18 **Abstract**

19 Gross primary production (GPP) stands as a crucial component in the terrestrial carbon cycle,
20 greatly affected by large-scale circulation adjustments. This study explores the influence of El
21 Niño-Southern Oscillation (ENSO) and Indian Ocean Dipole (IOD) on China's GPP, utilizing
22 long-term GPP data generated by the Boreal Ecosystem Productivity Simulator (BEPS). Partial
23 correlation coefficients between GPP and ENSO reveal substantial negative associations in
24 most parts of western and northern China during the September-October-November (SON)
25 period of ENSO development. These correlations shift to strongly positive over southern China
26 in December-January-February (DJF), then weaken in March-April-May (MAM) in the
27 following year, eventually turning generally negative over southwestern and northeastern China
28 in June-July-August (JJA). In contrast, the relationship between GPP and IOD basically exhibits
29 opposite seasonal patterns. Composite analysis further confirms these seasonal GPP anomalous
30 patterns. Mechanistically, these variations are predominantly controlled by soil moisture during
31 ENSO events (except MAM) and by temperature during IOD events (except SON).
32 Quantitatively, China's annual GPP demonstrates modest positive anomalies in La Niña and
33 negative IOD years, in contrast to minor negative anomalies in El Niño and positive IOD years.
34 This results from counterbalancing effects with significantly greater GPP anomalous
35 magnitudes in DJF and JJA. Additionally, the relative changes in total GPP anomalies at the
36 provincial scale display an east-west pattern in annual variation, while the influence of IOD
37 events on GPP presents an opposing north-south pattern. We believe that this study can
38 significantly enhance our understanding of specific processes by which large-scale circulation
39 influences climate conditions and, in turn, affects China's GPP.

40

41 **Key words:** Gross primary production, China, El Niño-Southern Oscillation, Indian Ocean
42 Dipole, BEPS

43

44 **1.Introduction**

45 Vegetation photosynthesis, a pivotal physiological process affecting the terrestrial carbon cycle,
46 predominantly governs variations in the net biome productivity (NBP), surpassing the impact
47 of total ecosystem respiration (Piao et al., 2020; Wang et al., 2022; Wang et al., 2018). Gross
48 primary production (GPP) represents the total amount of carbon dioxide assimilated by plants
49 per unit time through the photosynthetic processes, acting as a crucial carbon flux in mitigating
50 anthropogenic CO₂ emissions (Gough, 2012; Houghton, 2007). However, despite evident long-
51 term increasing trends in GPP, primarily attributed to CO₂ fertilization (Ryu et al., 2019;
52 Schimel et al., 2015; Yang et al., 2022), it also shows regional and global interannual variations.
53 These variations are largely linked to climate fluctuations driven by ocean-atmosphere
54 interactions and the teleconnections (Wang et al., 2021b; Ying et al., 2022). To date, the impact
55 of such teleconnections on China's GPP remains insufficiently documented.

56
57 The El Niño-Southern Oscillation (ENSO) exerts a significant influence on the global terrestrial
58 carbon cycle, which is the dominant mode of inter-annual climate variability (Bauch, 2020;
59 Kim et al., 2017; Wang et al., 2016; Wang et al., 2018; Zeng et al., 2005). Within this context,
60 GPP typically assumes a leading role in shaping the response of terrestrial carbon sinks to
61 ENSO events (Ahlstrom et al., 2015; Wang et al., 2018; Zhang et al., 2018). Global patterns
62 reveal a negative GPP anomaly of approximately $-1.08 \text{ Pg C yr}^{-1}$ during El Niño years,
63 contrasting a positive GPP anomaly of about $1.63 \text{ Pg C yr}^{-1}$ in La Niña years (Zhang et al.,
64 2019). However, the impact of ENSO on GPP exhibits significant regional differences. At
65 present, while existing researches have predominantly focused on the response of tropical GPP
66 to ENSO, studies specific to China are relatively limited. Liu et al. (2014) highlighted the effects
67 of ENSO on crop growth in the North China, and Li et al. (2021) demonstrated that the response
68 of GPP to El Niño varies with the phase of the Pacific Decadal Oscillation (PDO) in the eastern
69 China.

70
71 ENSO is not the sole global climatic oscillation, influencing the terrestrial carbon cycle.

72 Another significant player is the Indian Ocean Dipole (IOD), a tropical coupled ocean-
73 atmosphere mode (Saji et al., 1999), which also affects the terrestrial carbon cycling by
74 modulating the climate circulations (Wang et al., 2022; Wang et al., 2020; Wang et al., 2021b;
75 Yan et al., 2023). Research indicates that IOD events can influence precipitation in China, with
76 effects lasting from the year of the event through the subsequent summer (Zhang et al., 2022a).
77 Zhang et al. (2022b) also proved that extreme positive IOD (pIOD) events in 2019 affected the
78 precipitation in summer 2020 in Eastern China, and proposed that the summer precipitation in
79 the following year was mainly affected by IOD in northern China, while by ENSO in the
80 Yangtze River Basin. Additionally, a prior study explored the influence of the extreme
81 pIOD event in 2019 on GPP anomalies across the Indian Ocean rim countries. It suggested a
82 conspicuous negative GPP anomaly occurred in eastern China during the September-October-
83 November (SON) (Wang et al., 2021b).

84

85 The primary objective of this study was to comprehensively assess the impact of ENSO and
86 IOD events on GPP in China. To this end, we initially employed partial correlation analysis to
87 elucidate the relationship between GPP and climate anomalies, specifically soil moisture and
88 temperature, induced by ENSO and IOD events across various seasons. The analysis utilized
89 historical long-term GPP data spanning from 1981 to 2021, simulated by the Boreal Ecosystem
90 Productivity Simulator (BEPS) model. The aim was to get a preliminary understanding of the
91 influence exerted by ENSO and IOD. Furthermore, composite analysis was adopted to illustrate
92 the actual responses during distinct events, including individual ENSO and IOD occurrences.
93 The ensuing discussion will delve into the analysis results on national, regional, and provincial
94 scales.

95

96 2.Datasets and methods

97 2.1 Datasets used

98 The sea surface temperature (SST) dataset are derived from the Monthly NOAA's Extended
99 Reconstructed Sea Surface Temperature version 5 (ERSSTv5) (Muñoz, 2019). It is generated
100 on a $2^\circ \times 2^\circ$ grid, using statistical methods to enhance spatial completeness. Commencing from
101 January 1854 to the present, the monthly SST data includes anomalies computed with respect
102 to a 1971-2000 monthly climatology.

103

104 Meteorological data were adopted from ECMWF Reanalysis v5 (ERA5)-Land monthly
105 averaged data with $0.1^\circ \times 0.1^\circ$ grids, including 2m surface air temperature (TAS), and
106 volumetric soil moisture (SM) during the period from 1981 to 2021. ERA5-Land was created
107 by replaying the land component of the ECMWF ERA5 climate reanalysis at a higher resolution
108 compared to ERA5. Reanalysis combines model data with global observations into a consistent
109 dataset based on the laws of physics. The original soil moisture data was divided into four layers
110 based on different surface depths. These layers were depth-weighted and then aggregated into
111 the average soil moisture to a depth of 289cm ($\text{m}^3 \text{m}^{-3}$).

112

113 GPP spanning from 1981 to 2021 was simulated by the BEPS model, featuring a horizontal
114 resolution of $0.0727^\circ \times 0.0727^\circ$. The BEPS model, originally developed for Canadian boreal
115 ecosystems, has been re-constructed for GPP simulations on the global scale (Chen et al., 1999;
116 Chen et al., 2012). BEPS is a process-based model driven by satellite-observed leaf area index
117 (LAI), meteorological data, land cover types, soil texture, and CO_2 concentration to simulate
118 the daily carbon flux of terrestrial ecosystems (Chen et al., 2019; Liu et al., 1997). The input
119 data used to drive GPP in this study include ERA5 meteorological data (Hersbach et al., 2023),
120 GLOBMAP LAI product (Liu et al., 2012), Land Cover Classification System (LCCS)
121 generated by the Food and Agriculture Organization (FAO) of the United Nations (Friedl and
122 Sulla-Menashe, 2019), Harmonized World Soil Database v1.2 from FAO (Fischer et al., 2008),

123 and CO₂ concentration based on the Global Monitoring Laboratory from NASA (Lan et al.).
124 Notably, BEPS distinguishes itself from other models through the organic combination of
125 remote sensing data and mechanistic modelling. It produces simulation datasets for GPP, Net
126 primary productivity (NPP) and evapotranspiration (ET). Key features of BEPS include the
127 incorporation of sunlit-shaded leaf stratification strategy (Norman, 1982). The model calculates
128 canopy-level photosynthesis by summing the GPP of sunlit and shaded leaves (Chen et al.,
129 1999).

$$130 \quad GPP = A_{sun}LAI_{sun} + A_{shade}LAI_{shade} \quad (1)$$

$$131 \quad LAI_{sun} = 2 \cos \theta \left[1 - \exp \left(-\frac{0.5\Omega LAI}{\cos \theta} \right) \right] \quad (2)$$

$$132 \quad LAI_{shade} = 1 - LAI_{sun} \quad (3)$$

133 where A_{sun} and A_{shade} represent the amount of photosynthesis at per sunlit and shaded leaf,
134 respectively; LAI_{sun} and LAI_{shade} represent the canopy-level sunlit and shaded LAI,
135 respectively; Ω is the foliage clumping index indicating the influence of foliage clustering on
136 radiation transmission, and θ is the solar zenith angle.

