show an overestimation of O<sub>3</sub> mixing ratio, though LES simulates a lower bias (RMSE = 5.49 ppbv, MAE = 4.32 ppbv) compared to the mesoscale domain D02 (RMSE = 16.01 ppbv, MAE = 15.05 ppbv) at the Deer Park station. Like O<sub>3</sub>, the LES results exhibit lower biases at both stations for NO<sub>2</sub> when compared with the TCEQ observations. Although the LES performs better, the results in this domain still show biases, which are likely induced by the uncertainties and coarser resolutions of the emissions inventories used in this study (Herrmann and Gutheil, 2022). Also, the temporal variability of the WACCM boundary conditions used in our simulations may introduce transport errors as identified in other regional modeling studies (Tang et al., 2023). In contrast to NO<sub>2</sub>, HCHO follows an opposite diurnal pattern with lower concentration in the morning hours and higher concentration in the afternoon due to photochemical reactions of primary and oxygenated VOCs (Zhang et al., 2022). The temporal distributions of NO<sub>2</sub> and HCHO are different as afternoon HCHO is a product of emitted HCHO and secondary HCHO produced from other precursors, thus higher in the afternoon when atmospheric oxidation is high (Nowlan et al., 2018). Isoprene, a major precursor to daytime O<sub>3</sub> production, shows higher concentrations in the late afternoon (Fig. 4), as the biogenic emissions are dependent on temperature and light (Rinne et al., 2002; Guenther et al., 2006; Zeng et al., 2023). In addition, surface and column concentrations of NO<sub>2</sub>, HCHO and O<sub>3</sub> from Pandora spectrometers are used to evaluate the model's performance as shown in the Supplementary Materials (Fig. S4). We also see the LES domain D04 show improved column concentration of HCHO, NO<sub>2</sub> and O<sub>3</sub>, which is consistent with the diurnal variations of the pollutants from the Pandora spectrometers.

350 **Figure 4: Contour maps are horizontal distributions of simulated O<sub>3</sub> (first column), NO<sub>2</sub> (second column), HCHO (third column) and isoprene (fourth column) near the surface at 15:00 CDT for D02 (first row) and D04 (second row) simulations. Dots represent TCEQ observations of O<sub>3</sub> and NO<sub>2</sub> and Pandora observations of NO<sub>2</sub> and HCHO. Isoprene and other key VOCs are validated separately.**

To understand O<sub>3</sub> formation, an accurate model interpretation of its VOC precursors is needed. We, therefore, validate our modeled VOCs by comparing key VOCs that are measured by the Proton Transfer Reaction – Mass Spectrometry (PTR-MS) at San Jacinto Battleground State Historical site (29.753 °N, 95.091 °W), a TRACER-AQ site (Fig. 5). The comparison results indicate the model adequately reproduces observations, with results from the LES domain D04 better matching observed VOCs, especially for acetaldehyde, isoprene, HCHO, methyl ethyl ketone (MEK), toluene and xylenes. Although acetone is largely underestimated in the mesoscale D02 simulations, the LES results better reproduce observations. We also acknowledge that the difference in measurement time (30 s) and model average time (1 h), as well as representing a station with one model grid cell may account for further disparities between the model and station measurement. This intercomparison considers daytime VOC concentrations, while the San Jacinto site has previously reported anomalous, high isoprene and MEK concentrations overnight that may likely arise from anthropogenic activity instead of biogenic emission and oxidation (Shrestha et al., 2023). The daytime intercomparison here likely reflects the local biogenic contributions to isoprene.

365

**Figure 5: Comparison of daily concentration averages (over 8:00 – 16:00 CDT) of selected VOCs from our simulations in D02 and D04 and measurements at the San Jacinto Battleground State Historical site.**

### 370 3.2 Vertical Profiles

We next examine simulated vertical profiles of key meteorological and chemical fields to study the role of boundary layer mixing in modifying surface levels of air pollutants. Simulated vertical profiles of  $O_3$  and key meteorological variables are compared with sonde measurements from TRACER-AQ over two launch sites, La Porte and Galveston Bay, as shown in Fig. 6. The trajectories of sondes can drift gradually from the launch sites to higher altitudes; therefore, simulation results aloft are selected according to sonde positions to minimize comparison bias of the vertical profiles. For potential temperature, the LES domain D04 provides a better match with observations than the mesoscale domain D02. Additionally, the LES domain D04 simulates a PBL height (PBLH) of approximately 1.3 km at the Galveston Bay launch site, comparable with sonde measurements of about 1.1 km (Fig. 6d). At the Galveston Bay site, the LES overestimates wind speed by  $\sim 3 \text{ m s}^{-1}$  near the surface and  $\sim 2 \text{ m s}^{-1}$  at 1.3 km altitude when compared to sonde observations. Similarly, from the surface to  $\sim 0.5 \text{ km}$  altitude, wind speed is also overestimated by the model by a maximum value of  $\sim 1.5 \text{ m s}^{-1}$ , a 30 % difference based on the observations at the La Porte site. For relative humidity, the model simulates contrasting patterns below and above  $\sim 1.3 \text{ km}$  altitude and underestimates relative humidity by 30 % below this transition altitude in the Galveston Bay region. Compared with the Galveston site, modeled vertical profiles of relative humidity depict smaller biases compared to observations at the La Porte site, with less bias from the LES domain than the mesoscale domain. The larger model-observation discrepancy at the Galveston station may be related to the proximity of the station to the open water surface of the Gulf of Mexico, as the rapid changes in air dynamics over the land-sea interface typically could not be accurately resolved through modeling (Ward et al., 2020). In addition, land surface parameterization in models in accurately modifying surface sensible and latent heat fluxes may vary over land and near water surfaces, thus further affecting simulated moisture metrics (Kantha Rao and Rakesh, 2019). Similarly, the NCEP-FNL meteorology at a  $1^\circ \times 1^\circ$  coarse resolution used to drive our modeling may also introduce simulated

390 moisture bias at upper altitudes, which could primarily be due to inaccurate surface soil moisture that cannot be well represented at this coarse resolution (Ochsner et al., 2013).

