Abstract. Global warming poses a major threat to marine ecosystems, which fulfill important functions for humans and the climate. Ecosystem models are therefore increasingly used to estimate future changes in the functioning of marine ecosystems. However, projections differ notably between models. We propose that a major uncertainty factor in current models is that they ignore the high adaptive potential of phytoplankton, key players in marine ecosystems. Here, we use a 0-dimensional evolutionary ecosystem model to study how phytoplankton adaptation can affect estimations of future ecosystem-level changes. We found that phytoplankton adaptation can notably change simulated ecosystem dynamics, with the effect depending on environmental conditions. In a steady environment, adaptation allows for a more efficient use of resources, which enhances primary production and related ecosystem functions. In a warming environment, on the contrary, adaptation mitigates dominance changes among functionally different taxa and consequently leads to weaker changes in related ecosystem functions. Our results demonstrate that by neglecting phytoplankton adaptation, models may systematically overestimate future changes in the functioning of marine ecosystems. Future work can build on our results and include evolutionary processes into more complex model environments.

1 Introduction

Global warming leads to a rapid reorganization of marine ecosystems, which poses a major threat to their functioning (Pecl et al., 2017). Since changes in the functioning of marine ecosystems directly impact humans and even feed back on the climate, understanding them is crucial (Pecl et al., 2017; Prentice et al., 2015). Ecosystem models have proven a valuable tool

in this regard, but projections differ notably between models (Laufkötter et al., 2015, 2016). Current models largely ignore the high adaptive potential of phytoplankton (Laufkötter et al., 2015, 2016; Munkes et al., 2021), which are key players in marine ecosystems (Litchman et al., 2015). Here, we fill this gap by using an evolutionary ecosystem model to study the effect of phytoplankton adaptation to global warming on projected changes in ecosystem functioning. We apply the model to the Baltic Sea, which is impacted by above-average levels of multiple stressors (Reusch et al., 2018).

Marine ecosystems are of great importance for human societies. Primary production by phytoplankton contributes about half of global photosynthesis (Field et al., 1998) and drives the biological carbon pump, which involves the fixation and export of atmospheric carbon to the deep ocean (Basu and Mackey, 2018). Cyanobacteria, on the contrary, pose a threat to marine ecosystems due to their toxicity and ability to fix atmospheric nitrogen, which can shift the nutrient balance towards eutrophication (Backer and McGillicuddy, 2006; Gustafsson et al., 2012, 2017; Schindler et al., 2008). Finally, marine food webs from phytoplankton at the base, via zooplankton as secondary producers, up to fish as top predators represent commercially relevant resources with great importance for coastal regions around the globe (Atkinson et al., 2004; Everson, 2000; Lomartire et al., 2021; Weatherdon et al., 2016), form the base of the marine food web (Fenchel, 1988), drive biogeochemical cycles (Hutchins and Fu, 2017), and even feed back on ocean physics (Hense, 2007; Sathyendranath et al., 1991). Furthermore, phytoplankton related ecosystem functioning feeds back on the climate, e.g., through changes in the export of atmospheric carbon into deeper water layers (biological carbon pump) (Basu and Mackey, 2018) or the planktonic production of dimethyl sulfide, which seeds cloud formation (Wingenter et al., 2007). However, due to global warming, the role of phytoplankton in marine ecosystems is changing.

As they form the basis of the marine food web and drive biogeochemical cycles, phytoplankton play a key role in the functioning of marine ecosystems. Climate change-related alterations in phytoplankton dynamics can therefore have far-reaching repercussions for marine ecosystem functioning. Phytoplankton respond to global warming by through changes in their phenology, which are expressed, for example, in has led to an earlier and prolonged blooming season in the Baltic Sea, for example (Wasmund et al., 2019). The resulting mismatches with higher trophic levels like zooplankton and fish alter food web structures and may eventually lead to ecosystem-level changes (Asch et al., 2019; Edwards and Richardson, 2004; Winder and Schindler, 2004a). In addition, the poleward migration of phytoplankton

~~causes changes in species composition and abundance (Poloczanska et al., 2013), which may additionally affect zooplankton and fish stocks (Fossheim et al., 2015). Indeed, fisheries are already impacted by warming related changes (Peterson et al., 2017). Finally~~In addition, warming and eutrophication promote harmful algal blooms, which pose a threat to animal and human health (Glibert et al., 2014; Gobler et al., 2017; Paerl et al., 2015).~~To conclude, ongoing global warming will lead to changes in phytoplankton and consequently, to changes in the functioning of marine ecosystems.~~ Since these ecosystem-level changes like these are expected to have a direct impact on human well-being and the climate (Pecl et al., 2017; Prentice et al., 2015), predicting them is of great importance.

Ecosystem models offer the possibility to assess future ecosystem-level changes ~~in ecosystem functioning~~. For example, ecosystem models can be integrated into global ocean circulation models to simulate future changes in net primary production on global scale, but models do not even agree on the direction of change (Laufkötter et al., 2015). Similarly, regional models for the Baltic Sea cannot agree on the future development of cyanobacteria blooms regarding timing, concentrations, and nitrogen fixation (Hense et al., 2013; Meier et al., 2011; Neumann, 2010). These uncertainties can notably affect estimations of future ocean deoxygenation (Long et al., 2021), nutrient load (Reusch et al., 2018; Wasmund et al., 2001), and harmful algal bloom dynamics (Hallegraeff, 2010; Paerl et al., 2015).~~To conclude, the validity of current model projections remains questionable.~~ Since model projections form the base of political decision making (Intergovernmental Panel on Climate Change (IPCC), 2022; Meier et al., 2014), there is an urgent need to improve their informative value. A first step could be to identify the key processes that affect ecosystem functioning. One key process that is lacking in most ecosystem models~~all models above and similar models (Daewel and Schrum, 2013; Dzierzbicka-Głowačka et al., 2013; Savehuk, 2002)~~ is the evolutionary adaptation of phytoplankton.

~~Owing to t~~heir large population sizes and short generation times, allow phytoplankton possess a high potential to quickly adapt to environmental changes. Evolution experiments, observations, and resurrection experiments ~~showed~~demonstrated that phytoplankton adaptation can be relevant on perennial or even shorter time scales (Hattich et al., 2024; Irwin et al., 2015; Jin and Agustí, 2018). Due to the crucial role of phytoplankton in marine ecosystems, considering phytoplankton adaptation in models may notably alter~~change~~ projected changes in ecosystem functioning (Ward et al., 2019).

105 ———Some ecosystem models ~~have~~ already considered ~~the~~ evolutionary ~~processes in~~
~~adaptation of~~ phytoplankton~~—~~, such as the natural selection from a diverse standing stock
(Banas, 2011; Bruggeman and Kooijman, 2007; Dutkiewicz et al., 2020; Follows et al., 2007;
Ward et al., 2012), ~~the instantaneous acclimation of cellular resource allocation and metabolism~~
(Kerimoglu et al., 2017; Smith et al., 2016a), ~~or the evolutionary adaptation in the form of~~
~~mutation and selection. So far~~ Models including the latter, from here on called *evolutionary*
ecosystem models, have ~~generally~~ been used ~~as a strategy to reduce model complexity~~ (Merico
110 et al., 2009; Pahlow et al., 2008), ~~to identify the drivers of phytoplankton diversity~~ (Wirtz,
2013), ~~or to~~ study the spatial distribution and/or temporal evolution of different functional traits
(Beckmann et al., 2019; Clark et al., 2011; Daines et al., 2014; Le Gland et al., 2021; Sauterey
et al., 2017; Terseleer et al., 2014). Only a few evolutionary ecosystem models, ~~however~~, have
already addressed questions related to ecosystem functioning. For example, Smith et al.
115 (2016b), ~~Acevedo-Trejos et al. (2018), and Chen et al. (2019) identified—studied a—~~trade-offs
between phytoplankton size-diversity, ~~and~~ productivity, ~~and export production depending on~~
~~the frequency of environmental disturbance~~. Sauterey ~~and~~ Ward (2022) investigated drivers
of phytoplankton C:N stoichiometry, which affects the efficiency of the biological carbon
pump. Finally, Cherabier ~~and~~ Ferrière (2022) studied the effect of bacterial adaptation to
120 global warming on the microbial loop and the resulting impact on primary production.

So far, however, no model has explicitly addressed the question of how phytoplankton
adaptation to global warming could affect the functioning of a marine ecosystem. A first step
~~can~~ might be to estimate the effect of adaptation on warming-related changes in phytoplankton
community composition. Different phytoplankton functional groups fulfill different functions
125 in the ecosystem, for example, by contributing differently to the biological carbon pump
(sinking speed), the nitrogen cycle (nitrogen fixation), and the energy transfer to higher trophic
levels (food quality, susceptibility to predation) (Litchman et al., 2015). To our knowledge,
there is only one model to date that considers competition between multiple phytoplankton
functional groups and their adaptation to global warming simultaneously (Hochfeld and
130 Hinners, 2024). Using this model, Hochfeld ~~and~~ Hinners (2024) demonstrated that adaptation
can significantly reduce simulated phytoplankton responses to global warming in terms of
changes in bloom timing and relative taxa abundance. However, it has not been studied yet how
adaptation-related changes in phytoplankton responses may affect ecosystem functioning.

Here, we use ~~a slightly modified version of~~ the Hochfeld ~~and~~ Hinners (2024) model
135 to estimate for the first time how phytoplankton adaptation may affect warming-related changes

hat formatiert: Englisch (Vereinigte Staaten)

in different ecosystem functions, including primary production, secondary production, carbon export, nitrogen fixation, and resource use efficiency (RUE). We apply the model to the Baltic Sea, which is already impacted by above-average levels of warming, nutrient load, and deoxygenation (Reusch et al., 2018). Due to the 0-dimensional setup of the model, we do not evaluate absolute changes in ~~the above-mentioned~~ ecosystem functions. Instead, we focus on how phytoplankton adaptation may change the future contribution of primary production to these ecosystem functions. Our study is a first step to improve model projections of ~~future~~ ecosystem-level changes that future work can build upon.