137

138 The accuracy of carbon flux products simulated by BEPS has been validated in previous studies
139 (Chen et al., 2019; He et al., 2021). We also used the measured site data from ChinaFlux
140 (<http://chinaflux.org/>) and National Tibetan Plateau Third Pole Environment (Li et al., 2013)
141 (Table S1) to assess the performance of BEPS simulated GPP (Fig. S1). Our analysis reveals a
142 high consistency between simulated and observed GPP, with an average R² of 0.77 ($p < 0.05$)
143 and an average root mean square error (RMSE) of 1.70 gC m⁻² day⁻¹. In addition, the global
144 terrestrial GPP from FluxSat product Version 2.2 (Joiner et al., 2018) was also used to assess
145 the reliability of BEPS GPP. FluxSat GPP is obtained by using light-use efficiency (LUE)
146 framework based on Moderate-resolution Imaging Spectroradiometer (MODIS) satellite data,
147 eliminating the dependency on other meteorological input data. The comparison between BEPS
148 GPP and FluxSat GPP data revealed a robust agreement, with a correlation coefficient (r) of
149 0.63 ($p < 0.05$) and a RMSE of 1.1 Pg C yr⁻¹ (Fig. S2). These consistencies underscore the
150 reliability of the BEPS GPP data in capturing terrestrial carbon flux dynamics.

151 **2.2 Anomaly calculation**

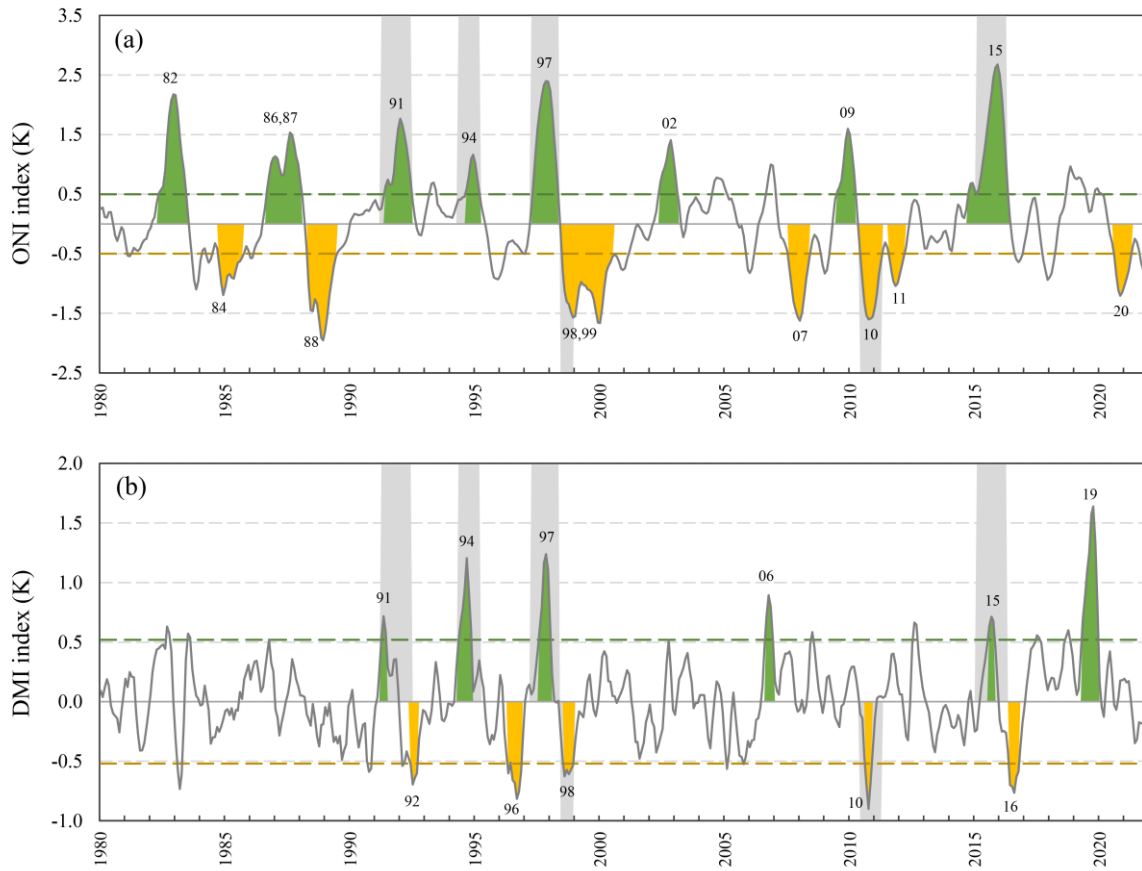

152 To calculate anomalies, we initially eliminated the long-term climatology to get rid of the
153 seasonal cycle. Subsequently, we subtracted the 7-year running average for each grid to
154 eliminate the decadal oscillation and long-term trends for all the variables. Further, refinement
155 involved smoothing the derived GPP and climate anomalies using a 3-month running average
156 to remove the intra-seasonal variability. For consistency, the BEPS simulated GPP data was
157 resampled to $0.1^\circ \times 0.1^\circ$. To align with this, non-vegetated areas in the climate data were
158 masked according to the resampled BEPS GPP, uniformity in spatial representation.

159 **2.3 Definition of climate events**

160 The Oceanic Niño Index (ONI) is used to define ENSO events (Fig. 1a), which represents the
161 3-month running mean SST anomaly in the Niño 3.4 region (5°N - 5°S , 120° - 170°W). The
162 positive phase of an ENSO event (El Niño) is characterized by the ONI exceeding $+0.5\text{K}$ for
163 five consecutive overlapping 3-month periods. Conversely, the negative phase of an ENSO
164 event (La Niña) occurs when the ONI is below -0.5K for five consecutive overlapping 3-month
165 periods. The severity of the event can be further categorized into weak ($0.5\sim-0.99$), moderate
166 ($1.00\sim-1.49$), strong ($1.50\sim-1.99$) and extremely strong (≥ 2.00) based on the absolute value
167 of the ONI. To qualify for a specific rating, an event should meet or exceed a threshold for at
168 least three consecutive overlapping three-month periods.

169
170 Moreover, the Dipole Mode Index (DMI) is employed to identify IOD events (Saji et al., 1999).
171 The DMI is calculated from SST differences between the Western Equatorial Indian Ocean
172 (10°S - 10°N , 50° - 70°E) and the South-eastern Equatorial Indian Ocean (10°S - 0°N , 90° - 110°E)
173 (Fig.1b). Given that the short duration of IOD events with a tendency to peak during the SON,
174 the standard deviation of SON DMI (0.52K from 1981 to 2021) is used as the criterion for
175 identifying IOD events. A positive phase IOD (pIOD) event is defined when the absolute value
176 of DMI is greater than or equal to one standard deviation (0.52K) for three consecutive 3-

177 month periods. Additionally, a strong pIOD event is identified if the DMI value exceeds two
 178 standard deviations (1.04 K).

179
 180 Fig.1 Time series of the Oceanic Niño Index (ONI) (a) and the Dipole Mode Index (DMI) (b) from 1980
 181 to 2022. The positive phase events (El Niño and positive Indian Ocean Dipole (pIOD)) are filled in
 182 green and the negative phase events (La Niña and negative IOD (nIOD)) are filled in yellow, and the
 183 events are also labeled with a two-digit year. The green and yellow dashed lines represent the positive
 184 and negative thresholds for El Niño-Southern Oscillation (ENSO) and IOD, respectively. The gray
 185 background indicates years with the simultaneous ENSO and IOD events.

186 2.4 Partial correlation analysis

187 To comprehensively assess the impacts of ENSO and IOD on GPP, while accounting for the
 188 influence of other events, partial correlation analysis (pcor) was employed, following the
 189 previous studies (Saji and Yamagata, 2003; Wang et al., 2021b). The definition of *pcor* for *x*
 190 and *y*, controlling for *z*, is given by:

191
$$pcor_{yx.z} = \frac{r_{yx} - r_{yz}r_{xz}}{\sqrt{1-r_{yz}^2}\sqrt{1-r_{xz}^2}} \quad (4)$$

192 where r_{yx} is the correlation of the dependent variable y and the explanatory variable x (e.g.,
 193 DMI), and the same is for r_{yz} and r_{yx} . The two-tailed Student's t -test was used to calculate
 194 the statistical significance of each pixel result:

195
$$t = pcor_{yx.z} \sqrt{\frac{n-2-k}{1-pcor_{yx.z}^2}} \quad (5)$$

196 where n and k are the number of samples and conditioned variables, respectively.