The vertical structures of temperature show reasonable performance compared with observations at both sites, with the LES domain slightly performing better (+0.5 °C bias) than the mesoscale domain (+0.7 °C bias). Simulated O<sub>3</sub> profiles also show biases comparing with observed profiles. The LES domain D04 overestimates O<sub>3</sub> mixing ratio while the mesoscale domain  
395 D02 underestimates it over both sites. Discrepancies between model and observations may be attributed to the time lag between sonde measurements and simulation outputs. Minute-to-minute changes in wind speed and directions affect the distribution and dispersion of air masses (Li et al., 2019), thus the time differences may affect the model-observation comparison. In addition, the accuracy of reanalysis meteorological datasets, which are used to drive model simulations, in representing vertical profiles of key meteorological factors and their diurnal evolution may also contribute to the comparison discrepancy. We  
400 further investigate the temporal evolution of the vertical cross-section at the University of Houston and La Porte in the Supplementary Materials (Fig. S5) and show the LES domain captures the peak low-level O<sub>3</sub> concentration (96 ppb) between 18:00 UTC (13:00 CDT) and 21:00 UTC (16:00 CDT) when compared to ground-based Lidar measurements from TRACER-AQ (90 - 125 ppb).

In addition, we compare the evolution of O<sub>3</sub> and NO<sub>2</sub> vertical profiles from the mesoscale domain D02 and LES domain D04  
405 to show cross-domain differences in resolving variations of pollutants vertically (Fig. 7). As the day progresses, simulated O<sub>3</sub> mixing ratio near the surface increases, reaching up to 80 ppb in the LES domain in the late afternoon. In the early morning, O<sub>3</sub> increases while NO<sub>2</sub> decreases with height, indicating high O<sub>3</sub> accumulation aloft from the nocturnal stable layer and high NO<sub>x</sub> emissions from surface anthropogenic activities during morning rush hours. A more well-mixed atmosphere during the daytime then reflects higher dispersion of pollutants from the surface to aloft. The inter-domain comparison shows contrasting  
410 results in O<sub>3</sub> profile both below and above the PBL. O<sub>3</sub> in the LES domain D04 decreases with height within the PBL and gradually increases above 2 km, which is generally in line with lidar observations. More inter-domain comparison of diurnal evolution of vertical profiles of key meteorological and chemical factors are shown in Fig. S6. Following the comparative evaluation of the meteorology and chemistry across domains and between modeling and observations, the LES domain D04 provides a more realistic atmospheric condition.

415

420

Figure 6: Comparison of vertical profiles of temperature, relative humidity, wind speed, potential temperature, and O<sub>3</sub> mixing ratio from the TRACER-AQ ozonesondes over Galveston Bay (12:47 CDT; a-e) and La Porte (13:07 CDT; f-j) with model results (13:00 CDT). The black lines represent observations; the blue dashed lines are for the D02 results with a resolution of 2700 m; the green dashed lines are for the LES D04 results with a resolution of 300 m.

Figure 7: Domain-averaged vertical profiles of O<sub>3</sub> (left panel) and NO<sub>2</sub> (right panel) at 09:00 (blue), 12:00 (brown) and 15:00 CDT (black). Domain D02 results are shown as solid lines while the LES results over the D04 domain are represented as dashed lines.

### 425 3.3 O<sub>3</sub> formation regime

Next, we investigate the variability of O<sub>3</sub> production under different formation regimes. High O<sub>3</sub> production rate (P(O<sub>3</sub>)) occurs in the Central Houston region and extends towards the Houston Ship Channel during the daytime (Fig S7). Previous studies have found that O<sub>3</sub> formation is driven by a non-linear photochemical reaction under NO<sub>x</sub>-limited and VOC-limited regimes, and determined by different sensitivity indicators (Sillman et al., 2003; Ye et al., 2016). However, O<sub>3</sub> sensitivity indicators, including L<sub>N</sub>/Q and FNR, may vary spatially and at different times due to the spatial and temporal heterogeneity of total radical loss via NO<sub>x</sub> and radical production as well as the mixing ratio of HCHO and NO<sub>2</sub> (Jin and Holloway, 2015). Figure 8 shows a spatial distribution of surface photochemical regimes associated with O<sub>3</sub> production from the simulated LES domain. Here, L<sub>N</sub>/Q indicates O<sub>3</sub> production is mainly a VOC-limited regime (L<sub>N</sub>/Q > 0.5) in the morning, and then transitions into a NO<sub>x</sub>-limited regime (L<sub>N</sub>/Q < 0.5) in the late afternoon. However, regions around Baytown, Texas City and Deer Park exhibit a VOC-limited or transitional regime also in the late afternoon. The FNR of the whole Houston area in the morning is less than 1.2, indicating that a VOC-limited regime is prevalent during this hour and a noontime transition into a NO<sub>x</sub>-limited regime is also observed. It is worth noting that the transitional regime between a VOC-sensitive and NO<sub>x</sub>-sensitive regime as defined by the FNR indicator varies with regions as described by Duncan et al. (2010). Previous findings by Schroeder et al. (2017) define the FNR transition regime over Houston between 0.7 < FNR < 2.0, based on the relative rate of radical termination from radical-radical interactions to radical-NO<sub>x</sub> interactions. The ratio of FNR changes in response to the changes in VOCs and NO<sub>x</sub>, and variations in NO<sub>2</sub> may have greater impacts on the ratio than variations in HCHO. Thus, it is difficult to define an explicit cut-off for the FNR transition regime based on fluctuations in NO<sub>2</sub>. Ambient changes in HCHO and NO<sub>2</sub> respond immediately to changes in emissions sources and FNR will change in accordance, depending on which is predominant. Thus, using the ratio of radical production through HCHO and loss through NO<sub>x</sub> provides a more useful determinant for estimating FNR transition ratio of O<sub>3</sub> sensitivity. Hence, using model estimated values of the transition regime from the L<sub>N</sub>/Q indicator, we calculated the threshold for FNR transition regime, and find a range of 0.6 < FNR < 1.8 lies in the transition regime zone. Based on the similarities in the radical indicator approach to define the FNR transition regime, our associated range of FNR values is fairly consistent with the range described by Schroeder et al. (2017).

The discrepancy in our work compared to other studies relating to the modeled P(O<sub>3</sub>) when using either L<sub>N</sub>/Q or FNR may be attributed to differences in model chemistry and spatial resolution. Previous studies from Ren et al. (2013) and Mazzuca et al. (2016) used a simplified alkene chemistry in the Carbon Bond mechanism, version 5 (CB05) and overpredicted O<sub>3</sub> production in the morning in locations where alkenes dominate VOC reactivity. The alkene chemistry from the MOZART-T1 chemical mechanism used in our work considers relative alkene contributions from biogenic sources (Emmons et al., 2020), which is not often considered in other chemical mechanisms.