2 Materials and Methods

2.1 Model description

To study how phytoplankton adaptation to global warming may affect ~~predicted~~ simulated future changes in ecosystem functioning, we ~~use~~ ~~have slightly extended~~ the model from Hochfeld ~~and~~ Hinners (2024). A ~~more~~ detailed description of the model is available in Hochfeld ~~and~~ Hinners (2024) and the associated supplementary material. ~~In summary,~~ ~~the~~ model simulates the dynamics of phytoplankton, zooplankton, dissolved inorganic nitrogen, and dead organic matter (detritus) in a 0-dimensional framework (Fig. B1). ~~Since we focus on phytoplankton and their functions in the marine ecosystem, we resolve~~ ~~three~~ different phytoplankton functional groups ~~common to the Baltic Sea are resolved.~~ Like Hochfeld & Hinners (2024), we chose ~~three of the most common functional groups in the Baltic Sea,~~ dinoflagellates, diatoms, and diazotrophic cyanobacteria, ~~and~~ Each functional group is represented ~~each group~~ by a common taxon or by a complex of common taxa. For dinoflagellates and diatoms, ~~the model~~ we simulate two cold-water species of the genera *Apocalathium* and *Thalassiosira*, respectively. For cyanobacteria, ~~we simulate~~ ~~the model considers~~ a complex that represents the dominant nitrogen-fixing genera in the Baltic Sea, *Nodularia*, *Aphanizomenon*, and *Anabaena* (Karlsson et al., 2005; Stal et al., 2003). Like ~~in~~ other modeling studies (Hense and Beckmann, 2006; Hinners et al., 2015; Lee et al., 2018), ~~we assume~~ cyanobacteria ~~are assumed~~ to be non-grazeable due to toxicity, while dinoflagellates and diatoms are equally grazed by zooplankton.

~~_____~~ To ensure an accurate representation of phytoplankton phenology under ~~ongoing global~~ warming ~~conditions~~, the model ~~additionally~~ ~~explicitly~~ resolves phytoplankton life cycle dynamics, ~~including growing and resting stages.~~ ~~For all functional groups, the model differentiates between a resting stage and a vegetative growing stage, with growth being limited~~

by light, temperature, and dissolved inorganic nitrogen. The cyanobacteria life cycle additionally includes a diazotrophic growing stage, which can fix atmospheric nitrogen (N_2) and is therefore not limited by dissolved inorganic nitrogen. Hence, dissolved inorganic nitrogen is taken up by all phytoplankton growing stages except for the diazotrophic growing stage of cyanobacteria. The nitrogen content of all dead phytoplankton and zooplankton cells fills the detritus pool, which is remineralized back into bioavailable nitrogen at a constant rate. Due to sinking of detritus and stochastic burial of phytoplankton resting cells, nitrogen is lost from the system. Nitrogen can be replenished through the resuspension of previously buried resting cells and cyanobacterial nitrogen fixation.

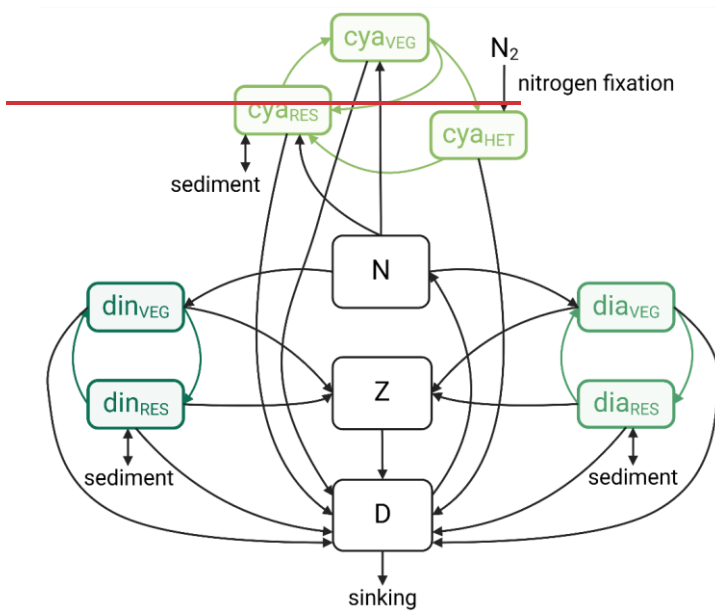

Figure 1: Components of the ecosystem model including compartments for dissolved inorganic nitrogen (N), detritus (D), and zooplankton (Z), along with agent-based life cycles of dinoflagellates (din), diatoms (dia), and cyanobacteria (cya). Each life cycle is represented by a resting stage (RES) and a vegetative growing stage (vegetative cells, VEG). For cyanobacteria, the model simulates a second, nitrogen fixing growing stage (vegetative cells with heterocysts, HET). The figure additionally shows the nitrogen fluxes between the different ecosystem components, and the sinks and sources of nitrogen (sinking of detritus, burial of phytoplankton resting cells and resuspension of phytoplankton resting cells, cyanobacterial nitrogen fixation). The figure was adapted from Hoehfeld & Hinners (2024) and created with BioRender.com.

The key feature of the model ~~does not only consider competition for nitrogen between different phytoplankton taxa, but also changes~~ is the flexibility in two temperature-dependent functional traits. The first flexible trait, the optimum temperature for growth, adapts through random mutations. Mutations occur during reproduction and lead to a randomized change in the optimum temperature, with small changes being much more likely than large changes. Cell size, on the contrary, ~~does not~~ responds randomly to temperature but plastically ~~to temperature~~, with the cell size decreasing linearly with increasing temperature (Atkinson et al., 2003). For further details on the implementation of mutations and plasticity, see Hochfeld ~~and~~ Hinners (2024). The model additionally considers that changes in cell size affect metabolic cell properties (Litchman et al., 2007; Marañón et al., 2013; Ward et al., 2017), which in turn determine the nitrogen-limited growth rate (Grover, 1991). Since trait changes such as those described above affect individual cells, the model uses an agent-based approach after Beckmann et al. (2019) to simulate the dynamics of agents (super-individuals) with their individual phenotypic trait values. Zooplankton, dissolved inorganic nitrogen, and detritus, on the contrary, are represented by compartments, i.e., collections of cells or molecules described by their averaged properties and their concentration.

2.2 Model modifications ~~Ecosystem functions~~

~~Our~~ We slightly ~~extended version of~~ the Hochfeld ~~and~~ Hinners (2024) model described above ~~allows us to analyze~~ by adding the explicit calculation of different ecosystem functions, including carbon export, cyanobacterial nitrogen fixation, and resource use efficiency (RUE).

We calculate carbon export from the carbon content of buried phytoplankton resting cells and the carbon that is exported through sinking of detritus. Detritus contains the dead phytoplankton and zooplankton cells, as well as the remains from unassimilated feeding. Following Ward et al. (2012), we divide detritus into dissolved inorganic matter (DOM) and particulate organic matter (POM), ~~in a 50:50 ratio, with of which~~ only POM ~~being~~ is exported ~~into~~ deeper water layers. The distinction between POM and DOM represents a modification of the previous publication (Hochfeld and Hinners, 2024), in which we assumed that the entire detritus pool sinks. Since the sinking of detritus depends quadratically on the detritus concentration, we increased the original sinking rate by a factor of 4, from 0.097 d⁻¹ to 0.388 d⁻¹, to keep the mass loss per time step similar to the original version of the model. The sinking rate represents the only parameter value that was changed in comparison to the version published in Hinners and Hochfeld (2024). ~~For the taxonomic groups in our model, we divide~~

hat formatiert: Nicht Hervorheben

~~detritus 50:50 between POM and DOM (Ward et al., 2012). Since the model calculates in nitrogen units, we use the Redfield ratio to convert nitrogen into carbon (Redfield, 1934).~~

To determine the amount of fixed atmospheric nitrogen, we assume that all the fixed nitrogen is converted into biomass. Thus, we define nitrogen fixation as the biomass built up by the diazotrophic cyanobacteria life cycle stage during each time step.

Finally, following Ptacnik et al. (2008), we calculate resource use efficiency (RUE) as the ratio of phytoplankton biomass and dissolved inorganic nitrogen. Since the cyanobacteria in our model can fix atmospheric nitrogen, we use simulations without cyanobacteria to derive RUE. Hence, we only consider the RUE of dinoflagellates and diatoms. Both dinoflagellates and diatoms are grazed by zooplankton; to avoid grazing-related biases in RUE, we additionally exclude zooplankton from RUE simulations.

2.3 Model scenarios

To understand how the adaptation of phytoplankton to different environments affects model estimations of associated related ecosystem functions, we implement evaluate four different model scenarios, which are adopted from based on Hochfeld and Hinners (2024) (Table 1). Since our simulations are affected by random processes, e.g., during mortality and mutation, we perform seven simulations for each scenario and average the output to ensure robust results. Each simulation is run over 100 years.

The first two model scenarios C (control) and CA (control and adaptation) represent control scenarios, which are forced with a steady seasonal temperature and irradiance forcing for present-day conditions in the Gulf of Finland. We use the same forcing as Hochfeld & Hinners (2024). The two control scenarios C and CA serve as spin up for two global warming scenarios W (warming) and WA (warming and adaptation). We simulate global warming is simulated by adding a steady temperature increase of 0.3 °C per decade to the seasonal temperature forcing, which corresponds to the IPCC scenario SSP3-7.0 (Allan et al., 2021). While adaptation in the optimum temperature is disabled in C and W, it is enabled in CA and WA. In this way, we can study how the (in)ability of phytoplankton to adapt to their environment may affect ecosystem functioning.

~~In the four model scenarios presented above, the resuspension of phytoplankton resting cells from the sediment is disabled. Hochfeld & Hinners (2024) found that resuspension tends to slow down adaptation to global warming and can hence weaken adaptation related effects.~~

255 ~~For completeness, we performed additional control and warming simulations in which we enabled resuspension (CAR: control, adaptation, and resuspension, WAR: warming, adaptation, and resuspension) and observed a similar effect. Thus, we do not explicitly analyze and discuss these simulations here; an example is shown in Fig. B1.~~

260 **Table 1:** Overview of the four model scenarios that we evaluate in this article. All scenarios are adopted from Hochfeld and Hinners (2024). For each scenario, we run seven different simulations over 100 years and average the output to ensure robust results. *Control* represents a present-day seasonal temperature forcing for the Gulf of Finland. *Warming* adds a constant temperature increase of 0.3 °C per decade to the control forcing (IPCC scenario SSP3-7.0, Allan et al., 2021).

| | No adaptation | Adaptation |
|---------|---------------|------------|
| Control | C | CA |
| Warming | W | WA |

3 Results

265 3.1 Model validation ~~Seasonal phytoplankton dynamics~~

The simulated seasonal phytoplankton dynamics ~~and the reasons for differences between scenarios~~ are described in detail in Hochfeld and Hinners (2024). In summary, the two control scenarios C and CA produce ~~a realistic seasonal cycle for the focal phytoplankton taxa, including~~ a spring bloom of dinoflagellates and diatoms, a summer bloom of cyanobacteria, and a second but weaker bloom of diatoms in autumn (Fig. B2). The simulated bloom succession agrees reasonably well with recent monitoring data from the Baltic Sea, despite slight differences in spring bloom timing (Hjerne et al., 2019). As discussed in Hochfeld and Hinners (2024), the simulated bloom succession is realistic for the focal phytoplankton taxa (Fig. 2). ~~In CA, where phytoplankton can adapt, competition for nitrogen drives adaptation to individual temperature niches, which reduces competition pressure. Due to reduced competition with diatoms, cyanobacteria can initiate a stronger summer bloom, which increases the amount of nitrogen in the system through nitrogen fixation. The higher concentration of nitrogen, in turn, allows for stronger blooms of dinoflagellates and diatoms.~~

275 ~~The two warming scenarios W and WA were found to reproduce trends that have been observed in the Baltic Sea over the past decades (Hochfeld and Hinners, 2024), including an earlier and prolonged phytoplankton blooming season (Wasmund et al., 2019) as well as an~~

Kommentiert [I2R1]: What about zooplankton?

hat formatiert: Englisch (Vereinigte Staaten)

hat formatiert: Englisch (Vereinigte Staaten)

hat formatiert: Englisch (Vereinigte Staaten)

hat formatiert: Englisch (Vereinigte Staaten)

increase in cyanobacterial summer biomass (Suikkanen et al., 2007). The warming-related changes in bloom timing and cyanobacteria biomass were shown to be weaker in the presence of adaptation by up to 9 d and 56 %, respectively (Hochfeld and Hinners, 2024). Adaptation to the increasing temperatures in WA enhances the competitiveness of non-pre-adapted taxa. Thus, non-pre-adapted diatoms can compete more strongly with pre-adapted cyanobacteria, which leads to a weaker cyanobacterial summer bloom (Hochfeld and Hinners, 2024).