197

198 **2.5 Composite analysis**

199 When enumerating the years of ENSO and IOD events, we retained all the years of IOD events
 200 and ENSO events of above the moderate intensity. Individual events and compound events were
 201 categorized and summarized in Table 1. In this study, a compound event refers to the
 202 simultaneous occurrence of ENSO and IOD, primarily El Niño & pIOD and La Niña & negative
 203 IOD (nIOD). IOD typically peaked in the September-October-November (SON, yr0), while
 204 ENSO peaked in the December(yr0)-January(yr1)-February(yr1) (DJF), and the influence of
 205 the two events could extend until the summer of the following year. Therefore, we selected four
 206 seasons from SON to June-July-August (JJA) in the following year for composite analysis in
 207 this study. In addition, the year 1991 was excluded due to the strong eruption of Mount Pinatubo,
 208 which had a large impact on the global carbon cycle (Mercado et al., 2009).

209

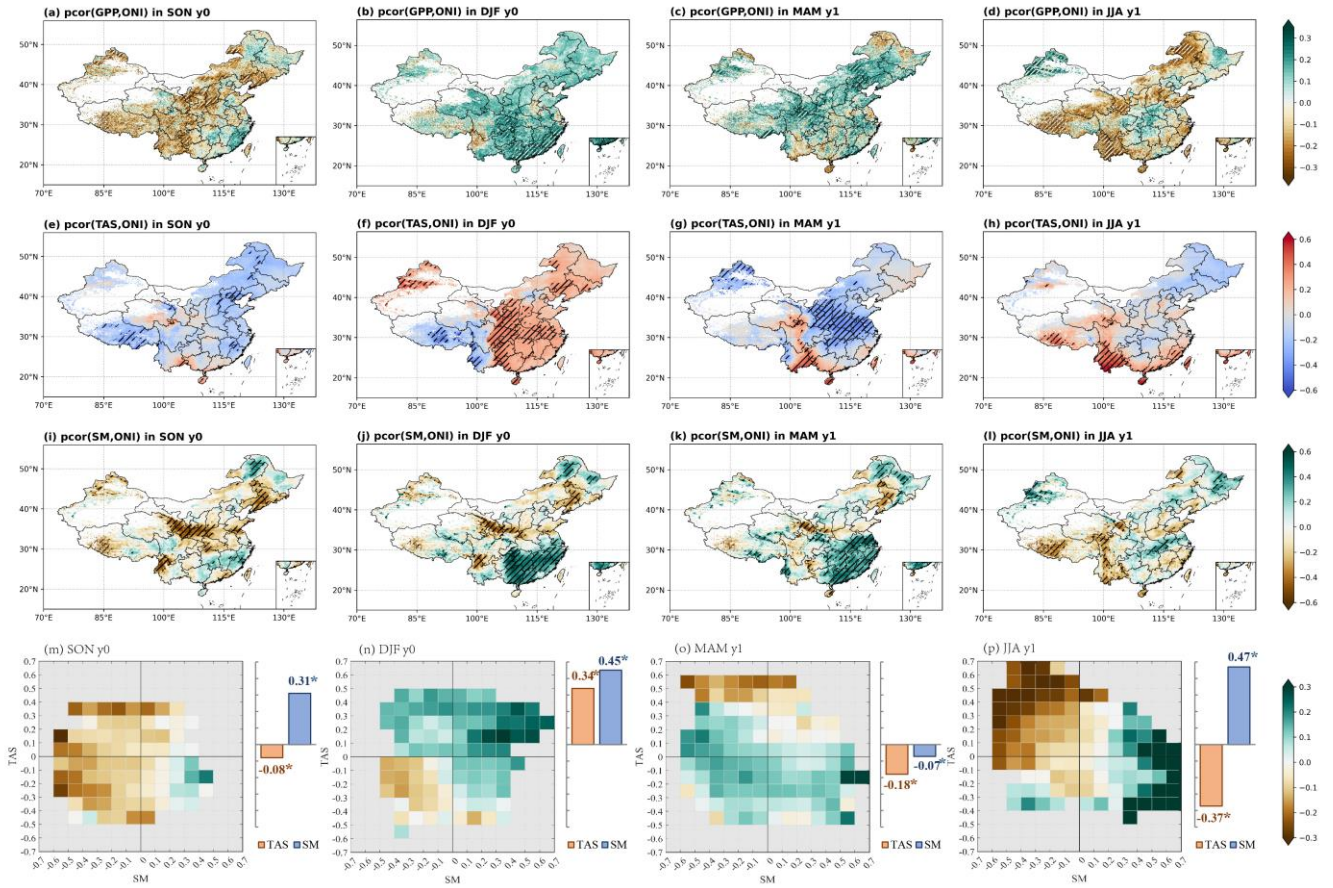

210 **Table 1.** Occurrences of ENSO and IOD events from 1981 to 2021.

Events	Years
El Niño	1982, 1986, 1987, 2002, 2009
La Niña	1984, 1988, 1999, 2007, 2011, 2020
pIOD	2019
nIOD	1992, 1996, 2016
El Niño & pIOD	1994, 1997, 2015
El Niño & nIOD	-
La Niña & pIOD	-
La Niña & nIOD	1998, 2010

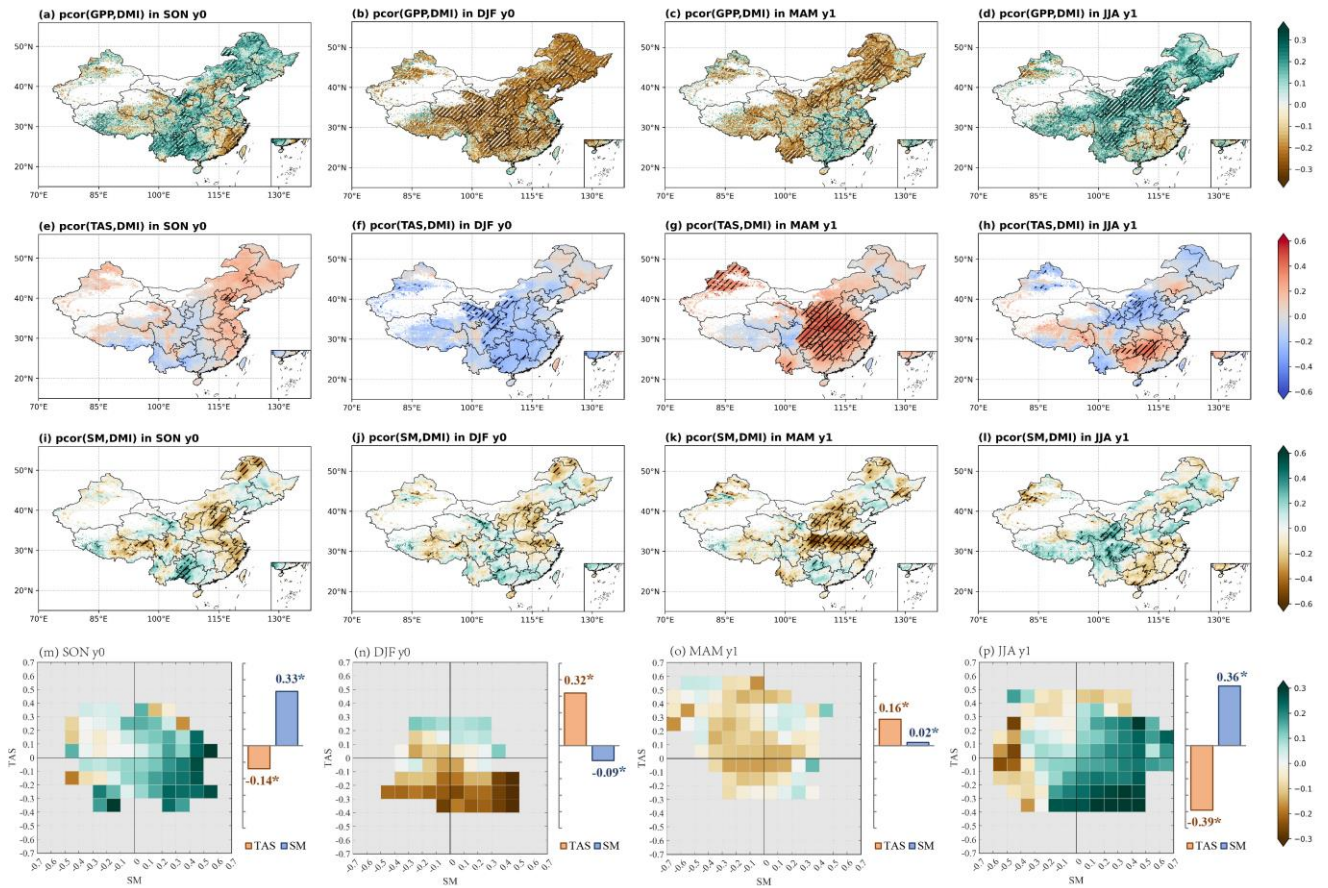

211

212 **3.Results**

213 **3.1 Historical relationship between GPP and ENSO**

214
 215 Fig. 2 Spatial patterns of partial correlation coefficients (*pcor*) between ONI and gross primary productivity
 216 (GPP) (a-d), surface air temperature (TAS) (e-h), soil moisture (SM) (i-l) in different seasons, controlling
 217 for the effect of DMI. Hatched areas represent significance at $p \leq 0.05$ based on the two-tailed Student's *t*-
 218 test. (m-p) Heatmaps represent the relationships of the *pcor* patterns among GPP, TAS, and SM, and bar
 219 charts illustrate the pattern correlations of these *pcor* values between GPP and TAS and SM on the national
 220 scale for each season. We here use seasonal average temperature as a mask to exclude regions with
 221 temperatures below zero, thereby minimizing the influence of phenology on GPP. Notably, asterisks (*) in
 222 the bar charts denote significance at $p < 0.05$.