455

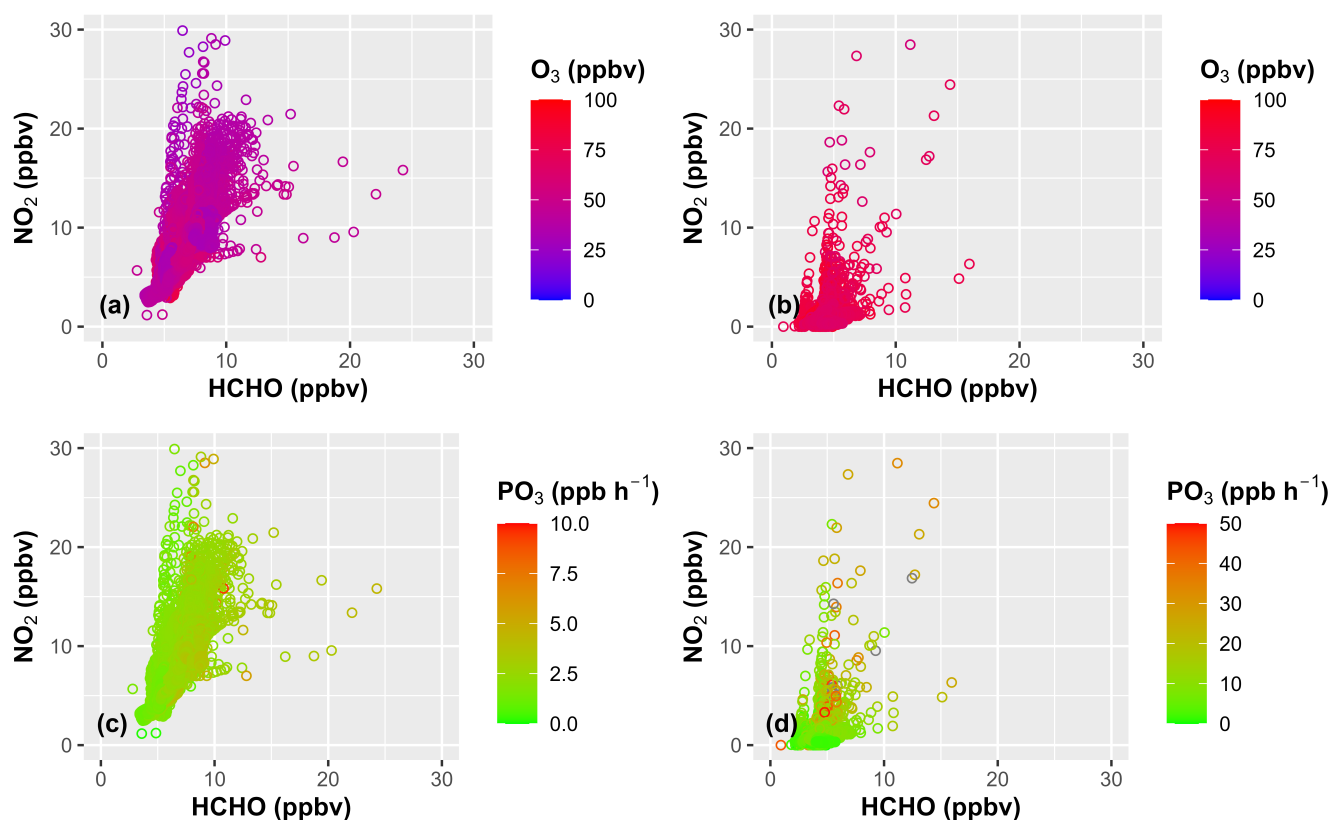

**Figure 8: Spatial distributions of the  $O_3$  formation regime determined by  $L_N/Q$  (upper panel) and FNR (lower panel) at 09:00 CDT, 12:00 CDT and 15:00 CDT. Calculated based on results from the LES domain over Houston.**

The non-linear process of  $NO_2$  and HCHO in relation to  $O_3$  formation and sensitivity regimes is further discussed in Fig. 9 from the model simulations. In Fig. 9,  $PO_3$  describes the rate of ozone production under different sensitivity regimes at specific diurnal hours while  $O_3$  as a function of  $NO_2$  and HCHO depicts the overall daytime concentration of  $O_3$  under these regimes. In the morning, when  $NO_2$  is high but HCHO is low,  $PO_3$  is higher with increasing HCHO, indicating a VOC-limited regime. Though we note that the production rate of  $HO_x$  ( $OH + HO_2$ ) radicals is lower than their loss rate during this period under high  $NO_2$  concentrations, thus leading to a lower production of  $O_3$  in the morning than in the afternoon. In the Supplementary Materials (Fig. S8), the maximum net  $PO_3$  in the morning is estimated at  $10 \text{ ppb h}^{-1}$  over the whole of Houston. In contrast, during the afternoon when  $NO_2$  is low but HCHO is high,  $PO_3$  increases with increasing  $NO_2$  levels and indicates a  $NO_x$ -limited regime. During this period, the rate of  $HO_x$  radical production is higher following the oxidation of VOCs by OH, thus

enhancing  $PO_3$  in the afternoon. An increase in  $HO_2$  reaction rate under a  $NO_x$ -limited regime leads to the enhancement of  $O_3$  production (Li et al., 2023). The dependence of  $O_3$  concentrations on  $NO_x$  levels during daytime chemistry shows that the  $O_3$  mixing ratio is a maximum when  $NO_x$  levels are low ( $< 10$  ppbv; Fig. S8).  $PO_3$  reaches  $50$  ppb  $h^{-1}$  in the late afternoon, which is higher than the average afternoon  $O_3$  production of  $20 - 30$  ppb  $h^{-1}$  observed during the DISCOVER-AQ campaign (Mazuca et al., 2016). This further shows the high  $O_3$  production during the TRACER-AQ campaign in 2021. The distinction, however, between these photochemical regimes is not simple and may be influenced by meteorology or unique environmental characteristics (De Foy et al., 2020; Li et al., 2023).

475

**Figure 9:**  $O_3$  (upper panel) and  $PO_3$  (lower panel) as a function of  $NO_2$  and  $HCHO$  for 09:00 CDT (a and c) and 15:00 CDT (b and d) in Houston from the LES domain. NOTE: we use different color scales for morning and afternoon periods for distinct understanding of ozone formation at different times.