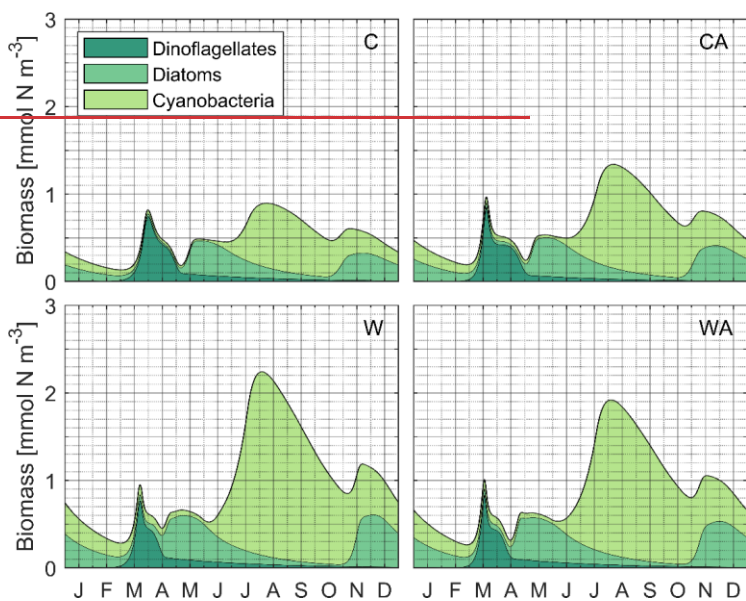

Figure 2: Accumulated phytoplankton biomass during the last simulation year of the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). For each scenario, the output of seven different simulations was averaged. The colors indicate the share of dinoflagellates, diatoms, and cyanobacteria in the total phytoplankton biomass.

3.2 Seasonal zooplankton dynamics

For all model scenarios, In contrast to phytoplankton, Hochfeld and Hinners (2024) did not validate the seasonal dynamics of zooplankton against monitoring data. Here, we find that zooplankton biomass peaks during phytoplankton spring bloom following the peak in phytoplankton biomass (Fig. B3); remember that the we model simulates cyanobacteria as single summer-blooming phytoplankton taxon, which is we assumed to be non-grazeable due to

Formatiert: Block, Einzug: Erste Zeile: 1,27 cm

hat formatiert: Englisch (Vereinigte Staaten)

Formatiert: Einzug: Erste Zeile: 1,27 cm

305 toxicity. Despite these simplifications in the model, the simulated seasonal pattern is indeed reasonable for some of the common zooplankton taxa in the Baltic Sea (Dutz et al., 2010; Feike et al., 2007). ~~Although all four model scenarios agree on a general seasonal pattern, both bloom timing and amplitude differ notably between them (Fig. 3 and Table 2), with the differences being statistically significant according to a *t* test (Table A1).~~

310 ~~In the control scenario with phytoplankton adaptation, CA, we observe an earlier and stronger zooplankton bloom than in the control scenario without phytoplankton adaptation, C (Fig. 3). In CA, zooplankton peak 16 d earlier than in C with a 52 % higher peak amplitude (Table 2). These findings resemble the dynamics of phytoplankton under control conditions, which develop an earlier and stronger spring bloom if they can adapt (Fig. 2).~~

315 ~~— Likewise, zooplankton show similar responses as phytoplankton to global warming, including a shift in bloom timing towards winter and an increase in peak amplitude, with the responses being weaker when phytoplankton adaptation is enabled (Fig. 3). While the zooplankton spring bloom peaks 17 d and 5 d earlier in W and WA, bloom amplitude increases by 92 % and 21 %, respectively (Table 2). In conclusion, zooplankton strongly resemble the dynamics of phytoplankton in all four model scenarios.~~

320 ~~— Irrespective of these similarities between phytoplankton and zooplankton, however, the time lag between their bloom peaks differs notably between the four model scenarios. Under control conditions, we observe a time lag of 13 d and 8 d in C and CA, respectively (Table 2). The two warming scenarios W and WA, on the contrary, produce a comparable and notably shorter time lag of only 4 d. Thus, in our simulations, warming seems to reduce the time lag between phytoplankton and zooplankton blooms. In addition, we find that the time lag correlates negatively with the peak amplitudes of both phytoplankton and zooplankton, meaning that the higher the amplitude, the shorter the time lag (Fig. B2). While both correlations are significant, the time lag correlates notably stronger with zooplankton peak amplitude than with phytoplankton peak amplitude ($r(26) = -0.99$, $p = 2.05 \times 10^{-21}$ for zooplankton and $r(26) = -0.81$, $p = 2.41 \times 10^{-7}$ for phytoplankton).~~

325

Figure 3: Zooplankton biomass during the last simulation year of the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). For each scenario, we averaged the output of seven different simulations.

Table 2: Average zooplankton timing, peak abundance, and time lag to the phytoplankton peak in spring for the two control scenarios C (control) and CA (control and adaptation), along with the associated standard deviations. Also shown are the corresponding average warming related changes in W (warming), and WA (warming and adaptation), including propagated errors. For each scenario, we calculated average values from the last simulation year of seven different simulations. Please note that warming related changes in zooplankton peak abundance are not presented as absolute values but as relative changes. A series of *t* tests revealed that the differences between all four scenarios are statistically significant at the 0.05 level; see Table A1 for details.

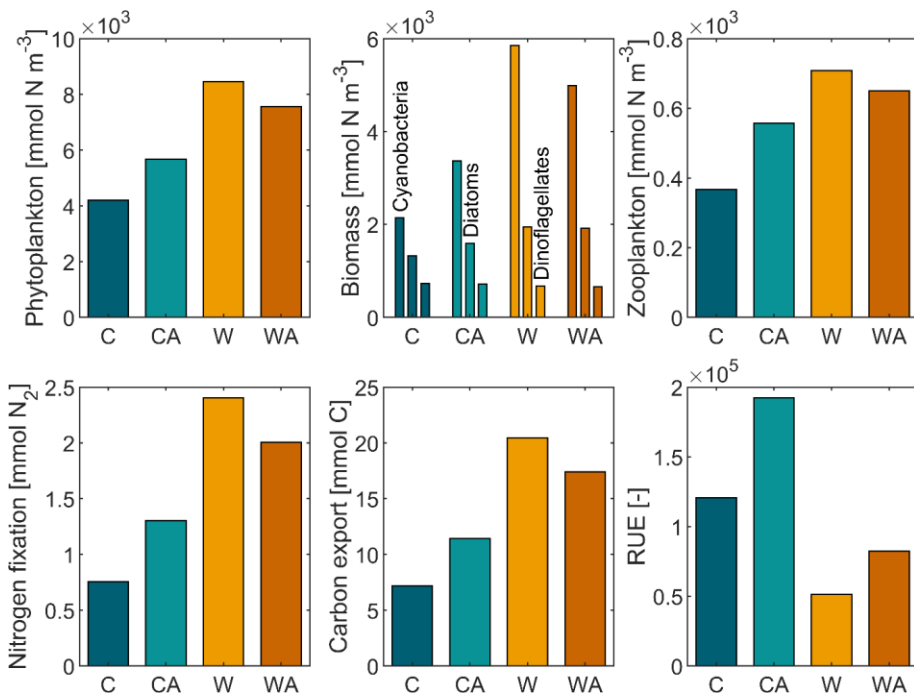

| | C | CA | W | WA |
|-------------------------------------|--------------|--------------|-----------------|------------------|
| Timing [d] | 102.4 ± 2.0 | 86.5 ± 2.4 | -16.9 ± 2.3 | -5.5 ± 2.6 |
| Abundance [μmol N m ⁻³] | 244.8 ± 17.2 | 373.0 ± 46.0 | +92.4 % ± 7.4 % | +21.2 % ± 13.0 % |
| Time lag [d] | 12.9 ± 2.4 | 8.0 ± 2.5 | -8.7 ± 2.8 | -3.5 ± 2.8 |

3.2.3 Annual balances

The annual balances of our simulated ecosystem functions are shown in Fig. 14 for the last simulation year of all four model scenarios. Figure 14 reveals that phytoplankton produce ~10 times more biomass than zooplankton per year and hence dominate biomass production in

our simulations. Primary production, in turn, is dominated by cyanobacteria, while dinoflagellates account for the smallest amount of ~~annual~~ primary production per year.

Formatiert: Block

350 **Figure 14:** Annual balances of ~~our simulated different~~ ecosystem functions for the last simulation year of the four model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). For each scenario, annual balances were averaged from seven different simulations. The differences between the four scenarios are statistically significant at the 0.05 level, except for dinoflagellates in W and WA (Table A1).