223

224 Fig. 3 Same as Fig.2, but for DMI, controlling the effect of ONI.

225

226 We analyzed the *pcor* patterns between GPP and climate anomalies across different events
 227 using long time series data (Figs. 2 and 3). Following this, we calculated pattern correlation
 228 coefficients between the GPP and climate *pcor* patterns, aiming to investigate the varying
 229 impacts of key climate drivers (TAS and SM) on photosynthesis across different seasons (Figs.
 230 2m-p, and 3m-p).

231

232 Figure 2 reveals notable seasonal variations in the *pcor* patterns between GPP, related climate
 233 anomalies, and ONI index in December-January-February (DJF) when ENSO peaked,
 234 controlling the effect of DMI in September-October-November (SON) when IOD peaked.
 235 During SON, significant negative *pcor* between GPP and ONI is observed in regions including
 236 the Tibetan Plateau, Southwestern China, Loess Plateau, and Liaoning province (Fig. 2a).
 237 Clearly, this pattern aligns closely with the *pcor* pattern between soil moisture and ONI (Figs.

238 2a and i). The pattern correlation analysis between GPP and both TAS and SM underscores the
239 dominance of SM in influencing GPP anomalies, indicated by a correlation coefficient of 0.31
240 ($p < 0.05$). This finding suggests that the soil moisture deficit induced by El Niño largely
241 inhibits vegetation photosynthesis during this season (Fig. 2m).

242

243 Along with the peak of ENSO events in DJF, the *pcor* pattern between GPP and ONI exhibits
244 a distinct shift from the pattern in SON. Notably, DJF showcases significant positive *pcor*
245 values over large areas in southern China and weak positive *pcor* in the North and Northeastern
246 China (Fig. 2b). During this period, soil moisture still serves as a more influential factor in
247 driving GPP changes, reflected in a nation-wide pattern correlation coefficient of 0.45 ($p < 0.05$)
248 (Fig. 2n). Specifically, sufficient soil moisture during El Niño, coupled with higher winter
249 temperatures, contribute to a substantial enhancement in GPP across Southern China. In
250 contrast, the impact is weaker in the North and Northeast China due to the vegetation being in
251 the non-growing season, and localized soil water deficits (Figs. 2b, f, and j). In addition, GPP
252 experiences inhibition in some areas of southwestern China due to low temperatures and soil
253 drought.

254

255 Subsequently, the positive *pcor* of GPP decreases, or even turns slightly negative from DJF to
256 March-April-May (MAM) in southern China, primarily attributed to shifts of temperature (Figs.
257 2c and g). On a nationwide scale, temperature becomes the dominant factor in this period, but
258 it exhibits a negative correlation with GPP, with a spatial correlation coefficient of -0.18 ($p <$
259 0.5). This negative correlation is mainly due to negative GPP and positive temperature in the
260 southwest region, and positive GPP and negative temperature in the northern region (Figs. 2c
261 and 2g). Specifically, the negative *pcor* of GPP in southwest China is due to soil moisture
262 shortages (Fig. 2k). In the northern region, where a large area of croplands exists (Fig. S11),
263 human management practices may have a greater impact on GPP, particularly in the spring
264 when the growing season begins. However, these human management practices (e.g., irrigation,
265 fertilization, pesticide use) are not considered in the BEPS model, which could introduce

266 significant uncertainties in simulated GPP over cropland areas. Additionally, in some
267 grasslands of northern Hebei and parts of neighboring Inner Mongolia, GPP shows positive
268 *pcor* during El Niño events, possibly due to the strong legacy effects of climatic conditions in
269 DJF period.

270

271 Moving into JJA, the *pcor* of GPP exhibits widespread negative values again (Fig. 2d). In
272 general, during El Niño, increased soil moisture and lower temperatures greatly contribute to
273 enhanced GPP, while drier soil moisture and higher temperatures inhibit the increase in GPP
274 (Fig. 2p). Regionally, higher temperatures and lower soil moisture both contribute to the
275 negative GPP anomalies over southwestern China. However, lower soil moisture
276 predominantly curtails GPP over the Tibetan Plateau, the Yellow River basin, and northeastern
277 Inner Mongolia. Overall, the correlation coefficients between GPP and TAS and SM in summer
278 are comparable, with soil moisture exhibiting a slightly higher effect, represented by a
279 correlation coefficient of 0.47 ($p < 0.05$), compared to a correlation coefficient of -0.37 ($p <$
280 0.05) for temperature.

281

282 **3.2 Historical relationship between GPP and IOD**

283 In comparison, the *pcor* patterns between GPP and DMI in SON, controlling for the effect of
284 ONI, exhibit nearly opposite patterns to those between GPP and ONI (Figs. 2 and 3). In detail,
285 GPP demonstrates significant positive *pcor* values with DMI in southwestern China and eastern
286 Inner Mongolia, but displays significant negative *pcor* with DMI in southeastern China during
287 SON (Fig. 3a). In terms of climate drivers, during the pIOD events, for instance, wetter soil
288 and lower temperatures both benefit the significant enhancement in GPP in southwestern China,
289 while higher temperatures largely contribute to the enhancement in GPP over eastern Inner
290 Mongolia. Conversely, GPP is largely inhibited by the dry conditions in southeastern China
291 (Figs. 3e and i). Overall, soil moisture dominates the GPP anomaly in China, with a correlation
292 coefficient of 0.33 ($p < 0.05$) (Fig. 3m).

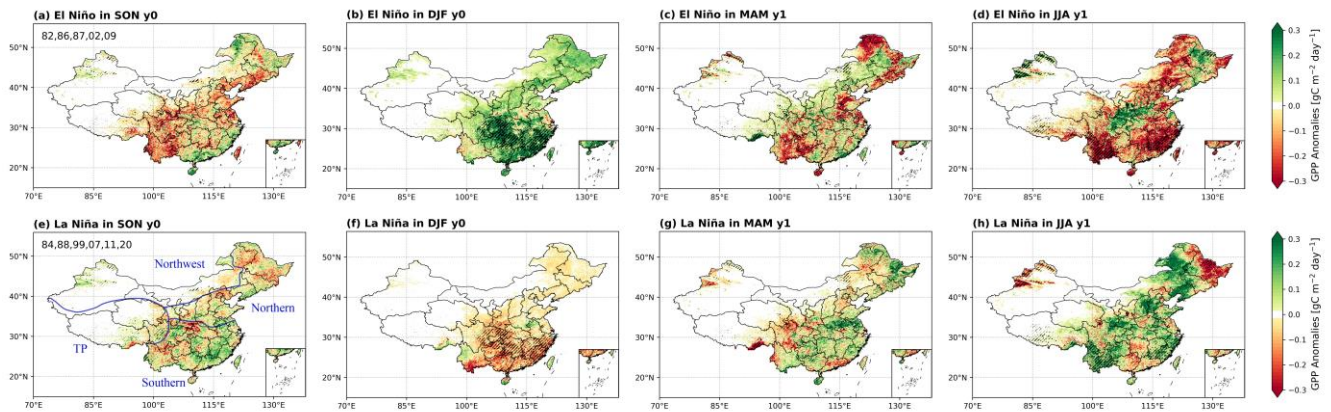

293 In DJF, GPP exhibits widespread significant negative *pcor* with DMI (Fig. 3b), primarily due
294 to the widespread negative *pcor* of temperature, characterized by a correlation coefficient of
295 0.32 ($p < 0.05$) (Figs. 3f and n). Moving into MAM, the significant negative *pcor* between GPP
296 and DMI carried on from those in DJF, but shifts to weak positive *pcor* in southeastern China,
297 driven by the significant positive *pcor* of temperature (Figs. 3c and g). However, the significant
298 negative *pcor* of soil moisture in the Jianghuai Basin and North China still negates the positive
299 effect of temperature (Fig. 3k). During this period, temperature remains the dominant factor,
300 with a nation-wide pattern correlation coefficient of 0.16 ($p < 0.05$) with GPP (Fig. 3o).