480

Since the observed  $NO_x$ - $O_3$ -VOC chemistry in Fig. 8 shows some spatial heterogeneity of the  $O_3$  sensitivity regimes, we further examine the photochemical production of  $O_3$  in relation to different environments over Houston. Figure 10 shows the diurnal variability of  $O_3$  and  $NO_x$  and the  $O_3$  sensitivity regime indicators over four regions including Central Houston, La Porte, Brazoria-Galveston region (BGR) and the whole of Houston. According to Hossain et al. (2021), the contributions from

485 point sources in La Porte, Texas City near Galveston and downtown Houston contribute most to O<sub>3</sub> formation as point sources  
alongside other mobile sources. The stations also represent different pollution characteristics to understand how unique  
emission sources affect the overall photochemical sensitivity to PO<sub>3</sub>. For example, heavy power plants contribute the most  
NO<sub>x</sub> in a VOC-limited regime and transportation in a NO<sub>x</sub>-limited regime (Jin and Holloway, 2015). According to Nowlan et  
al. (2018), the highest NO<sub>x</sub> emissions in Houston are from the metropolitan area from mobile sources. Among other HRVOCs,  
490 light olefins (including butene, ethane and propane) emissions dominate La Porte and Houston Ship Channel from  
petrochemical plants (Murphy and Allen, 2005). We show that NO<sub>x</sub> levels are highest (NO<sub>2</sub> = 26 ppbv; NO = 6 ppbv) during  
the early morning over La Porte, followed by Central Houston (NO<sub>2</sub> = 22 ppbv; NO = 6 ppbv) and lowest at the Brazoria-  
Galveston region. The high level of NO<sub>x</sub> over La Porte is mainly due to emissions from petrochemical plants and marine  
vessels at the HSC (Kim et al., 2011) and other mobile sources. On the other hand, NO<sub>x</sub> emissions over Central Houston are  
495 from mobile sources (Nowlan et al., 2018; Kim et al., 2011), while the NO<sub>x</sub> levels from BGR can be attributed to petroleum  
refining sources around Texas City (Souri et al., 2018). Notably, NO<sub>x</sub> levels are generally low from the late morning hours  
into the afternoon and underline the diurnal variability of NO<sub>x</sub> emission sources as well as the fast photodissociation of NO<sub>x</sub>.  
Although the NEI anthropogenic emissions inventory reasonably captures these diurnal patterns, improvements are further  
needed given its overestimation of NO<sub>x</sub> in Houston.

500 The diurnal variation of L<sub>N</sub>/Q and FNR indicates that O<sub>3</sub> formation is mainly a VOC-limited regime in the early morning over  
the Central Houston, La Porte and Whole Houston (domain average), and then transitions into a NO<sub>x</sub>-limited regime later in  
the day (Fig. 10). During the morning hours, the lower O<sub>3</sub> mixing ratio in Central Houston and La Porte is mainly associated  
with a VOC-limited regime due to higher NO<sub>x</sub> levels; however, they increase gradually towards noontime as NO<sub>x</sub> decreases  
with increasing VOCs. This is consistent with previous studies that have shown that O<sub>3</sub> production is mainly suppressed by  
505 high NO<sub>x</sub> concentrations in a VOC-limited regime (Li et al., 2011). On average, O<sub>3</sub> formation is mainly NO<sub>x</sub>-limited in the  
afternoon (between 11:30 and 16:00 CDT) across all the regions, and the high O<sub>3</sub> (Fig. 10) is dependent on the daytime  
abundance of RO<sub>2</sub> and HO<sub>2</sub> radicals through the photolysis of O<sub>3</sub>, HCHO and other secondary VOCs (Ma et al., 2022). In the  
Brazoria-Galveston region, the high O<sub>3</sub> in the early morning hours is associated with O<sub>3</sub> production being mainly NO<sub>x</sub>-limited  
between 6:30 and 7:30 CDT (L<sub>N</sub>/Q < 0.5) before transitioning to a VOC-limited regime in the remaining hours of the morning  
510 (8:00 and 11:30 CDT). During this NO<sub>x</sub>-limited period, high sources of NO<sub>2</sub> rapidly increases O<sub>3</sub> formation (Duncan et al.,  
2010; Schroeder et al., 2017). In addition, we show how O<sub>3</sub> formation regime may vary spatially with height in the  
Supplementary Information (Fig. S9). We find that the production of O<sub>3</sub> is under a VOC-limited regime at the surface in the  
morning and transitions into a NO<sub>x</sub>-limited regime in the upper atmosphere (> 200 m AGL) due to the rapid photochemical  
consumption nature of NO<sub>x</sub> near the surface.