355

360

Annual primary production, i.e., total phytoplankton biomass, For cyanobacteria, annual biomass increases under global warming, with the increase being more than halved by 56 % weaker if phytoplankton thermal adaptation is enabled (Table 3). Under control conditions, on the contrary, total phytoplankton cyanobacteria biomass is by ~3552 % higher with thermal adaptation. The observed development of annual primary production is predominantly driven by cyanobacteria and to a lesser extent by diatoms, while While diatoms follow a similar trend, however with smaller differences between the scenarios, dinoflagellates show a contrasting

development (Fig. B4). ~~Dinoflagellate annual biomass decreases slightly under global warming and is comparable between C and CA as well as W and WA, respectively. Thus, thermal adaptation does not seem to have a notable effect on the biomass production of dinoflagellates. Despite the contrasting development of dinoflagellates, total phytoplankton biomass follows the same trend as cyanobacteria and diatoms.~~ This finding is underlined by strong positive correlations between total phytoplankton biomass, cyanobacteria, and diatoms, while dinoflagellates correlate negatively with all three (Fig. 25). In all four model scenarios, total phytoplankton biomass correlates strongest with cyanobacteria ($0.98 \leq r \leq 1$) and weakest with dinoflagellates ($-0.73 \leq r \leq -0.07$).

~~Annual secondary production, i.e., Zooplankton annual biomass, also correlates positively with the annual biomasses of diatoms, cyanobacteria, and total phytoplankton primary production.~~ Under control conditions, correlation is strongest with diatoms ($r \geq 0.81$), while under global warming, zooplankton biomass correlates strongest with total phytoplankton biomass ($r \geq 0.60$). In addition, zooplankton biomass production is notably affected by phytoplankton adaptation, ~~which is consistent with our findings from the previous section.~~ Under control conditions, zooplankton produce by ~52 % more biomass if phytoplankton can adapt. Under global warming, zooplankton biomass increases, with the increase being by ~73 % weaker when phytoplankton adaptation is enabled.

The annual amount of fixed atmospheric nitrogen mirrors the annual biomass of cyanobacteria, which is confirmed by a strong positive correlation in all four model scenarios with $r \geq 0.99$. Under control conditions, cyanobacteria fix ~72 % more nitrogen when adaptation is enabled. Global warming leads to an increase in nitrogen fixation, ~~and hence the nitrogen input into the system,~~ by ~218 % in W and ~54 % in WA, respectively.

Carbon export correlates positively with both phytoplankton and zooplankton biomass, with the correlation being stronger with phytoplankton, which dominate biomass production ($r \geq 0.90$ vs. $r \geq 0.69$). Among phytoplankton, carbon export correlates strongest with cyanobacteria, which dominate primary production ($r \geq 0.85$). In addition, carbon export is notably affected by phytoplankton adaptation. Under present-day conditions, carbon export is by ~59 % higher in CA than in C. Global warming leads to an increase in carbon export by ~184 % in W and ~52 % in WA, respectively.

Finally, resource use efficiency (RUE) decreases under global warming in our simulations, with the decrease being similar with and without phytoplankton adaptation (~57 % and ~58 %, respectively). Independent of the climate scenario, RUE is always higher if

phytoplankton can adapt. Phytoplankton adaptation leads to an increase in RUE by ~59 % and ~61 % under control and warming conditions, respectively.

In conclusion, all ecosystem functions that we investigate in this study, except for dinoflagellates and RUE, show similar developments in the four model scenarios. This is underlined by strong positive correlations, which are significant at the 0.05 level (Fig. B53). While RUE is excluded from correlations as it was derived from simulations without cyanobacteria and zooplankton, Dinoflagellates, on the contrary, correlate (mostly) negatively with all other ecosystem functions: correlations with dinoflagellates are only partly significant, though. Independent of their direction, all correlations notably change their strength between the four model scenarios. Under control conditions, all correlations are stronger if phytoplankton adaptation is enabled. This pattern reverses under global warming, where correlations are weaker with adaptation. This weakening is particularly strong for zooplankton, for which the negative correlation with dinoflagellates turns slightly positive in WA.

Formatiert: Einzug: Erste Zeile: 1,27 cm

~~**Table 3:** Average annual balances for the two control scenarios C (control) and CA (control and adaptation), along with the associated standard deviations. Additionally shown are the corresponding average warming related changes in W (warming), and WA (warming and adaptation), including propagated errors. For each scenario, we calculated average values from the last simulation year of seven different simulations. Please note that the warming related changes in W and WA are not presented as absolute values but as relative changes. A series of *t* tests demonstrated that the differences between all four model scenarios are statistically significant at the 0.05 level with only one exception (dinoflagellates in W and WA). See Table A2 for details.~~

| | C | CA | W [%] | WA [%] |
|--|----------------|----------------|--------------|--------------|
| Dinoflagellates [mmol N m ⁻³] | 732.7 ± 9.2 | 718.1 ± 15.1 | -8.6 ± 2.4 | -8.8 ± 3.0 |
| Diatoms [mmol N m ⁻³] | 1327.6 ± 44.0 | 1591.8 ± 78.5 | +46.3 ± 3.4 | +20.2 ± 5.1 |
| Cyanobacteria [mmol N m ⁻³] | 2140.8 ± 80.9 | 3367.2 ± 524.8 | +173.3 ± 3.9 | +48.2 ± 15.9 |
| Phytoplankton [mmol N m ⁻³] | 4201.1 ± 121.9 | 5677.0 ± 597.2 | +101.4 ± 3.0 | +33.2 ± 10.8 |

420 **Figure 25:** Correlation matrices showing the correlation coefficients between ~~the simulated different~~ ecosystem functions for the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). For C and CA, we calculated correlation coefficients using the

annual balances from the last 95 years of seven different simulations. For W and WA, however, we only used the last 40 years to capture warming-related changes. All correlations shown here, except for those with dinoflagellates, are significant at the 0.05 level according to a *t*-test (see Fig. B53). Please note that resource use efficiency (RUE) is not included since we derived RUE from simulations without cyanobacteria and zooplankton.

4 Discussion

In this study, we used an evolutionary ecosystem model to analyze how ecosystem functioning may change in response to global warming, and how these changes may be affected by phytoplankton adaptation. ~~We found~~Our results show that ~~phytoplankton and zooplankton respond similarly to global warming, with the responses being weaker in the presence of phytoplankton adaptation. Likewise,~~warming-induced changes in primary production and associated ecosystem functions are generally less pronounced if phytoplankton adaptation is enabled ~~in our simulations.~~ In addition, we found that most ecosystem functions are significantly positively correlated, and that the strength of these correlations differs between model scenarios.

4.1 Primary production ~~hytoplankton~~

The model projects an increase in ~~total phytoplankton biomass~~annual primary production in response to global warming. This increase is predominantly driven by cyanobacteria, which are pre-adapted to high temperatures (Collins and Boylen, 1982; Lehtimäki et al., 1997; Nalewajko and Murphy, 2001). This finding agrees with observations, ~~which have revealed~~showing a strong increase in Baltic Sea cyanobacterial summer biomass in the Baltic Sea over the past decades (Suikkanen et al., 2007), as well as with a modeling study projecting future increases in cyanobacteria biomass and primary production for several areas of the Baltic Sea (Meier et al., 2011).

Our simulations further suggest that phytoplankton adaptation can lead to a weakened increase in cyanobacteria biomass, and hence, primary production, under global warming. In Hochfeld and Hinners (2024), we discuss extensively how adaptation can influence the competition between different phytoplankton groups. In summary, under steady temperature conditions, adaptation leads to increased primary production across phytoplankton taxa due to niche separation. Under global warming, the adaptation of spring-blooming diatoms to higher

Formatiert: Einzug: Erste Zeile: 1,27 cm

455 ~~temperatures leads to a stronger competition with the summer-blooming cyanobacteria,~~
~~weakening the bloom of the latter. However, even when phytoplankton adaptation is taken into~~
~~account, our simulations still suggest an increase in cyanobacteria biomass under global~~
~~warming.~~ A further increase in cyanobacteria in the future can have severe consequences for
the ecosystem, for example, due to their toxicity for higher trophic levels (Chorus and Welker,
460 2021; Quesada et al., 2006; Repavich et al., 1990) and their ability to fix atmospheric nitrogen.
~~We discuss potential impacts of increasing nitrogen fixation in Sect. 4.4. Future work can build~~
~~on our results by including an explicit representation of cyanotoxin production and its effects~~
~~on higher trophic levels.~~

~~While diatoms also increase under global warming, dinoflagellates show a slight~~
~~warming-related decrease in annual biomass. This finding disagrees with observations, which~~
~~report a shift from diatom to dinoflagellate dominance during spring bloom over the past~~
~~decades in several areas of the Baltic Sea (Klais et al., 2011). These observations, however, are~~
~~on functional group level, while we simulate one focal species per group. Resurrection~~
~~experiments with our focal cold-water dinoflagellate of the genus *Apocalathium* revealed that~~
465 ~~encystment strongly depends on temperature, and that the temperature threshold for encystment~~
~~remained constant over the past century of global warming at around 6 °C (Hinners et al., 2017).~~
~~However, experiments by Kremp et al. (2009) showed that encystment strategies vary among~~
~~Baltic cold-water dinoflagellates, with temperature not always being the main trigger~~
~~mechanism. Thus, our model may not be appropriate for estimating future changes in overall~~
470 ~~spring bloom dynamics but only changes in our focal species.~~

~~Considering the dinoflagellate *Apocalathium* specifically, warming leads to an earlier~~
~~onset of encystment and hence an earlier termination of the spring bloom. As a result, less cysts~~
~~are produced and the inoculum decreases, weakening the spring bloom of *Apocalathium* over~~
~~the years as global warming progresses. Consequently, our simulations suggest that warming~~
475 ~~induces negative feedback in the life cycle of *Apocalathium*. However, Hinners et al. (2017)~~
~~found that *Apocalathium* has decreased its encystment rate over the past century of global~~
~~warming, which prevents an abrupt bloom termination at temperatures around 6 °C. To test if~~
~~a decrease in the encystment rate could weaken the negative feedback in our simulations, we~~
~~performed additional simulations in which we artificially decreased *Apocalathium*'s encystment~~
480 ~~rate at the rate measured by Hinners et al. (2017). The simulations reveal that a corresponding~~
~~decrease in the encystment rate leads to an even stronger decrease in the biomass of~~
~~*Apocalathium* under global warming (Fig. B4). This suggests that the encystment rate of~~

~~*Apocalathium* may respond differently to future climate change than to past climate change, or that we are missing another crucial factor. Further research is needed, for example in the form of evolution experiments. In addition, future work can build on our model and include an explicit representation of adaptation in the encystment rate of *Apocalathium*.~~

~~— On the contrary to *Apocalathium*, our focal cold water diatom of the genus *Thalassiosira* benefits indirectly from warming due to the increase in cyanobacterial nitrogen fixation. The more nitrogen is fixed in summer, the stronger is the bloom of *Thalassiosira* in autumn. A stronger autumn bloom adds more spores to the inoculum, and a larger inoculum allows for a stronger bloom of *Thalassiosira* in spring, which is further promoted by the weaker bloom of *Apocalathium*. The stronger spring bloom of *Thalassiosira* further increases the inoculum pool, which, in turn, further enhances the autumn bloom. Thus, on the contrary to *Apocalathium*, warming indirectly induces positive feedback in the life cycle of *Thalassiosira*, which is mainly driven by the response of cyanobacteria and, to a lesser extent, by that of *Apocalathium*.~~