301

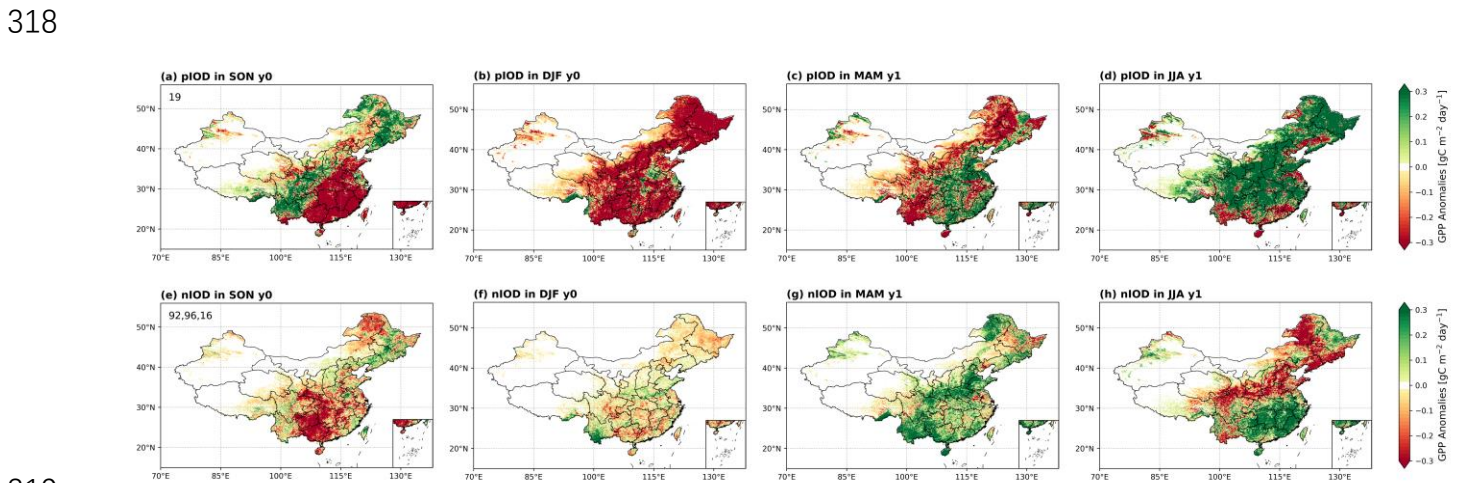

302 In JJA, the situation undergoes a change, showing the significant positive *pcor* of GPP over
303 southwestern, north and northeast China, and weak negative *pcor* over southeastern China (Fig.
304 3d). In other words, lower temperatures and gradually wetter soil are conducive to the increase
305 in vegetation photosynthesis, but heat and dry conditions cause the weak inhibition of
306 photosynthesis in southeastern China during the pIOD (Figs. 3p). However, unlike the ENSO
307 event, the role of temperature is slightly higher than that of SM in the IOD event, and the
308 correlations between GPP and TAS and SM are -0.39 and 0.36 ($p < 0.05$), respectively.

309

310 **3.3 GPP anomalies caused by specific ENSO and IOD events**

311
 312 Fig. 4. Spatial distributions of seasonal composite GPP anomalies for ENSO events, (a-d) for El Niño,
 313 and (e-h) for La Niña. The black slashes indicate areas where El Niño events differ significantly from
 314 La Niña events ($p \leq 0.05$) based on the Student's two-sample t -test. The two-digit year in first column
 315 denote the years used for composite analysis. Additionally, China is divided into four regions:
 316 Northwest China, Tibetan Plateau, Northern China, and Southern China, as shown in (e), which is used
 317 in the following context.

319
 320 Fig. 5. Similar to Fig. 4, but for spatial distributions of seasonal composite GPP anomalies for IOD
 321 events, (a-d) for pIOD, and (e-h) for nIOD. We did not conduct the significance test here owing to the
 322 limited samples.

323

324 While we have elucidated the historical relationship between GPP and ENSO and IOD events
325 through partial correlation coefficients and discussed the underlying climate drivers, we here
326 specifically selected actual events to conduct a composite analysis. This approach aims to
327 further comprehensive understanding of the effects of ENSO and IOD events on GPP variations
328 in China.

329

330 **3.3.1 ENSO-induced GPP anomalous patterns**

331 The impacts of El Niño and La Niña events exhibit opposite influences on GPP with obvious
332 seasonal variations (Fig. 4). Specifically, during SON, GPP anomalies are relatively weak,
333 indicating some suppressions over southwestern China and north China during El Niño events,
334 primarily attributed to dry conditions there (Figs. 4a and S4a). As ENSO peaks in DJF, GPP is
335 significantly strengthened during El Niño events and suppressed during La Niña events,
336 especially over southern China (Figs. 4b and f), aligning well with the patterns of *pcor* between
337 GPP and ONI, controlling the effect of DMI (Fig. 2b). Concurrently, the widespread higher
338 temperatures and wetter soil moisture both contribute to enhanced GPP over southern China
339 during El Niño events (Figs. S3b and S4b), while colder temperatures and drier soil moisture
340 lead to GPP suppression there during La Niña (Figs. 2f and 3f). In MAM as ENSO weakens
341 and vegetation starts to grow in the extratropics, the enhanced GPP over southern China in DJF
342 during El Niño events diminishes, even transitioning into a notable GPP reduction over
343 southwestern China, north China, and northeastern China (Fig. 4c). This transition is conspired
344 by phenological and climate changes including colder temperatures and prolonged dry
345 conditions (Figs. S3c and S4c). The GPP pattern exhibits the opposite transition in La Niña
346 (Fig. 4g). Moving to JJA, dry and hot conditions (Fig. S3d and S4d) lead to significant negative
347 GPP anomalies in southeastern and southwestern China in El Niño (Fig. 4d), whereas cool and
348 wet conditions result in positive GPP anomalies in La Niña events (Fig. 4h). Overall, GPP
349 anomalies induced by ENSO events in DJF and JJA are more pronounced than those in SON
350 and MAM, corresponding to the life cycle of event and vegetation growth periods, respectively.

351 Crucially, they demonstrate distinct GPP patterns, with significant enhancements in DJF and
352 reductions in JJA during El Niño events and reverse during La Niña events, aligning well with
353 the *pcor* pattern between GPP and ONI, controlling for the effect of DMI (Fig. 4). In addition,
354 the effect of ENSO on vegetation in southern China appears more substantial.