515

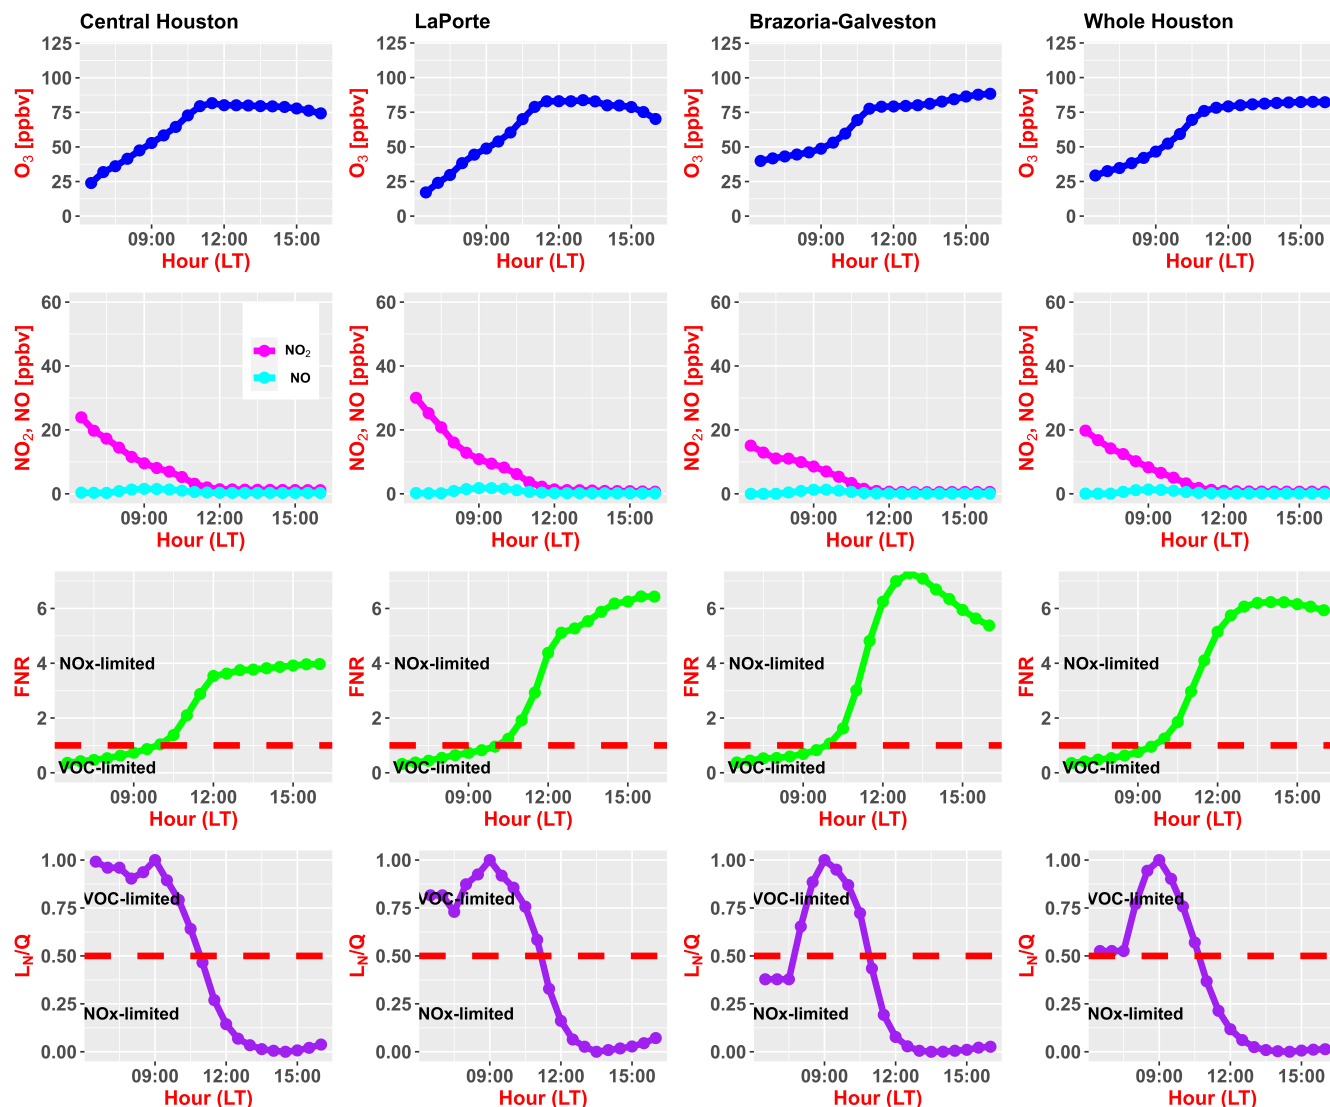

Figure 10: Diurnal variations of O<sub>3</sub> (first row), NO and NO<sub>2</sub> (second row), FNR (third row) and L<sub>w</sub>/Q (fourth row) in the near-surface layer averaged over Central Houston (first column), La Porte (second column), Brazoria-Galveston (third column) and the whole LES domain (fourth column). Results are from the LES domain (D04).

### 520 3.4 OH reactivity

We further quantify the total OH reactivity ( $K_{OH}$ ) to characterize the roles of VOCs in the formation of O<sub>3</sub>.  $K_{OH}$  is defined as the sum of concentrations of OH reactants multiplied by their reaction rate coefficients (Yang et al., 2016; Fuchs et al., 2017; Ma et al., 2022), as shown in Eq. (4)

$$K_{OH} = \sum_i^n K_{VOC_i} \times [VOC_i] \quad (4)$$

525 where  $[VOC_i]$  is the VOC concentrations and  $K_{VOC_i}$  is the corresponding reaction rate coefficients. In this study,  $K_{OH}$  is calculated from 29 major modeled VOC species which are grouped into three groups, including non-methane VOCs (NMVOCs), OVOCs and biogenic VOCs (BVOCs). The NMVOCs consist of alkanes (ethane, propane and lumped alkanes with  $C > 3$ ), alkenes (ethene, propene/propylene, lumped alkenes with  $C > 3$ ), alkynes (acetylene), aromatics (benzene, toluene, xylene) and glyoxal, while the BVOCs include isoprene and monoterpenes (limonene,  $\alpha$ -pinene,  $\beta$ -pinene,  $\beta$ -caryophyllene and other sesquiterpenes). The OVOCs species are mainly secondary VOC species and include ketones (methyl vinyl ketone, methyl ethyl ketone, acetone), aldehydes (formaldehyde, acetaldehyde, methacrolein, benzaldehyde, glycolaldehyde, lumped aldehyde), acids (formic acid, acetic acid), and alcohols (methanol, ethanol and phenol). Table 1 provides a summary of the total OH,  $O_3$  and  $NO_3$  reactivity with individual VOC species. The OH reactivity analysis shows isoprene is the highest contributor to total  $K_{OH}$  at noon (12:00 CDT) at  $9.86 \text{ s}^{-1}$  (35.76 %), followed by CO (12.98 %), HCHO (12.21 %), Bigalk 530 (lumped alkanes; 6.29 %), and  $NO_2$  (4.46 %). The contribution of the daytime reactivity of isoprene to the total  $K_{OH}$  is substantial and very high when compared to other urban studies by Fuchs et al. (2017, 20 %) and Ma et al. (2022, 5 %). The contribution of HCHO (12.21 %) and acetaldehyde (4.88 %) as the most dominant OVOC species in reactivity with OH is consistent with the established literature from other locations (Whalley et al., 2016; Ma et al., 2022). Also, the high value of HCHO reactivity is related to the high values from the oxidation of isoprene, as HCHO in the Houston-Brazoria region is 540 predominantly from VOC oxidation (Parrish et al., 2012; Zhou et al., 2014). For most species, the modeled  $K_{OH}$  reduces at 15:00 CDT compared to the noontime, while isoprene was higher at 15:00 CDT ( $9.98 \text{ s}^{-1}$ ; 46.61 %). In addition, we consider the modeled reactivity of  $O_3$  and  $NO_3$  with VOCs and show that the total  $O_3$  reactivity is dominated by the BVOCs. For example, the ozonolysis of  $\beta$ -caryophyllene increases from  $0.39 \text{ s}^{-1}$  at noon to  $0.84 \text{ s}^{-1}$  (27.07 %) in the late afternoon, due to the increased concentration of  $O_3$  at 15:00 CDT.