~~— To conclude, our results demonstrate that the responses of different phytoplankton taxa affect each other due to differences in their physiology and function. Thus, when simulating ecosystem level responses to changing environments, it is crucial for models to include functionally different taxa with their individual physiologies (e.g., life cycle dynamics) to account for feedback and competition. As already demonstrated by Hoehfeld & Hinners (2024a), an adequate representation of competition also requires an explicit simulation of evolutionary adaptation.~~

4.2 Nitrogen fixation

Our model results suggest a strong warming-related increase in nitrogen fixation in the future, which is a direct result of the projected increase in cyanobacterial summer biomass. Today, the Baltic Sea is already impacted by above-average levels of nutrient load (Reusch et al., 2018). For example, nitrogen-driven eutrophication turned the Baltic Sea into one of the most hypoxic ocean areas worldwide, with severe consequences for productivity, biodiversity, and biogeochemical cycling (Breitburg et al., 2018). In the future, global warming is expected to further increase the vulnerability of coastal systems to nutrient loading as harmful algal bloom events become more likely and pose an increasing threat to animal and human health (Glibert et al., 2014; Gobler et al., 2017; Paerl et al., 2015).

hat formatiert: Englisch (Vereinigte Staaten)

hat formatiert: Englisch (Vereinigte Staaten)

520 Since the 1970s, nutrient management strategies have been applied to the Baltic Sea
catchment area, resulting in a reduction of anthropogenic nitrogen load by ~25 % (Reusch et
al., 2018). At the same time, however, nitrogen load by fixation increased notably (Gustafsson
et al., 2017). Model simulations demonstrated that the contribution of nitrogen fixation to the
525 total nitrogen load to the Baltic Sea increased from almost 20 % in the 1980s to almost 35 % in
the 2000s, so that the total nitrogen load decreased by only ~9 % (Gustafsson et al., 2017). For
the future, our results suggest that the extent of nitrogen fixation in the Baltic Sea will further
increase with rising temperatures. Even though this increase may be limited by adaptation and
the resulting stronger competition between cyanobacteria and other phytoplankton taxa, higher
530 temperatures will still have a positive effect on nitrogen fixation. Thus, the importance of
nitrogen fixation for the nitrogen budget of the Baltic Sea will most likely continue to increase
and further mitigate the success of nutrient management strategies. Therefore, nutrient
management strategies urgently need to account for nitrogen load by fixation to be successful
in the future. Since our projected increase in nitrogen fixation is significantly reduced if we
535 consider phytoplankton adaptation, we strongly recommend that models used for assessment
consider phytoplankton adaptation to realistically estimate future nitrogen load by fixation.

4.32 Secondary production Zooplankton

Our simulated changes in secondary production in zooplankton responses to global warming
qualitatively agree with our simulated changes in total primary production responses of
540 phytoplankton; in both cases, responses are weaker if phytoplankton adaptation is enabled. In
our warming scenarios, both phytoplankton and zooplankton increase in abundance. A study by
Richardson and Shoeman (2004) demonstrated that the abundance of herbivorous
zooplankton significantly depends on their phytoplankton prey (bottom-up control), meaning
that a warming-related increase in phytoplankton will most likely lead to an increase in
545 zooplankton abundance. Like our findings regarding overall primary production and nitrogen
fixation, we observe that the consideration of phytoplankton adaptation leads to a weakened
increase in zooplankton biomass under global warming. These results indicate that future efforts
to model ecosystems in terms of trophic transfer should consider phytoplankton adaptation as
a crucial factor.

550 In addition, our simulations show a warming-related earlier shift in bloom timing
towards winter for both phytoplankton and zooplankton, with the shift being stronger for
zooplankton (Table A2). The resulting decrease in the time lag between primary producers and

~~grazers stands in contrast to findings from other studies reporting a warming-related increase in time lag. Hence, our model does not produce a warming-related increase in the time lag between phytoplankton and zooplankton blooms as suggested by several studies (Edwards and Richardson, 2004; Winder and Schindler, 2004a, b; Adrian et al., 2006). Instead, the time lag between phytoplankton and zooplankton tends to decrease in our warming scenarios compared to the corresponding control scenarios. This decrease in time lag is strongly connected to zooplankton peak amplitude, with higher peak amplitudes coinciding with shorter time lags. Higher zooplankton peak amplitudes indicate stronger grazing on phytoplankton, and hence stronger top-down control. This means that the time lag between phytoplankton and zooplankton seems to decrease when top-down control increases.~~

~~The decreasing time lag in our simulations may result from our simplistic representation of zooplankton. We assume that zooplankton grazing depends exclusively on phytoplankton biomass and do not consider potential effects of irradiance and temperature. Moreover, we neglect both zooplankton life cycle dynamics and adaptation. However, observations show that several zooplankton taxa peak earlier in the season in response to global warming (Richardson, 2008). Dam (2013) interprets the observed phenological shifts in zooplankton as a combination of ecological and evolutionary responses. For example, Dam (2013) argues that zooplankton do not only respond to changes in temperature itself but also to phenological changes in prey, which select for fast growing zooplankton. Indeed, However, observations revealed that some phytoplankton and zooplankton taxa indeed show synchronous shifts in bloom timing, for example diatoms and *Daphnia* (Adrian et al., 2006). Some studies even suggest a warming-related decrease in the time lag between phytoplankton and zooplankton (Aberle et al., 2012; Almén and Tamelander, 2020). Consequently, the reduced time lag produced by our model indeed seems realistic for fast growing zooplankton taxa like *Daphnia*, which can quickly respond to phenological changes in their phytoplankton prey are “selected” in our global warming simulations by the earlier and stronger phytoplankton spring bloom. However, our model is not suitable for simulating slow growing zooplankton with longer and more complex life cycles such as copepods or larvae of the mussel *Dreissena polymorpha* (Adrian et al., 2006).~~

~~In conclusion, our results suggest that warming-related responses of fast-growing zooplankton may be closely related to responses of their phytoplankton prey. Thus, phytoplankton adaptation may indeed reduce zooplankton responses to global warming, and the effects of phytoplankton adaptation may even propagate further up the food chain. Future work can build on our model and study how a more complex representation of zooplankton,~~

~~including both fast and slow growing taxa, and higher trophic levels may be affected by phytoplankton adaptation.~~

4.43 Carbon export

590 Our simulations project a warming-related increase in carbon export in the future, which is ~~significantly reduced~~~~more than halved~~ if phytoplankton adaptation is enabled. The projected changes in carbon export correlate ~~significantly~~~~notably~~ with projected changes in biomass production, which are dominated by a strong increase in cyanobacterial summer biomass. In the Baltic Sea, cyanobacteria blooms have intensified over the last century of global warming
595 (Finni et al., 2001), especially during the last decades (Suikkanen et al., 2007). This development is reflected by sediment records, which show a simultaneous increase in cyanobacteria pigments and carbon content during the same period (Poutanen and Nikkilä, 2001). In the future, warming is expected to further increase summer primary production with a positive feedback on carbon export in several areas of the Baltic Sea (Tamelander et al., 2017).

600 ~~The ocean is a major sink for atmospheric carbon; the biological carbon pump is of similar magnitude to current carbon emissions from fossil fuels (Giering et al., 2020). Our results demonstrate that phytoplankton adaptation can have a significant impact on the amount of carbon exported, and therefore needs to be taken into account for predictions of the global carbon cycle.~~

605 ~~Even if our model results are consistent with these findings, we need to keep in mind that we use a 0-dimensional model setup, which cannot represent certain mechanisms that are crucial for carbon export. For example, we cannot explicitly simulate physical processes in the ocean like vertical mixing, including seasonal changes in stratification and mixed layer depth. In addition, crucial processes like gravitational particle sinking and fragmentation are only
610 included implicitly in our model, while we neglect vertical migration of zooplankton and nekton (Henson et al., 2022). Finally, in semi-enclosed ecosystems like the Baltic Sea, carbon export is not predominantly fueled by phytoplankton primary production but also by benthic primary production and riverine and terrestrial inputs (Goñi et al., 2000; Renaud et al., 2015; Tallberg and Heiskanen, 1998). Since these key processes (and maybe others) are lacking in our model,
615 we cannot interpret our results as projections of future carbon export. Instead, we interpret them as projections of the future contribution of primary production to carbon export. Our results~~

Formatiert: Einzug: Erste Zeile: 1,27 cm

reveal that the contribution of primary production to carbon export may increase in the Baltic Sea in the future and that phytoplankton adaptation may notably weaken this increase.

4.4 Nitrogen fixation

Our model results suggest a strong warming related increase in nitrogen fixation in the future, which is a direct result of the projected increase in cyanobacterial summer biomass. Today, the Baltic Sea is already impacted by above average levels of nutrient load (Reusch et al., 2018). For example, nitrogen driven eutrophication turned the Baltic Sea into one of the most hypoxic ocean areas worldwide, with severe consequences for productivity, biodiversity, and biogeochemical cycling (Breitburg et al., 2018). In the future, global warming is expected to further increase the vulnerability of coastal systems to nutrient loading as harmful algal bloom events become more likely and pose an increasing threat to animal and human health (Glibert et al., 2014; Gobler et al., 2017; Paerl et al., 2015).

Since the 1970s, nutrient management strategies have been applied to the Baltic Sea catchment area, resulting in a reduction of anthropogenic nitrogen load by 25 % (Reusch et al., 2018). At the same time, however, nitrogen load by fixation increased notably (Gustafsson et al., 2017). Model simulations demonstrated that the contribution of nitrogen fixation to the total nitrogen load to the Baltic Sea increased from almost 20 % in the 1980s to almost 35 % in the 2000s, so that the total nitrogen load decreased by only 9 % (Gustafsson et al., 2017). For the future, our results suggest that the importance of cyanobacterial nitrogen fixation for the nitrogen budget of the Baltic Sea will most likely continue to increase and further mitigate the success of nutrient management strategies. Therefore, nutrient management strategies urgently need to account for nitrogen load by fixation to be successful in the future. Since our projected increase in nitrogen fixation is more than halved if we consider phytoplankton adaptation, we strongly recommend that models used for assessment consider phytoplankton adaptation to realistically estimate future nitrogen load by fixation.