355

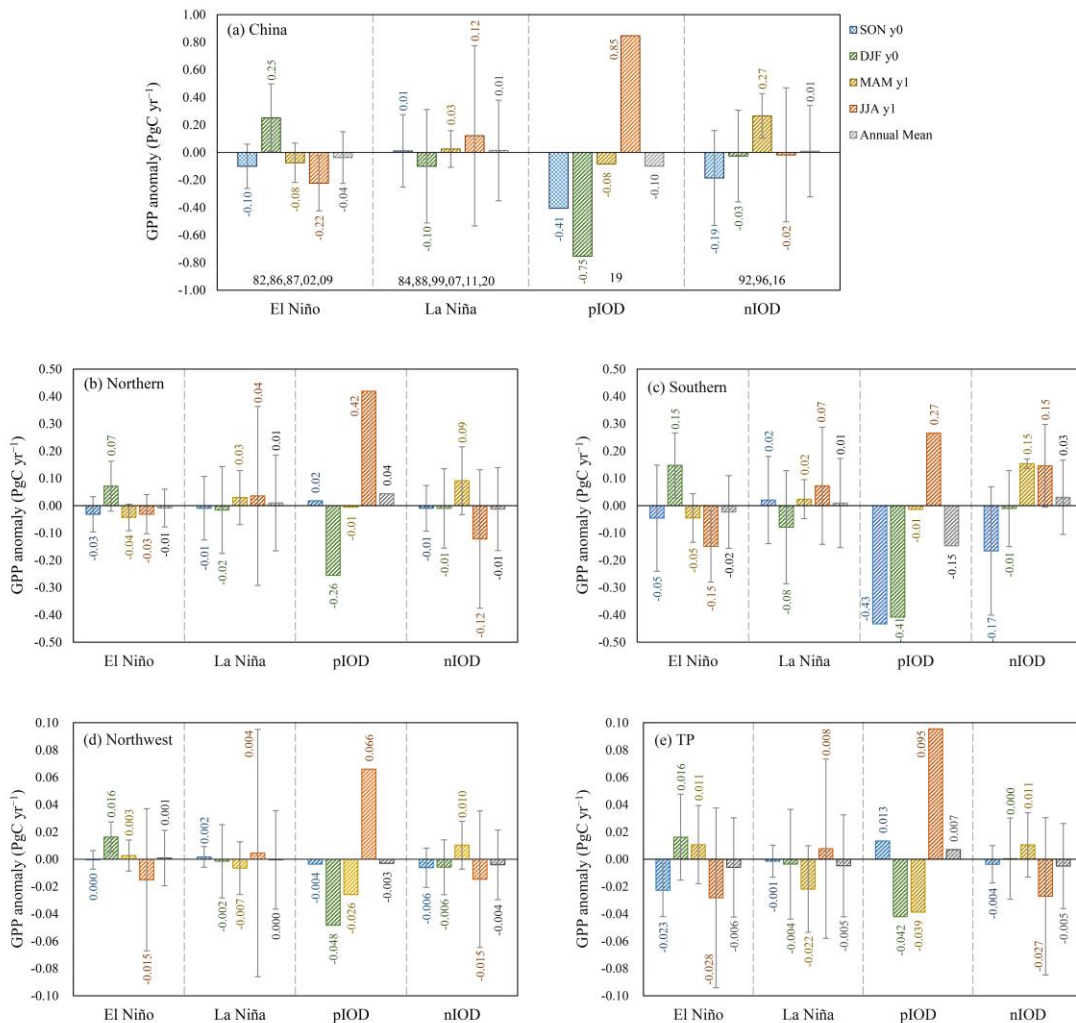

356 **3.3.2 IOD-induced GPP anomalous patterns**

357 During the period from 1981 to 2021, we only find one independent but extreme pIOD event
358 occurred in 2019 according to our criterion (Table 1). This extreme pIOD event extended from
359 June to December, a longer duration compared to other IOD events. Different from ENSO,
360 IOD basically peaks in SON. GPP anomalies induced by this extreme event align closely with
361 the long-term *pcor* patterns between GPP and DMI, controlling for the effect of ONI (Fig. 3).
362 Specifically, significant reductions in GPP occur in southeastern China in SON (Fig. 5a),
363 predominantly due to heat stress and severe drought conditions (Figs. S5a and S6a), consistent
364 with the findings revealed by Wang et al. (2021b). In DJF, the seasonal legacy of vegetation
365 state (Yan et al., 2023) and prolonged droughts lead to the widespread GPP reductions (Figs.
366 5b and S6b), outweighing the potential positive effect of higher temperatures (Fig. S5b). Of
367 course, the decline of GPP in southwestern China appears linked to lower temperatures (Figs.
368 5b and S5b). During MAM, the mitigation of soil moisture deficit and favorable higher
369 temperatures in southern China facilitate a shift in GPP from decline to increase (Fig. 5c). In
370 the north, persistent drought conditions notwithstanding (Fig. S6c), higher temperatures and
371 the onset of the growing season contribute to the enhanced GPP (Fig. 5c). In JJA, increased
372 precipitation over the Yangtze and Yellow River basins (Zhang et al., 2022) alleviates the soil
373 moisture deficits (Fig. S6d). Coupled with the relatively lower temperatures, this leads to
374 widespread GPP increases. Conversely, GPP suppressions in provinces south of 25°N and
375 around the Bohai Sea are attributed to higher temperatures and soil water deficits (Figs. 5d,
376 S5d, and S6d).

377

378 In contrast to the intense 2019 pIOD event, our composite analysis incorporates three weak
379 nIOD events, resulting in comparatively milder anomalies. In SON, different from pIOD event,
380 negative GPP anomalies in nIOD mainly appear in the provinces of Guizhou, Hunan, and
381 Guangxi (Fig. 5e), associated well with concurrent dry conditions (Fig. S6e). In DJF, although
382 the spatial pattern of soil moisture remains largely consistent with SON (Fig. S6f), a shift from
383 negative to positive temperature anomalies mitigates the evident GPP reductions (Fig. 5f). The
384 ongoing soil wetting and the onset of the growing season in northern hemisphere in MAM
385 result in the increased GPP over the Yellow River Basin and southwestern China (Figs. 5g, S5g,
386 and S6g). Subsequently, in JJA, the combination of wetter soil and lower temperatures
387 facilitates vegetation photosynthesis in southern China, while drier soil largely contributes to
388 the reduction in GPP in the north and northeastern China (Figs. 5h, S5h, and S6h).
389

390 **3.3.3 National and regional total GPP anomalies**

391
 392 Fig. 6. The seasonal and annual mean anomaly of GPP in different classified events for China (a), for
 393 Northern China (b), for Southern China (c), for Northwest China (d), and for Tibetan Plateau (e). The
 394 error bars show the standard deviation of different events in the composite analysis.

395
 396 We calculated the total GPP anomaly in China and various geographic regions for each
 397 classified event on both seasonal and annual scales (Fig. 6). Regionally, the geographical
 398 divisions include Northern China, Southern China, Northwest China, and Tibetan Plateau (Fig.
 399 4e). Notably, the North-South boundary aligns closely with the 0° isotherm in January and the
 400 annual precipitation line of 800 mm. The division between the North and the Northwest is

401 determined by the annual precipitation line of 400 mm, and the Tibetan Plateau is segmented
402 based on topographic factors.

403

404 In general, the GPP anomalies exhibit noticeable differences on the seasonal scale, while the
405 total annual anomalies do not show a significant magnitude due to the mutual offset of positive
406 and negative anomalies in different seasons. However, it is worth noting that our annual totals
407 are calculated from the SON in the developing year of the event to the JJA in the following
408 year. This method deviates from the traditional calendar year, and as per the conventional
409 definition of a “year”, the annual anomalies induced by these events can indeed be substantial.

410

411 Specifically, taking a national perspective (Fig. 6a), GPP anomalies during the El Niño and La
412 Niña events exhibit opposite signs in DJF and JJA, with greater magnitudes during these peak
413 periods of the events and the most vigorous growth period of vegetation, respectively. In terms
414 of the development process of the event, the annual anomaly of GPP is negative during El Niño,
415 with a magnitude of $-0.04 \pm 0.19 \text{ Pg C yr}^{-1}$, but positive during La Niña events, with a
416 magnitude of $0.01 \pm 0.37 \text{ Pg C yr}^{-1}$. The asymmetry of the positive and negative phases of IOD
417 is also evident in the total anomaly. For the pIOD event in 2019, GPP shows strong negative
418 anomalies with values of $-0.41 \text{ Pg C yr}^{-1}$ in SON and $-0.75 \text{ Pg C yr}^{-1}$ in DJF. Conversely, it
419 exhibits a marked positive anomaly in the following JJA, with a value of $0.85 \text{ Pg C yr}^{-1}$. The
420 annual total of GPP anomaly is opposite for pIOD and nIOD events, showing $-0.10 \text{ Pg C yr}^{-1}$
421 and $0.01 \pm 0.33 \text{ Pg C yr}^{-1}$, respectively. Moreover, large standard deviation indicated that there
422 are large uncertainties in the impact of different events, and each event has its uniqueness
423 (Capotondi et al., 2015).

424

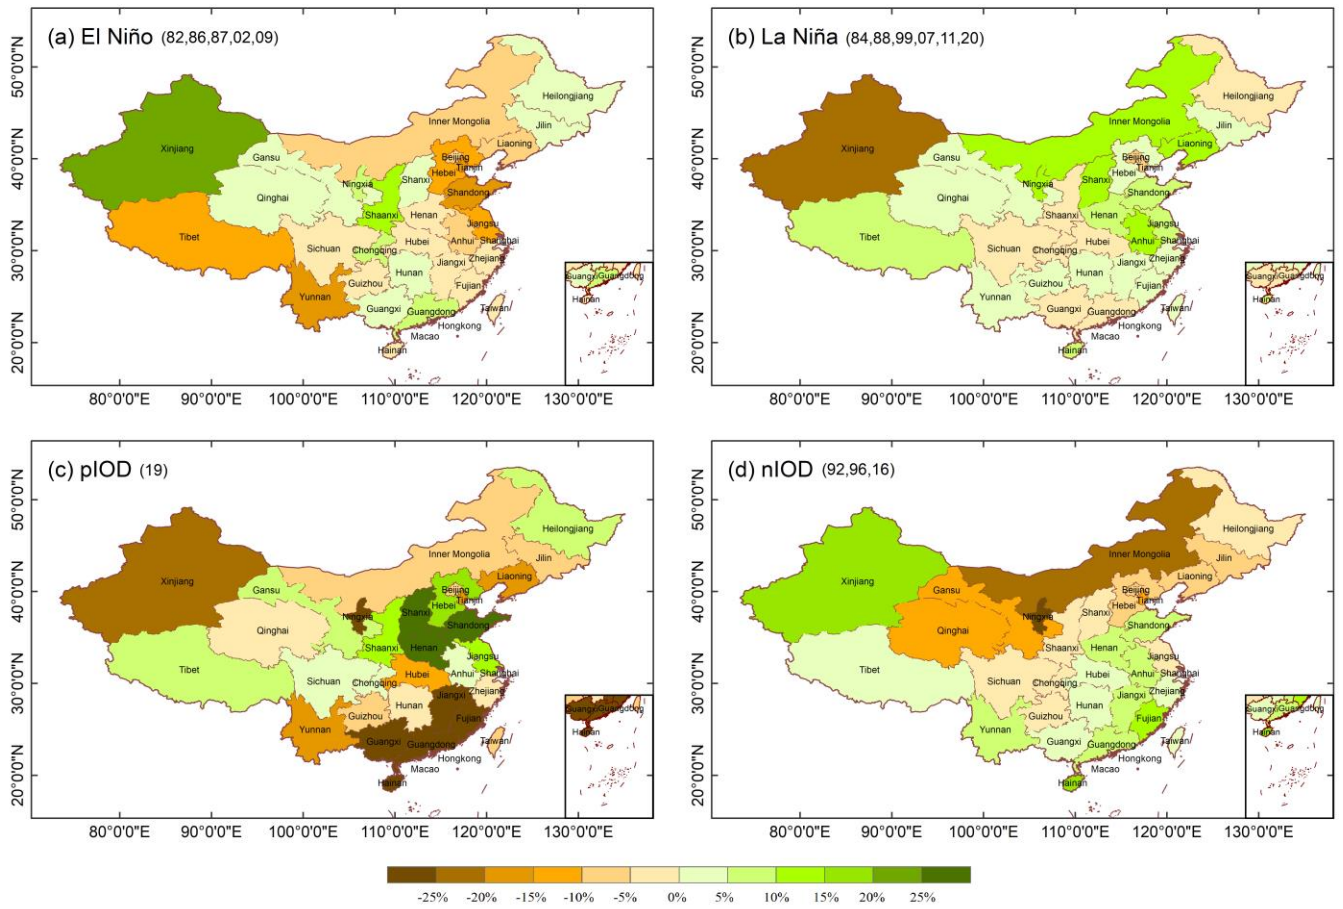

425 Additionally, the variation of GPP anomaly in each region is basically consistent with that at
426 the national scale, especially in the Southern. But regional differences indeed exist in the total
427 amount of GPP anomalies, demonstrating the difference in the impact of events on different
428 regions' GPP. Taking the 2019 extreme pIOD event as an example, the GPP showed a

429 significant negative anomaly in the Southern during the SON (Fig. 6c), resulting in negative
430 anomalies in GPP at the national scale (Fig. 6a), but weak positive anomalies in the Northern
431 and TP (Figs. 6b and e). Then, the GPP anomaly was close to zero in the Northern and Southern
432 in MAM (Figs. 6b and c), while it was still a significant negative anomaly in the Northwest
433 and TP (Figs. 6d and e). Moreover, the negative annual GPP anomalies in the Southern and
434 Northwest offset the positive anomalies of the TP and Northern, making a negative annual GPP
435 anomaly in the national of this event.