545 The overall breakdown of the VOC groups and their OH reactivity over the focused regions averaged from 6:30 to 16:00 CDT is summarized in Fig. 11. The daytime total VOC concentration is dominated by OVOCs (73 %), while BVOCs contribute the least ( $\sim 3$  %). In comparison to other regions, the maximum VOC concentration is observed in La Porte. On the other hand, the total  $K_{OH}$  is dominated by BVOCs (58 %) in the Central Houston region. From individual VOC species, NMVOCs species are mostly dominant with alkanes contributing to about 50–55 % of the total mixing ratio but are less reactive with OH radicals, 550 while alkenes are more reactive with OH radicals and contribute 60–65 % of the total  $K_{OH}$  from NMVOCs across all zones. For BVOCs, isoprene is highly dominant with monoterpenes contributing less than 2 % in the total BVOC mixing ratio and reactivity with OH and mixing ratio. Aldehydes are the most reactive OVOCs (70–73 %), and alcohols dominate the total OVOC concentration ( $\sim 50$  %).

Figure 12 shows the mixing ratio and OH reactivity of individually modeled compounds as a stacked area plot over the whole 555 Houston region. In the daytime, isoprene as the main biogenic species accounted for more than half of the total reactivity, while VOCs from anthropogenic activities and in oxygenated forms including alkanes, alkenes, aldehydes, alcohols and aromatics account for the other 50 % of the total OH reactivity. For NMVOCs and OVOCs, the total OH reactivity peaks at about 11:00 (CDT), while the OH reactivity of isoprene increases continuously during the day and peaks at 16:00 CDT. For

the mixing ratio, the NMVOCs peak in the early morning hours and gradually reduce towards late afternoon. Similar stacked  
 560 area plots for Central Houston, La Porte and the BGR are provided in the Supplementary Materials (Fig. S10-S12). The results  
 are consistent with the diurnal patterns observed over the whole Houston area, but a higher magnitude for total OH reactivity  
 of NMVOCs and OVOCs is observed in La Porte, while isoprene contributes the highest to the total  $K_{OH}$  in Central Houston.  
 The analysis of OH reactivity with VOC is important to estimate the potential of  $O_3$  formation from VOC oxidation. The  
 oxidation of VOC by OH produces  $RO_2$  and  $HO_2$  radicals, which is identified as the major contributor to  $O_3$  formation in  
 565 Houston (Zhou et al., 2014). While we show that isoprene contributes the highest to the total  $K_{OH}$  due to its high reactivity  
 with OH, it is unknown how much this affects  $O_3$  formation. A recent study from Li et al. (2023) shows that isoprene reactivity  
 did not increase during high  $O_3$  events during the NASA TRACER-AQ campaign, and shows similar OH reactivity on clean  
 $O_3$  days. OVOCs, similarly, show a high contribution to the total OH reactivity, particularly from HCHO and acetaldehyde,  
 however, they are considered the most important VOC species oxidized by OH that increases  $O_3$  production (Zhou et al., 2014;  
 570 Li et al., 2023). According to previous studies in Houston, HCHO represents the highest contributor to  $HO_2$  production (Parrish  
 et al., 2012; Ren et al., 2013; Wong et al., 2013). From the Supplementary Material (Table S2), we also show the photolysis  
 of HCHO, methyl glyoxal and glyoxal dominates the production of  $HO_x$  radicals over the whole Houston region. HCHO loss  
 rate through photolysis peaks (with a maximum of  $0.14 \text{ pptv s}^{-1}$ ) at 12:00 CDT, similar to other loss rates across cities in  
 Europe at  $0.28 \text{ pptv s}^{-1}$  (Nussbaumer et al., 2021). Industrial emissions are identified as the main primary source of HCHO in  
 575 the Houston area (Johansson et al., 2014) with an average emission over the Houston region estimated at  $8631.02 \text{ mol km}^{-2} \text{ hr}^{-1}$   
 over the simulation period based on the NEI inventory. In contrast, a comprehensive chemical analysis of airborne and ground  
 measurements of HCHO and emissions data concluded that HCHO is mainly from VOC oxidation in the Houston area (Parrish  
 et al., 2012). As HCHO is one of the major oxidation products of isoprene by OH (Sprengnether et al., 2002), we conclude  
 that high isoprene reactivity with OH enhances HCHO formation; the photolysis of HCHO forms  $HO_2$  which then increases  
 580 the potential of  $O_3$  formation.

**Table 1: Reactivity of OH,  $O_3$ , and  $NO_3$  with key chemical species ( $s^{-1}$ ) averaged over the LES domain.**

590 **3.5 AOC analysis**

The oxidative capacity of the atmosphere is important to understand the abundance of RO<sub>x</sub> radicals including HO<sub>2</sub>, OH and RO<sub>2</sub> radicals, which drive the production, transformation and recycling of O<sub>3</sub> (Liu et al., 2022). AOC is calculated as the sum of oxidation rates of various pollutants by the major oxidants (OH, NO<sub>3</sub> and O<sub>3</sub>) (Xue et al., 2016; Chen et al., 2020; Liu et al., 2022). In this study, AOC is calculated based on the modeled VOCs and their rate coefficients, as shown in Eq. (5-7), and does not account for the reactivity of OH, NO<sub>3</sub> and O<sub>3</sub> with other VOC oxidation products that are not included in the gas phase mechanism used within our WRF-LES-Chem modeling. Thus, we acknowledge that possible discrepancies may exist between

595

the calculated values of these reactivities and their actual measurements, as shown in previous studies (Mao et al., 2010; Ren et al., 2013).

$$\begin{aligned} \text{Total OH reactivity} = & \sum k_{OH+NMVOC_i}[NMVOC_i] + \\ & k_{OH+CH_4}[CH_4] + k_{OH+CO}[CO] + \\ & k_{OH+NO}[NO] + k_{OH+NO_2}[NO_2] + \\ & k_{OH+SO_2}[SO_2] + k_{OH+O_3}[O_3] + \dots \end{aligned} \quad (5)$$

$$\begin{aligned} \text{Total O}_3 \text{ reactivity} = & \sum k_{O_3+NMVOC_i}[NMVOC_i] + \\ & k_{O_3+CH_4}[CH_4] + k_{O_3+NO}[NO] + \\ & k_{O_3+NO_2}[NO_2] + \dots \end{aligned} \quad (6)$$

$$\begin{aligned} \text{Total NO}_3 \text{ reactivity} = & \sum k_{NO_3+NMVOC_i}[NMVOC_i] + \\ & k_{NO_3+CH_4}[CH_4] + k_{NO_3+NO}[NO] + \\ & k_{NO_3+NO_2}[NO_2] + k_{NO_3+SO_2}[SO_2] + \dots \end{aligned} \quad (7)$$