4.5 Resource use efficiency (RUE)

We furthermore analyzed how adaptation may influence RUE under global warming. Since we had to exclude nitrogen-fixing cyanobacteria and zooplankton grazing from RUE simulations, our assessments on potential effects of warming and adaptation on RUE are only valid for a two-species ecosystem including a cold-water dinoflagellates of the genus *Apoealathium* and a

~~cold-water diatoms of the genus *Thalassiosira*~~. For this species configuration, we found that adaptation increases resource use efficiency under both control and warming conditions. For both climate scenarios, adaptation is driven by competition for nitrogen, allowing ~~dinoflagellates *Apocalathium*~~ and ~~diatoms *Thalassiosira*~~ to use the available nitrogen optimally within their means.

~~*Apocalathium* can only grow within a specific temperature niche, with the freezing point of sea water at the lower end and the fixed temperature threshold of encystment (6 °C) at the upper end (Hinners et al., 2019). Within this fixed niche, *Apocalathium* adapts to lower temperatures under control conditions due to intraspecific competition for nitrogen. Since nitrogen concentration is highest during the initial phase of the bloom (Fig. B5), the environment selects for early bloomers with comparatively low optimum temperatures, which grow first and leave less nitrogen for individuals with higher optimum temperatures. Selection for early bloomers advances the bloom peak by more than 1 week compared to the control scenario without adaptation, which extends the bloom duration by a few days. Bloom duration, in this context, refers to the time during which growing stages reach a minimum concentration of 0.05 mmol N m⁻³.~~

~~On the contrary to *Apocalathium*, *Thalassiosira* is not restricted by its life cycle and can therefore occupy its optimal niche more flexibly. Under control conditions, *Thalassiosira* adapts to higher temperatures to (I) delay its bloom by ~18 d to reduce competition with *Apocalathium*, and (II) merge its spring and autumn blooms into a single bloom, which persists from June until December (Fig. B5). In this way, *Thalassiosira* can continuously take up nitrogen for 5 months in a row until light becomes limiting in winter.~~

~~When temperatures increase under global warming, RUE decreases but remains at a higher level when adaptation is enabled. Without adaptation, the spring bloom of *Apocalathium* is shifted by ~7 d towards winter, with the peak amplitude decreasing by ~18 % (Fig. B5). These warming-related changes lead to a decrease in bloom duration of more than 2 weeks. The spring and autumn blooms of *Thalassiosira* are shifted towards winter as well, and even more than the spring bloom of *Apocalathium* (~26 d and ~24 d, respectively). However, both *Thalassiosira* blooms only show minor changes in peak amplitude and duration.~~

~~With adaptation, *Thalassiosira* does not show notable warming-related changes in bloom timing, duration, or amplitude. The spring bloom of *Apocalathium*, on the contrary, is again by more than 2 weeks shorter, meaning that the shortening is not caused by lacking adaptation but by the fixed temperature threshold of encystment. Still, with adaptation, we~~

observe a slightly smaller shift in bloom timing of *Apocathium* with 5 d instead of 7 d, and a 16 % higher peak amplitude.

RUE is lower under global warming than under control conditions, both with and without adaptation. The warming-related decrease in RUE is predominantly driven by a fixed temperature-dependent life cycle trait of dinoflagellates (for details, see Hochfeld and Hinners, 2024), which terminates the dinoflagellate spring bloom at temperatures around 6°C and thus restricts dinoflagellate adaptation to the increasing temperatures. With adaptation, however, RUE is still higher than without, because diatoms are not restricted by their life cycle and can therefore optimize their nitrogen uptake even under global warming.

To conclude, our simulations show that adaptation generally allows for a more efficient use of resources and thus higher RUE. Models that ignore adaptation may hence systematically underestimate RUE under both present-day and future conditions. However, our projected warming-related decrease in RUE only applies to the species configuration in our model. We cannot make statements about future changes in RUE in other ecosystems with a different set of species. Future work can build on our results and investigate RUE in more complex ecosystems to make more general statements on future warming-related changes. In addition, our results demonstrate that future models should consider not only adaptation, but also possible species-specific constraints on adaptation, such as life cycle dynamics.

4.6 Control factors and feedbacks in our model ecosystem

We found that all ecosystem functions are positively correlated in our simulations, with except for dinoflagellate annual biomass (and RUE) being the only exception. Under control conditions, all correlations (regardless of their direction) are stronger when phytoplankton adaptation is considered, when niche separation allows for a stronger cyanobacterial summer bloom (see Sect. 3.1). Due to the stronger cyanobacterial summer bloom, more atmospheric nitrogen is fixed. The increase in nitrogen fixation is beneficial especially for diatoms, which can directly take up the newly available nitrogen in autumn. Dinoflagellates, however, do not benefit from increased nitrogen fixation. During spring bloom, dinoflagellates reach a higher maximum concentration than diatoms. Since we assume that zooplankton grazing depends on phytoplankton biomass only (see Sect. 4.2), grazing is stronger on dinoflagellates than on diatoms. Indeed, zooplankton peak during dinoflagellate spring bloom, meaning that dinoflagellates constitute the main food source for zooplankton. Hence, the stronger

715 ~~dinoflagellates grow due to increased nitrogen fixation, the more they are grazed by~~
~~zooplankton, and increased nitrogen fixation has no positive impact on dinoflagellate biomass.~~
~~Zooplankton, on the contrary, benefit indirectly from increased nitrogen fixation. To conclude,~~
~~adaptation induces positive feedback in our control simulations:~~ Dinoflagellates and diatoms
adapt to individual temperature niches to reduce competition for nitrogen, with the reduced
720 competition between diatoms and cyanobacteria allowing for a stronger cyanobacterial summer
bloom and hence increased nitrogen fixation (see Fig. B2 and Hochfeld and Hinners, 2024).
Zooplankton peak during dinoflagellate spring bloom (Figs. B2 and B3), meaning that
dinoflagellates constitute the main food source for zooplankton. Hence, the stronger
dinoflagellates grow due to increased nitrogen fixation, the more they are grazed by
zooplankton. While the increased cyanobacterial nitrogen fixation has a direct positive effect on
725 diatoms, zooplankton benefit indirectly through stronger grazing on dinoflagellates. Thus, the
increased cyanobacterial nitrogen fixation indirectly fuels zooplankton growth, while it directly
fuels the growth of diatoms. The result is an overall increase in biomass production, which, in
turn, increases carbon export. Dinoflagellates are the only losers in this scenario due to the
strong grazing pressure by zooplankton.

hat formatiert: Nicht Hervorheben

hat formatiert: Nicht Hervorheben

730 Under global warming, ~~however, adaptation leads to we observe a similar positive~~
~~feedback mechanism for W, where phytoplankton adaptation is disabled. For WA, on the~~
~~contrary, we find an overall weakening of correlations, even though if cyanobacteria are stronger~~
~~in than under control conditions WA than in CA. Correlations in WA are weaker especially for~~
~~dinoflagellates and zooplankton, with the negative correlation between them turning slightly~~
735 ~~positive. Correlations for diatoms are weakened as well but to a lesser extent. Due to the~~
~~stronger cyanobacterial summer bloom, nitrogen fixation increases in WA compared to CA,~~
~~which is again beneficial for diatoms. As a result, grazing pressure on diatoms increases and~~
~~weakens the positive correlation between diatoms and zooplankton. In addition to the enhanced~~
~~grazing pressure, there is another factor that reduces the benefit of the increasing cyanobacteria~~
~~for diatoms. As demonstrated by Hochfeld & Hinners (2024a), cyanobacteria restrict diatom~~
740 ~~adaptation to the increasing temperatures in WA due to their presence in summer, leading to a~~
~~stronger shift of the two diatom blooms towards winter. While this is not necessarily~~
~~problematic for the diatom autumn bloom if sufficient light is available, it is for the spring~~
~~bloom since dinoflagellates are present at lower temperatures. While diatoms benefit from the~~
~~increased nitrogen fixation, grazing pressure on them increases, weakening the positive~~
745 ~~correlation with zooplankton. In addition, as demonstrated by Hochfeld and Hinners (2024),~~
~~the presence of cyanobacteria in summer restricts diatom adaptation to the increasing~~

~~temperatures, causing~~ Thus, we observe a weaker positive correlation between diatoms and cyanobacteria ~~in WA than in CA~~. Due to the stronger grazing on diatoms, zooplankton are also less positively impacted by cyanobacteria. The weaker positive effect of cyanobacteria on diatoms and zooplankton is reflected in a slight weakening of the remaining positive correlations, and a notable weakening of the negative correlations with dinoflagellates. Furthermore, the reduced relative grazing pressure on dinoflagellates reverses the negative correlation with zooplankton, meaning that an increase in zooplankton biomass no longer implies a decrease in dinoflagellate biomass.

To conclude, cyanobacteria are the most important control factor in our model ecosystem, which is also confirmed by a principal component analysis (Fig. B6). First, cyanobacteria produce the highest amount of biomass per year. Second, due to their ability to fix atmospheric nitrogen, they directly control the biomass production of dinoflagellates and diatoms, and indirectly ~~that~~ of zooplankton. Cyanobacteria are therefore the main factor for carbon export in our simulations, which also agrees with observations as discussed above (see Sect. 4.43). However, the interdependencies between cyanobacteria and the other taxa may change depending on the climate scenario and the presence or absence of phytoplankton adaptation. ~~Under control conditions and in W, there are clear losers and winners of increased nitrogen fixation among the phytoplankton, with dinoflagellates being the losers and diatoms being the winners. In WA, these dynamics begin to reverse slightly since cyanobacteria restrict diatoms in their adaptation to higher temperatures.~~ These results demonstrate that by neglecting adaptation, we may be missing adaptation-related changes in taxa interactions, especially in changing environments, which can affect the entire ecosystem and hence its functioning.

4.7 Model biases and outlook

~~In the following, we discuss the simplifications and assumptions of our model that may bias our predicted changes in ecosystem functioning. Based on this discussion, we give suggestions for future modeling studies on climate-related ecosystem changes.~~

~~First, our model lacks a quantitative validation against observational data. For the Baltic Sea, phytoplankton observations at species level are sparse and insufficient in temporal resolution and/or coverage to allow for an extensive quantitative model validation. Data that provide sufficient temporal resolution and coverage are usually at functional group level and thus show the signal of the focal species superimposed on the signal of other species from the~~

Formatiert: Zeilenabstand: 1,5 Zeilen

780 same functional group. Thus, such data are not suitable for a quantitative model validation, but
they can still narrow down the seasonality of the focal species and hence provide information
on qualitative differences between the model taxa. Here, we used data at functional group level
from Hjerne et al. (2019) to validate our ecosystem model qualitatively (Sect. 3.1 and Fig. B2).
785 Due to the lack of an extensive quantitative validation, however, we only evaluate our results
qualitatively and focus on identifying fundamental relationships between phytoplankton
adaptation and ecosystem functioning.