436

437 In terms of the magnitude of GPP anomalies, they are more pronounced in the Northern and
438 Southern regions, characterized by lush vegetation, mostly less than 0.5 Pg C yr^{-1} .
439 Meanwhile, GPP anomalies are relatively weaker in the Northwest and TP regions, primarily
440 covered by grassland, generally less than 0.1 Pg C yr^{-1} . Further, we calculate the contributions
441 of different regions to the national total GPP anomaly in each event (Table S3), referencing an
442 index described in the article by Ahlstrom et al. (2015), as detailed in the supplementary method.
443 Overall, the GPP anomaly in the Southern region dominates the national GPP variation,
444 contributing approximately 68% to ENSO events and 46% to IOD events, respectively. The
445 Northern GPP anomaly contributes approximately 28% to the national GPP variation in ENSO
446 events and 39% in IOD events. In addition, the contribution of GPP anomaly in the Northwest
447 and TP regions to the national GPP variation is within 10%.

448 **3.3.4 Relative changes in total GPP anomalies at provincial scale**

449

450 Fig. 7. Spatial distributions of relative changes of total composite anomalies of GPP at provincial scale

451 for different classified events.

452 We presented the spatial patterns of mean GPP anomalies from the SON in the developing year
453 to the JJA in the decaying year (Fig. S7) and further calculated provincial total GPP anomalies
454 (Fig. S8 and Table S3). Provinces with more extensive forest coverage, such as Yunnan, central
455 provinces housing the Qinling Mountains, and northeast provinces where the Greater and
456 Lesser Hinggan Mountains are situated, exhibit relatively larger provincial GPP anomalies.
457 However, differences are apparent among different events (Fig. S8). Considering differences
458 in area and vegetation coverage across provinces, our focus centers on the relative change of
459 GPP anomalies (Fig. 7). It's important to note that, due to different years used in composite
460 analysis, our quantitative comparisons are limited to the same event within different provinces,
461 while qualitative descriptions are extended to different events.

462

463 El Niño events generally induce substantial GPP changes in two main regions with a relative
464 change of over 10% (Fig. 7a). One region encompasses the northern coastal provinces,
465 including Tianjin, Hebei, Shandong, and Jiangsu, while the other is situated in the western part,
466 including Xinjiang, Tibet, and Yunnan provinces. Yunnan, rich in forest resources, bears the
467 brunt of El Niño 's impact, exhibiting a total negative GPP anomaly of $-22.55 \text{ Tg C yr}^{-1}$ (Table
468 S4) and a relative change of approximately 16%. Despite comparable relative changes in GPP
469 for other provinces, their GPP anomalies are relatively smaller, within -5 Tg C yr^{-1} . Notably,
470 Xinjiang, characterized by a fragile forest steppe in the Altai and Tianshan Mountain regions,
471 consistently demonstrates substantial relative changes in GPP during both ENSO and other
472 events. Quantitatively, during the El Niño episode, Xinjiang witnesses a remarkable 24%
473 relative change in GPP, accompanied by a positive GPP anomaly of $-3.82 \text{ Tg C yr}^{-1}$. In contrast,
474 during the La Niña episode, provinces with notable relative changes are mainly concentrated
475 in the northern regions, such as Xinjiang, Inner Mongolia, Ningxia, Shanxi, and Liaoning
476 provinces (Fig. 7b). In addition, although the influence of ENSO on GPP in the southern China
477 is significant (Fig. 4), the total relative change through the year remains small due to the
478 cancellation of positive and negative anomalies in different seasons.

479 In the pIOD classification, only the 2019 extreme event is considered, resulting in the relative

480 change in GPP anomalies exceeding 10% in approximately half of the provinces. Notably,
481 Jiangxi, Fujian, Guangxi, Guangdong, and Hainan experience reductions of more than 25% in
482 GPP, with Jiangxi exhibiting the largest GPP anomaly of $-31.50 \text{ Tg C yr}^{-1}$. Conversely,
483 Shandong, Shanxi, and Henan witness increase of over 25% in GPP (Fig. 7c). During nIOD
484 events, northern provinces generally exhibit negative relative changes, while southern
485 provinces display positive relative changes.

486

487 In summary, the relative changes in total GPP anomalies at the provincial scale exhibit an east-
488 west pattern in annual variation. Meanwhile, the influence of IOD events on GPP presents an
489 opposing north-south pattern.

490 **4. Discussion**

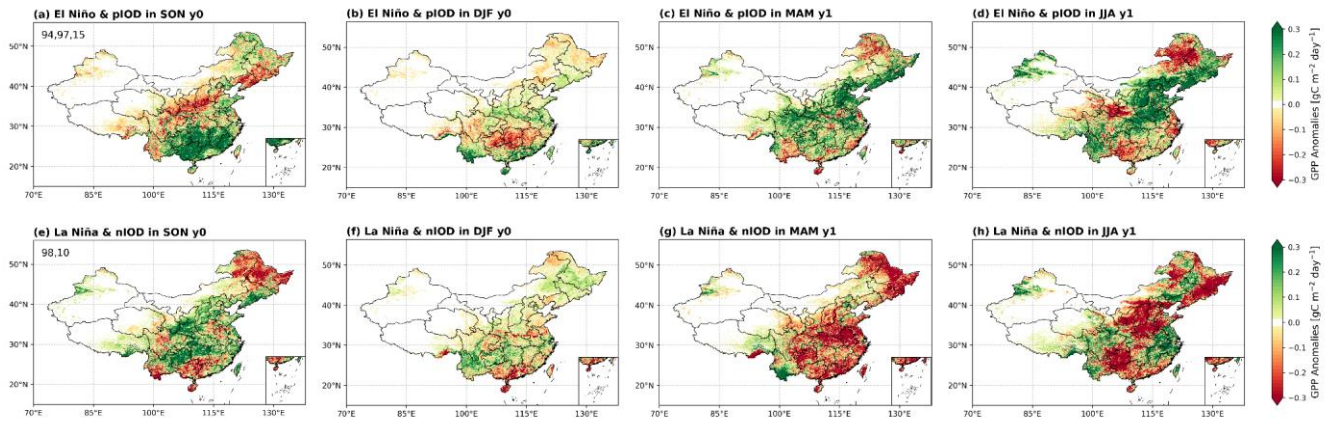

491 **4.1 Seasonal legacy effect**

492 While the legacy effects of climate on subsequent vegetation have been widely confirmed
493 (Bastos et al., 2020; Bastos et al., 2021), they were not fully accounted for in this study. During
494 ENSO and IOD events, temperature and soil moisture vary with seasons, resulting in diverse
495 conditions such as high temperature and drought, high temperature and wet, low temperature
496 and drought, and low temperature and wet across different regions and seasons. Vegetation
497 does not immediately respond to changes in climatic conditions change due to its
498 environmental resistance and self-regulation. These legacy effects are complex and vary by
499 region as ENSO or IOD events progress through different seasons.

500

501 Spring serves as a transitional period between the peak of the climatic event and the peak of
502 the growing season, making it challenging to fully explain the spatial patterns of GPP anomalies
503 in parts of northern China based on temperature and soil moisture. Higher temperatures during
504 DJF in El Niño events (Fig. 2f) can advance the growing season, subsequently impacting
505 vegetation in the following spring. Sanders-DeMott et al. (2020) have proved that a warm
506 winter can enhance the photosynthetic capacity of vegetation in the subsequent spring.
507 Additionally, Yan et al. (2023) quantified the influence of the preceding and contemporaneous
508 climatic conditions on NEP during the 1997/98 El Niño and pIOD compound event, showing
509 that legacy effects can counteract or even reverse the effects of contemporaneous climatic
510 conditions.

511 **4.2 The effect of compound ENSO and IOD events on China's GPP**

512
513 Fig. 8. Spatial distributions of seasonal composite GPP anomalies for compound events, (a-d) for El
514 Niño & pIOD events, and (e-h) for La Niña & nIOD events. The two-digit year in first column denote
515 the years used for composite analysis.