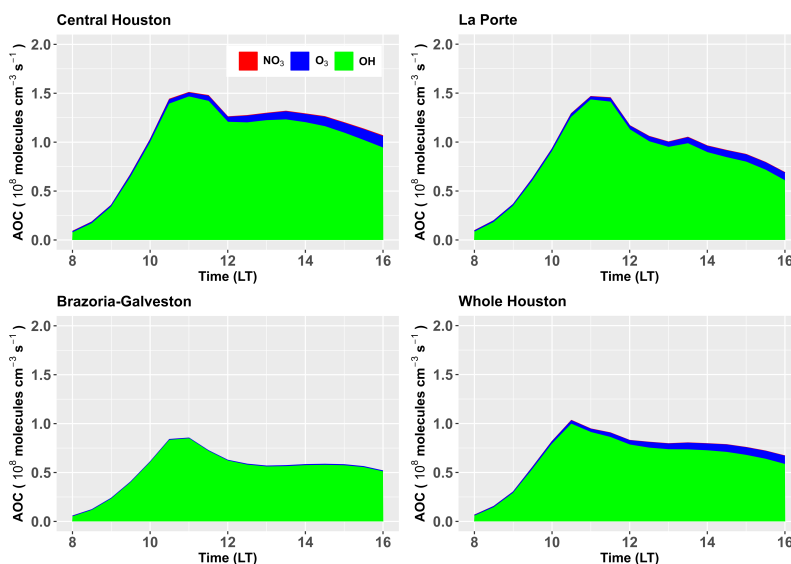

Figure 13 shows the time series of the model-calculated AOC over Houston. The estimated AOC daytime averages (08:00 – 16:00 CDT) is  $1.11 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ,  $0.88 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ,  $0.52 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$  and  $0.69 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$  respectively for Central Houston, La Porte, Brazoria-Galveston and Whole Houston. As shown in Fig. 13, the daily maximum AOC is observed in Central Houston and La Porte at  $1.5 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ , and much higher than those in the less polluted region in Brazoria-Galveston at  $0.8 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ . The daily maximum AOC is similar to other areas with high pollution from oil and gas in China ( $1.8 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ; Chen et al., 2020) or other urban areas in Hong Kong ( $1.3 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ; Xue et al., 2016) or Xiamen ( $1.3 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ; Liu et al., 2022).

The differences in AOC across these regions may be attributed to relatively higher solar radiation or pollutant concentrations among different sites (Zhu et al., 2020; Liu et al., 2022). As expected, OH is the major daytime oxidant, accounting for more than 90 % of the total AOC. In the late afternoon, the contribution of  $O_3$  to AOC increases up to 8-10 % in Central Houston and La Porte compared to the morning hours when they contribute less than 5 %. In addition, the higher contribution of  $O_3$  to AOC is attributed to the high concentration of alkenes in the region (Xue et al., 2016), and alkene ozonolysis increases as the day progresses with the abundance of  $O_3$ . AOC contributed by  $NO_3$  is negligible as  $NO_3$  can be quickly photodissociated during daytime thus having a low daytime concentration. Figure 14 elucidates the daytime variability of primary anthropogenic VOCs, OVOCs and trace species and their reactivity with OH,  $O_3$  and  $NO_3$ . In Brazoria-Galveston, the oxidation of alkanes, CO and methane ( $CH_4$ ) by OH increases slightly as the day progresses into late afternoon. The simulated OVOCs are the dominant contributor to OH reactivity and contribute 30-40 % of the total AOC across all regions. This is similarly evident over the whole of Houston. Further information from the Supplementary material shows that the total OH reactivity for OVOCs is much higher ( $1.36 \pm 0.59 \text{ s}^{-1}$ ) (mean  $\pm$  standard deviation) on average over the whole domain compared to other groups (see Table S3), while CO ( $0.72 \pm 0.29 \text{ s}^{-1}$ ),  $CH_4$  ( $0.2 \pm 0.09 \text{ s}^{-1}$ ), alkanes ( $0.3 \pm 0.12 \text{ s}^{-1}$ ), alkenes ( $0.28 \pm 0.16 \text{ s}^{-1}$ ), aromatics ( $0.05 \pm 0.03 \text{ s}^{-1}$ ), and  $SO_2$  ( $0.04 \pm 0.02 \text{ s}^{-1}$ ) also make up the averaged total OH reactivity, thus indicating the strong influence of anthropogenic emissions in Houston. The comparison across different zones shows that the oxidation of alkanes ( $0.39 \pm 0.19$