Second, simulation at species level may limit the generality of our results. Our projected
warming-related decrease in RUE, for example, results from a fixed temperature threshold in
the life cycle of the modelled dinoflagellate and hence only applies to the species configuration
790 in our model. We cannot make statements about future changes in RUE in other ecosystems
with a different set of species. Future work can build on our results and investigate RUE in
more complex ecosystems to make more general statements about future warming-related
changes. Nevertheless, we think that our simulated adaptation-related increase in RUE is robust
and independent of the species configuration in our model.

795 In addition to biases in phytoplankton, further biases may be introduced by our
simplistic representation of zooplankton. We assume that zooplankton grazing depends
exclusively on phytoplankton biomass and do not consider potential effects of irradiance and
temperature. Moreover, we neglect both zooplankton life cycle dynamics and adaptation. Thus,
the zooplankton in our model is entirely controlled by prey availability, which may be
800 reasonable for fast-growing taxa that were found to respond rapidly to changes in their
phytoplankton prey (Adrian et al., 2006). However, our representation of zooplankton is
inappropriate for simulating slow-growing taxa with longer and more complex life cycles
(Adrian et al., 2006). Future work can build on our model and study how a more complex
representation of zooplankton, including both fast- and slow-growing taxa, and higher trophic
805 levels may be affected by phytoplankton adaptation.

Finally, we use a 0-dimensional model setup, which may lead to biases in all predicted
ecosystem functions, particularly in carbon export. For example, we cannot explicitly simulate
physical processes in the ocean like vertical mixing, including seasonal and future changes in
stratification and mixed layer depth. Multiple studies suggest a future increase in ocean surface
810 stratification, which may reduce vertical nutrient fluxes and hence affect primary production,
marine food web dynamics, and carbon export (Capotondi et al., 2012; Hordoir and Meier,
2012; Sallée et al., 2021). Thus, our projected increase in primary production might not be

Formatiert: Einzug: Erste Zeile: 1,27 cm

815 repeated if our model accounted for future decreases in nutrient supply in a more stratified
system. However, an increase in primary production indeed seems likely under current
anthropogenic nutrient loads for several areas of the Baltic Sea, as predicted by a 3D coupled
biogeochemical-physical model (Meier et al., 2011). Considering carbon export specifically,
other crucial processes like gravitational particle sinking and fragmentation are only included
implicitly in our model, while we neglect vertical migration of zooplankton and nekton (Henson
820 et al., 2022). In addition, in semi-enclosed ecosystems like the Baltic Sea, carbon export is not
predominantly fueled by phytoplankton primary production but also by benthic primary
production and riverine and terrestrial inputs (Goñi et al., 2000; Renaud et al., 2015; Tallberg
and Heiskanen, 1998). Since these key processes (and maybe others) are lacking in our model,
we cannot interpret our results as projections of future carbon export. Instead, we interpret them
as projections of the future contribution of primary production to carbon export.

5 Conclusions

Our study demonstrates that phytoplankton adaptation ~~does not only~~ affects simulated
~~phytoplankton dynamics themselves but also~~ simulated ecosystem functions through bottom-
up control. The effect of phytoplankton adaptation on simulated ecosystem functions depends
830 on environmental conditions.

In a steady environment, phytoplankton adaptation allows for a more efficient use of
resources through niche separation, which, in turn, increases primary production. An increase
in primary production may enhance secondary production, nitrogen fixation, and carbon export,
and maybe even other ecosystem functions not included in this study. Thus, by neglecting
835 adaptation, models can systematically underestimate resource use efficiency in a steady
environment and hence ecosystem functions that are directly related to primary production. In
a warming environment, however, adaptation has the opposite effect. With the ability to adapt
to the increasing temperatures, non-pre-adapted taxa can mitigate the dominance of superior
pre-adapted taxa. Since different taxa fulfill different functions in the ecosystem, weaker
840 changes in their abundance lead to weaker changes in ~~related~~associated ecosystem functions.
By neglecting phytoplankton adaptation, models may therefore systematically underestimate
the resilience of phytoplankton communities to environmental change, which may lead to a
systematic overestimation of ~~overestimate~~ ~~warming-induced~~related changes in ecosystem
functioning. Thus, to realistically simulate ecosystem functioning in both steady and changing

845 environments, future models should not only consider multiple phytoplankton functional
groups due to their different roles in the ecosystem but also their potential to adapt to their
environment. ~~Our study furthermore suggests that models without adaptation may miss
adaptation-related interdependencies between taxa that may play out differently in steady and
changing environments and can hence lead to changes in ecosystem dynamics and functioning.~~
850 ~~In addition, our study highlights the importance of life cycle dynamics for phytoplankton
responses to global warming due to potential feedback mechanisms and/or adaptation
constraints.~~

Our study is a first step to improve model projections of future ecosystem-level changes.
Future work can build on our results, for example by expanding on our model ecosystem to
855 include multiple nutrients, a higher diversity of phytoplankton functional groups, a more
complex representation of zooplankton, and higher trophic levels. Another next step would be
to couple our or a similar evolutionary ecosystem model to a 1D or 3D physical environment
to allow for a more realistic representation of physically driven processes, e.g., biogeochemical
cycling. The performance of such an evolutionary biogeochemical-physical model could then
860 be tested against long-term evolutionary data (e.g., from sediment archives). Using such a
validated model for climate projections could notably improve ~~estimates~~ estimations of future
ecosystem-level changes.

Appendix B

890 Supporting figures for Sects. 2.3, 3.2, 3.3, 4.1, 4.5, and 4.6.

895 **Figure B1:** Components of the Hochfeld and Hinners (2024) ecosystem model including compartments
for dissolved inorganic nitrogen (N), detritus (D), and zooplankton (Z), along with agent-based life
cycles of dinoflagellates (din), diatoms (dia), and cyanobacteria (cya). Each life cycle is represented by
a resting stage (RES) and a vegetative growing stage (vegetative cells, VEG). For cyanobacteria, the
model simulates a second, nitrogen-fixing growing stage (vegetative cells with heterocysts, HET). The
figure additionally shows the nitrogen fluxes between the different ecosystem components, and the sinks
and sources of nitrogen (sinking of detritus, burial of phytoplankton resting cells and resuspension of
900 phytoplankton resting cells, cyanobacterial nitrogen fixation). The figure was adapted from Hochfeld
and Hinners (2024) and created with BioRender.com.

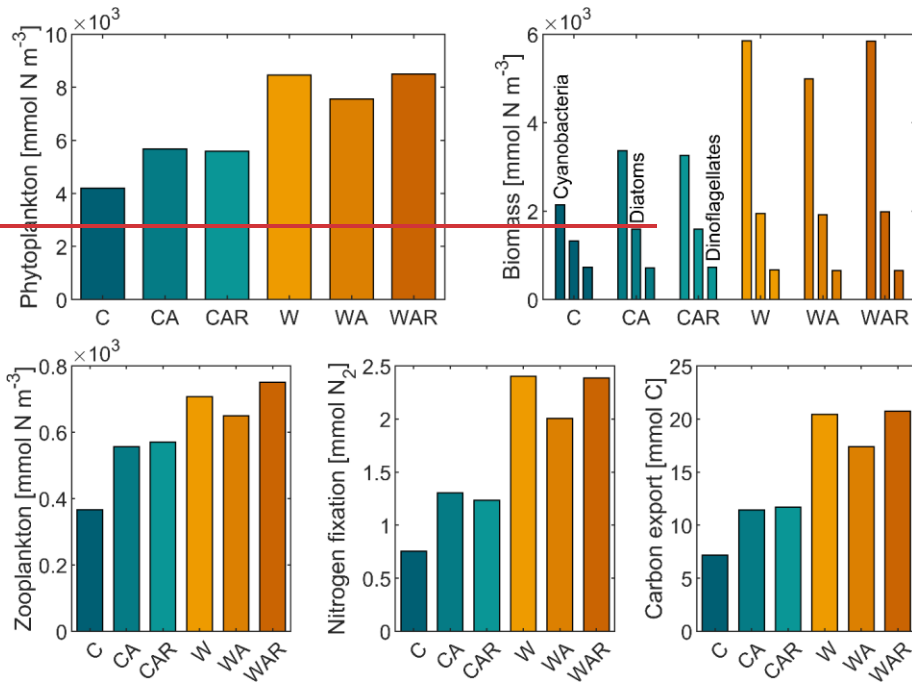

Figure B1: Annual balances for additional simulations with resuspension (C: control, CA: control and adaptation, CAR: control, adaptation, and resuspension, W: warming, WA: warming and adaptation, WAR: warming, adaptation, and resuspension). Carbon export is corrected for the carbon content of resuspended resting cells. Please note that we excluded resource-use efficiency (RUE) from the figure since RUE simulations with resuspension are not comparable with those without.

905

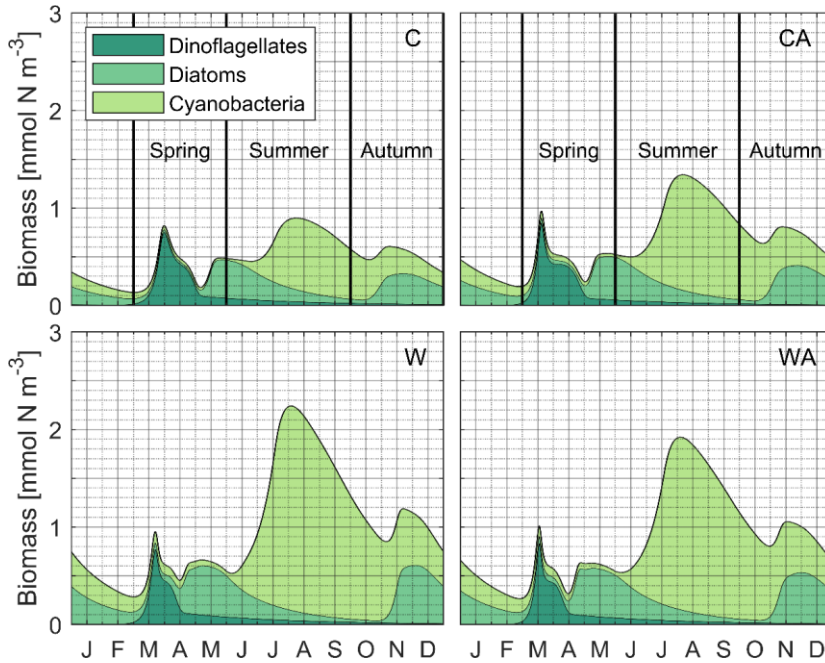

Figure B2: Accumulated phytoplankton biomass during the last simulation year of the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). For each scenario, the output of seven different simulations was averaged. The colors indicate the share of dinoflagellates, diatoms, and cyanobacteria in the total phytoplankton biomass. In the two control scenarios, black vertical lines show the observed timing of the Baltic Sea spring bloom, the cyanobacterial summer bloom, and the diatom autumn bloom (Hjerne et al., 2019, bloom periods were derived from Fig. 2C). Please note that the accumulated phytoplankton biomass shown in this figure includes both growing and resting stages integrated over the entire water column due to the 0-dimensional model setup, while the monitoring data by Hjerne et al. (2019) only cover the first 20 m. Thus, the figure most likely overestimates resting stage biomass compared to the monitoring data, meaning that the simulated biomass peak(s) of a taxon are most relevant for model validation, rather than the general presence of the taxon.

Figure B3: Zooplankton biomass during the last simulation year of the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). For each scenario, we averaged the output of seven different simulations.

925

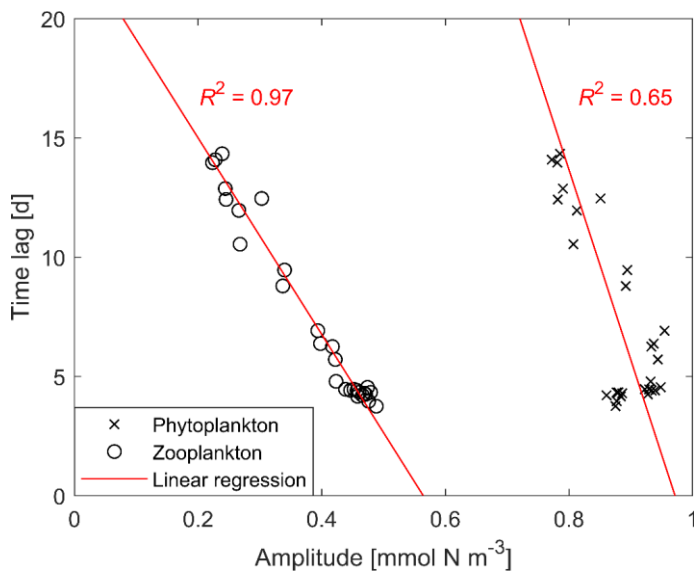

Figure B2: Time lag between phytoplankton and zooplankton blooms as a function of the peak amplitudes of phytoplankton and zooplankton, respectively. Shown are the time lags for the last simulation year of seven different simulations per model scenario, including linear regressions with both phytoplankton and zooplankton peak amplitudes and the corresponding R^2 values.

940

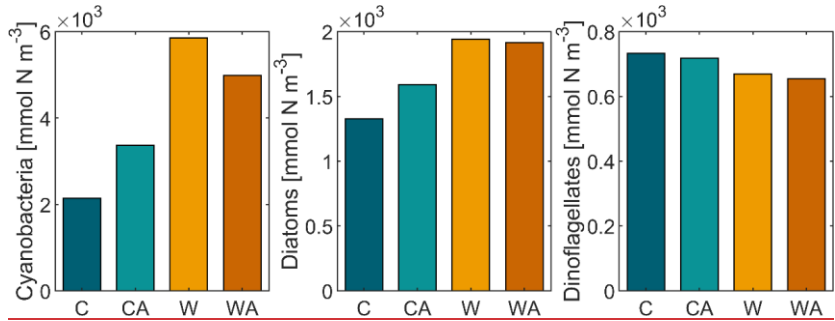

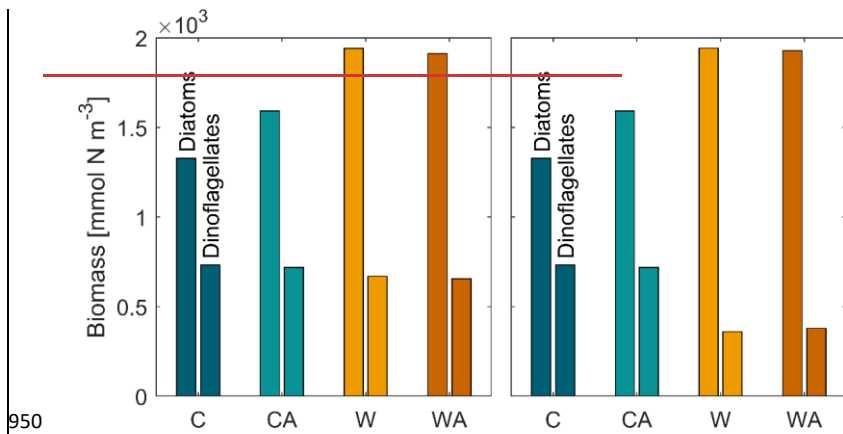

Figure B4: Annual balances of cyanobacteria, diatoms, and dinoflagellates for the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming adaption).

hat formatiert: Schriftart: Fett

945 **Figure B53:** Matrices showing the p -values for the correlations in Fig. 25 (Sect. 3.23). Model scenario abbreviations: C: control, CA: control and adaptation, W: warming, WA: warming and adaptation. Black numbers indicate that the corresponding correlations are statistically significant at the 0.05 level, while orange numbers indicate the opposite.

950 **Figure B4:** Annual biomasses of the cold water dinoflagellate *Apocalathium* and the cold water diatom *Thalassiosira* for the four different model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). Left: Results for our standard simulations with a fixed encystment rate of *Apocalathium*. Right: Results for additional simulations, in which we artificially decreased the encystment rate of *Apocalathium* at the rate found by Hinners et al (2017).
955

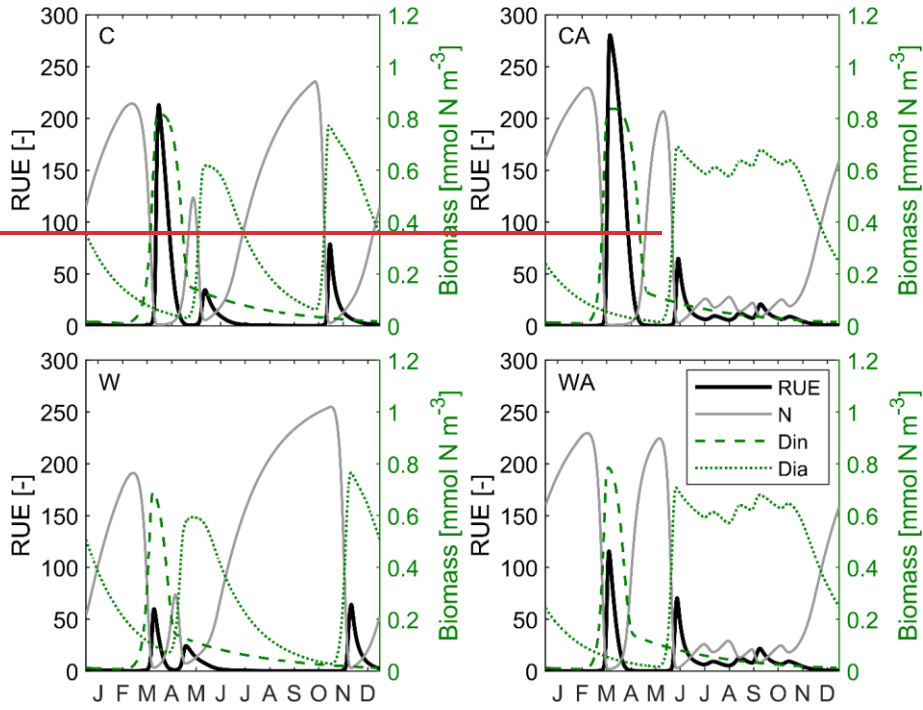

Figure B5: Resource use efficiency (RUE) of our focal dinoflagellate and diatom species of the genera *Apocalathium* and *Thalassiosira* throughout the seasonal cycle for all model scenarios (C: control, CA: control and adaptation, W: warming, WA: warming and adaptation). The figure shows results for the last simulation year, which were averaged over seven different simulations per scenario. Also shown are the nitrogen concentration (N), and the biomasses of *Apocalathium* (Din) and *Thalassiosira* (Dia).

960

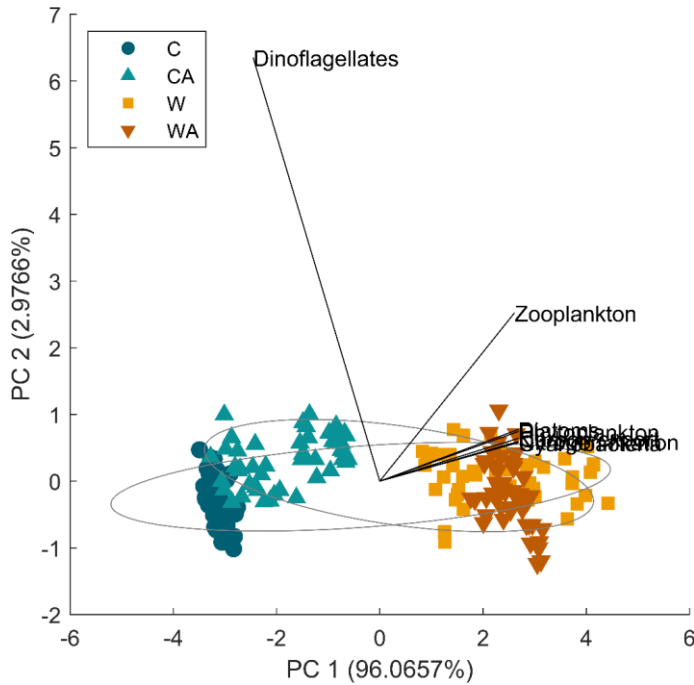

Figure B6: Results for a principal component analysis (PCA). The PCA shows that most variability in our model ecosystem can be explained by the first principal component (PC 1), which is associated with all model variables that are positively impacted by cyanobacteria. Zooplankton and especially dinoflagellates can be clearly identified as outliers.

965

Code availability

The model code and the scripts for evaluating the model output and creating the figures are available on GitHub at <https://github.com/Isabell-Hochfeld/Adaptive-Phytoplankton-Community-Model>, last access: April 23, 2024) and on Zenodo at <https://zenodo.org/doi/10.5281/zenodo.10693812> (version 1.1.0, Hochfeld, 2024). All code is written in MATLAB (version R2022a).

975

Author contribution

JH and IH designed the study. IH modified the model, performed the model simulations, and analyzed the model output. Both authors contributed to writing the manuscript.

980 **Competing Interests**

The authors declare that they have no conflict of interest.

Acknowledgements

985 We would like to thank the editorial board of Biogeosciences and two anonymous reviewers for their constructive feedback on our manuscript. Funding was provided through the project PhytoArk (K314/2020) funded by the Leibniz Association.