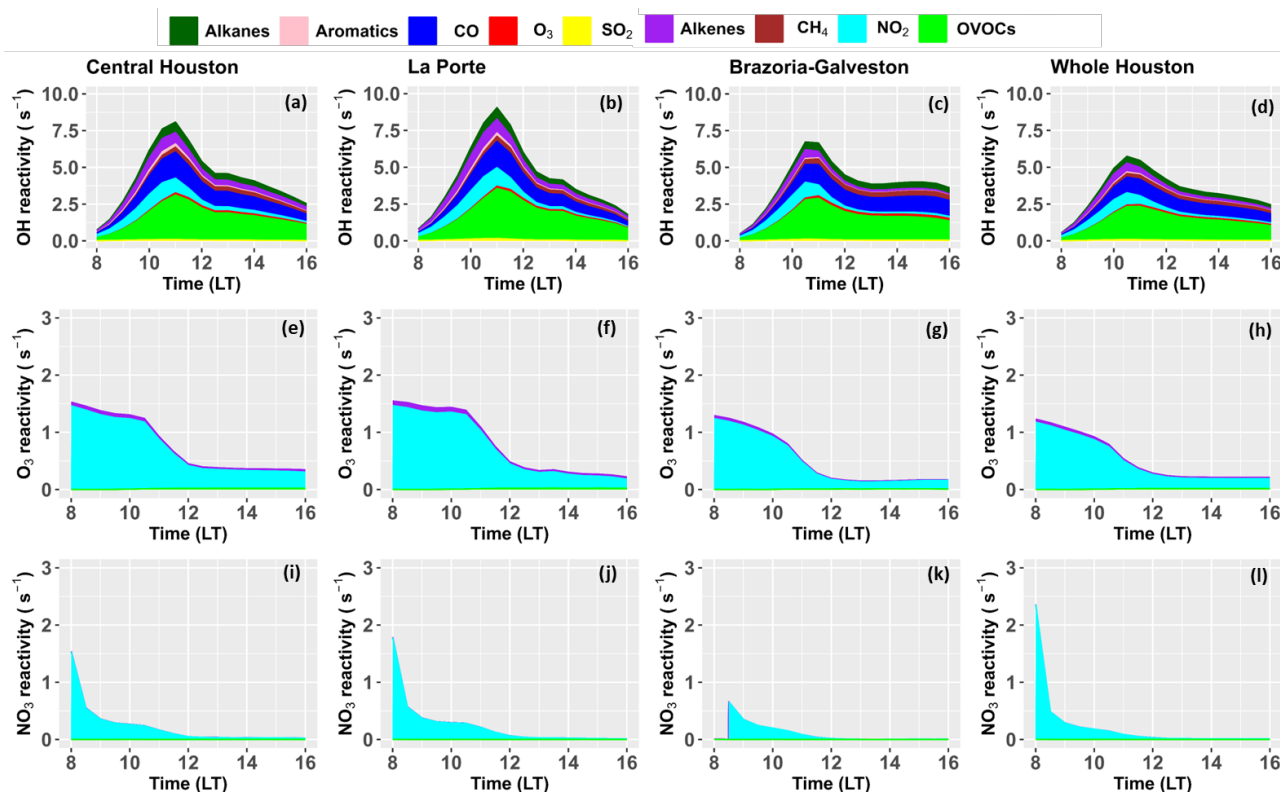

625  $\text{s}^{-1}$ ), aromatics ( $0.1 \pm 0.07 \text{ s}^{-1}$ ), and CO ( $0.93 \pm 0.47 \text{ s}^{-1}$ ) is highest over Central Houston, while the oxidation of alkenes ( $0.47 \pm 0.30 \text{ s}^{-1}$ ) and  $\text{SO}_2$  ( $0.06 \pm 0.04 \text{ s}^{-1}$ ) is mostly dominant over La Porte. In contrast, the OH reactivity via  $\text{CH}_4$  oxidation ( $0.27 \pm 0.13 \text{ s}^{-1}$ ) is the highest over the BGR region.  $\text{CH}_4$  represents an important factor that affects AOC, with OH +  $\text{CH}_4$  being an important sink for OH in the atmosphere (Morgenstern et al., 2013). Overall, this underlines the role of spatial characteristics and unique local anthropogenic emission sources, which may contribute to the overall photochemical processes.

630

Results are from the LES domain.**

#### 4. Conclusion

In this study, we investigate the detailed atmospheric photochemistry during a high O<sub>3</sub> episode during TRACER-AQ 2021 in Houston. During this episode, observed surface O<sub>3</sub> significantly exceeded national standards by 20-50 ppb, particularly in the Central areas of Houston. We use a high-resolution WRF-LES-Chem model to simulate atmospheric O<sub>3</sub> as well as the detailed atmospheric photochemistry associated with these O<sub>3</sub> exceedances. By resolving turbulence and eddies at a scale relevant for pollutant chemistry, the LES simulation 300 m spatial resolution adequately captures the surface concentration of O<sub>3</sub>, NO<sub>x</sub>, and HCHO, and provides an improved representation of temperature, wind speed and water vapor compared to the mesoscale WRF-Chem simulations.

Two indicators for the O<sub>3</sub> sensitivity regime ( $L_N/Q$  and FNR) are compared and show that the photochemical properties of O<sub>3</sub> formation in Houston is largely a VOC-limited regime in the morning hours and transitions into a NO<sub>x</sub>-limited regime in the afternoon. Additionally, the transition threshold for radical loss-initiation ratio,  $L_N/Q$ , is used to define the FNR transition regime, which is observed at  $0.6 < \text{FNR} < 1.8$ . Some local regions, including Baytown, Texas City and Deer Park show no diurnal variability in O<sub>3</sub> formation sensitivity regimes, due to unique environmental and emission sources. On September 8,

2021, the rapid radical production and recycling of HO<sub>x</sub> radicals and their reactivity with increased VOC emissions and reduced NO<sub>2</sub> emissions under a NO<sub>x</sub>-limited regime accelerated fast and high O<sub>3</sub> production. The total radical production rate of HO<sub>x</sub> radicals increased PO<sub>3</sub> in the afternoon hours, reaching 50 ppb h<sup>-1</sup>, and higher than the previously recorded average in the DISCOVER-AQ campaign.

655 Increased HRVOC emission is the main cause of radical production. The HO<sub>2</sub> radical is mainly formed from the oxidation of HCHO and represents the highest source of HO<sub>2</sub> in Houston. The oxidation of other OVOCs including acetaldehyde also enhances the production of HO<sub>2</sub> radicals, which contributes to increased O<sub>3</sub> production. Our analysis linked the high oxidation of isoprene to enhance the production of HCHO, thus increasing the potential of O<sub>3</sub> formation when oxidized by OH. Our results further underline the role of BVOCs and how they may account for enhanced O<sub>3</sub> production, which is consistent with  
660 some recent studies (Leong et al., 2017; Ma et al., 2022). Similarly, RO<sub>2</sub> sources are alkenes oxidation, as compared to the oxidation of alkanes and aromatics.

Overall, the role of anthropogenic emissions cannot be underestimated. Primary emissions of CO and non-methane hydrocarbons (alkenes and other alkanes) affect the overall AOC levels, though the contribution of each compound to AOC varies with location and time. OVOCs also contribute about 30-40 % to the total AOC. Our study thus concludes the important  
665 role of anthropogenic emissions in the production of RO<sub>2</sub> and HO<sub>2</sub> radicals, and how they may influence the enhancement or inhibition of O<sub>3</sub> formation, depending on the NO<sub>x</sub>-O<sub>3</sub>-VOC sensitivity regimes. This suggests the importance of further reductions in highly reactive anthropogenic VOCs to achieve further reductions in O<sub>3</sub> levels.

### Code and data availability

670 The source code of WRF-Chem is publicly available on GitHub at <https://github.com/wrf-model/WRF>. Observational data from TCEQ and Pandora can be downloaded from the TAMIS web interface (<https://www17.tceq.texas.gov/tamis/index.cfm>; last access: 30 June 2023) and the Pandonia Global Network (<https://www.pandonia-global-network.org/>; last access: 3 July 2023) respectively. The TRACER-AQ data is archived on the NASA webpage (<https://www-air.larc.nasa.gov/cgi-bin/ArcView/traceraq.2021>). The Lidar data from the TRACER-AQ campaign is also available on the NASA Tropospheric  
675 Ozone Lidar Network (<https://tolnet.larc.nasa.gov>).

### Authors contributions

AF performed the simulations, carried out the analyses and wrote the manuscript. YL conceived and supervised the study and revised the paper. JD provided guidance in modeling setup and contributed to the editing of the paper. RS, SU, PW, JS, GG, JF, ME and TG provided measurement datasets and contributed to the editing of the paper.