516
517 Indeed, despite IOD events being generally considered an independent coupled ocean-
518 atmosphere interaction (Saji et al., 1999), historical IOD events can occur in conjunction with
519 ENSO (Ham et al., 2017; Yang et al., 2015). These combined phenomena are most notable
520 represented by El Niño & pIOD and La Niña & nIOD events. Williams and Hanan (2011)
521 researched the interactive effects of ENSO and IOD on African GPP, relying on an offline
522 terrestrial biosphere model simulation. Their findings suggested that IOD could cause obvious
523 anomalous GPP over much of Africa, capable of suppressing or even reversing ENSO signals
524 in GPP anomalies. In addition, Yan et al. (2023) explored the interactive effects of ENSO and
525 IOD on seasonal anomalies of tropical net land carbon flux using the TRENDYv9 multi-model
526 simulations, revealing diverse effects in different sub-continent and seasons. We explore the
527 anomalies of GPP in compound events based on composite analysis (Fig. 8), and the spatial
528 patterns of soil moisture and temperature anomalies are shown in the appendix (Figs. S9 and
529 S10).

530
531 The spatial patterns of the GPP anomalies during concurrent ENSO and IOD events differ from

532 those in single events, although some similarities are evident. GPP anomalies in El Niño &
533 pIOD and La Niña & nIOD events are generally opposite, and we focus specifically on El Niño
534 & pIOD events here. In El Niño & pIOD events, GPP anomalies exhibit a general opposition,
535 with enhanced vegetation photosynthesis in the southern regions and inhibited in the northern
536 regions during SON. This spatial characteristic of GPP anomalies bears some resemblance to
537 that induced by El Niño alone (Figs. 4a and 8a). Weak GPP anomalies are generally observed
538 in DJF, with noticeable negative GPP anomalies in Guizhou and Hunan, and some positive
539 GPP anomalies in regions south of 25°N (Fig. 8b). Notably during DJF, while significant
540 positive GPP anomalies occur in El Niño events (Fig. 4b), simultaneous pIOD events induce
541 significant negative GPP anomalies (Fig. 5b). When both events coincide, their impacts seem
542 to largely counterbalance each other, resulting in a more neutral GPP anomaly. In MAM, GPP
543 increases in Northern China (Fig. 8c). Subsequently, in JJA, vegetation photosynthesis
544 experiences a significant increase in the Northern and Yunnan provinces (Fig. 8d).

545 It is worth noting that the impacts of compound events on China's GPP may not follow a
546 straightforward linear superposition of the effects of two individual events. While their effects
547 are nearly opposite when occurring separately, the positive and negative effects on GPP may
548 be not simply cancelled each other out when they coincide. This complexity arises from the
549 simultaneous occurrence of two tropical air-sea interaction modes, leading to intricate effects
550 on mid-latitude circulations. Given the limited number of compound events, further exploration
551 is necessary to unravel the effects of ENSO and IOD on GPP in China.

552

553 **4.3 Modulation of large-scale circulations on China's GPP**

554 China's GPP is intricately influenced by atmospheric circulations and sea surface temperature
555 (Li et al., 2021; Ying et al., 2022). Ying et al. (2022) showed significant correlations between
556 seasonal GPP variation in China and climate phenomena such as ENSO, Pacific Decadal
557 Oscillation (PDO), and Arctic Oscillation (AO), based on the Residual Principal Component
558 analysis. Their research indicated that these identified SST and circulation factors could

559 account for 13%, 23% and 19% of the seasonal GPP variations in spring, summer and autumn,
560 respectively. And Li et al. (2021) proved that GPP response to El Niño varied with PDO phases
561 during the growing seasons of typical El Niño years. Although both studies emphasized the
562 impact of ENSO on China's GPP and explored the roles of PDO and AO, the IOD was notably
563 absent from their analyses. Contrastingly, our study sheds light on the significant influence of
564 the extreme positive phase of IOD in 2019, showing a substantial negative GPP anomaly in
565 southeastern China during SON, aligning with findings by Wang et al. (2021b). Moreover, the
566 integration of partial correlation and composite analysis in our study elucidates the
567 considerable impact of IOD on China's GPP within this context. Importantly, our research
568 underscores the temporal and spatial variability in the effects of IOD and ENSO on GPP across
569 different seasons and regions. This complexity in ocean–atmosphere teleconnections implies
570 that other climate oscillations, such as Polar/Eurasia (polarEA) and Atlantic Multidecadal
571 Oscillation (AMO), might also contribute to influencing China's GPP (Zhu et al., 2017), which
572 is still worthy of further analysis and research.

573

574 **4.4 Uncertainties in BEPS Simulations**

575 The simulation of China's GPP by BEPS is subject to several sources of uncertainty inherent
576 in the model's structure, parameterizations, processes, and input data (Chen et al., 2012; Chen
577 et al., 2017; He et al., 2021a; Liu et al., 2018; Wang et al., 2021a). Leaf Area Index (LAI), a
578 crucial input for the BEPS model, is derived from global remote sensing data that inherently
579 possess uncertainties in spatial distribution and trend changes. Previous studies have
580 highlighted significant uncertainties in simulating carbon budget of global terrestrial
581 ecosystems when employing different LAI remote sensing data (Chen et al., 2019; Liu et al.,
582 2018). Foliage clumping index which is used to separate sunlit and shaded LAI can also cause
583 some uncertainties in simulating GPP, because the current version of BEPS used the time-
584 invariant satellite-derived clumping index (Chen et al., 2012). Biases in meteorological drivers,
585 such as precipitation, can further result in considerable uncertainties in simulating terrestrial

586 carbon cycle. The choice of precipitation products, for instance, has been shown to yield
587 considerable differences in simulated net land-atmosphere carbon flux (Wang et al., 2021c).
588 Moreover, BEPS model, like other terrestrial biosphere models, lacks consideration for
589 vegetation adaptability to rising CO₂ concentration, potentially leading to an overestimation of
590 the fertilization effect on GPP. In addition, the accuracy of simulations over agricultural areas
591 is compromised in BEPS, as it only considers crops with a C₃ photosynthetic pathway and
592 overlooks C₄ crops (He et al., 2017; He et al., 2021b; Ju et al., 2006). Although BEPS simulated
593 GPP demonstrates relatively high consistency with the measured GPP of Yingke Station (CRO),
594 located in the northwest of China, its accuracy lacks validation over the extensive farmlands in
595 north and northeastern China where various crops are grown (Fig. S11). Agricultural operations,
596 particularly irrigation, which can significantly impact GPP, are not considered in BEPS. He et
597 al. (2021a) revealed extensive wetting signals over croplands in arid and semi-arid areas which
598 exerted strong impacts on GPP and evapotranspiration simulations in BEPS after assimilating
599 the Soil Moisture Active Passive (SMAP) soil moisture product. Furthermore, photosynthetic
600 key parameters, such as carboxylation capacity at 25°C ($V_{\text{cmax},25}$), can largely determine the
601 performance in simulating GPP. After assimilating the solar-induced chlorophyll fluorescence
602 (SIF) from the Orbiting Carbon Observing Satellite-2 (OCO-2) to optimize $V_{\text{cmax},25}$ of different
603 plant functional types (PFTs) in BEPS, previous studies suggested the improvements in
604 simulating GPP at regional and global scales to some extent (He et al., 2019; Wang et al.,
605 2021a).

606

607 **5. Conclusion**

608 In this paper, we used partial correlation coefficients and composite analysis to investigate the
609 impacts of ENSO and IOD events on China's GPP during 1981–2021. The partial correlation
610 results reveal that the effects of ENSO and IOD on GPP and related climate in China exhibit
611 distinct seasonal variations and are basically opposite. Specifically, during SON, significant
612 negative *pcor* between GPP and ENSO is observed over the Tibetan Plateau, southwestern

613 China, Loess Plateau, and Liaoning. In DJF, strongly positive *pcor* occurs over southern China,
614 weakening in the subsequent MAM, albeit with some enhancements in northern Hebei and
615 neighboring Inner Mongolia. The *pcor* then turns generally negative in JJA. In contrast,
616 significant positive *pcor* between GPP and IOD is noted in southwestern and Northeast China
617 during SON. Subsequently, widespread negative *pcor* appears during DJF, persisting
618 significantly in most western and northern regions during MAM. In JJA, the *pcor* becomes
619 significantly positive in southwestern, north and northeast China. Moreover, the correlation
620 coefficients between GPP and climate show that GPP anomalies are primarily dominated by
621 SM during ENSO events except MAM, while temperature generally plays a more important
622 role during IOD events except SON.

623

624 The composite analysis results validate the patterns of GPP anomalies observed in the partial
625 correlation. Generally, China's annual total GPP demonstrates modest positive anomalies in La
626 Niña and nIOD years, contrasting with minor negative anomalies in El Niño and pIOD years.
627 This results from the counterbalancing effects, with significantly greater GPP anomalous
628 magnitudes in DJF and JJA. Regionally, GPP anomalies fluctuate more in the Southern and
629 Northern regions. The GPP anomaly in the Southern region dominates the national GPP
630 variation, with the contribution of 68% to ENSO events and 46% to IOD events, respectively.
631 On the provincial scale, western and northern provinces in experience larger relative annual
632 variations during ENSO events, with magnitudes exceeding 10%, exhibiting a general east-
633 west pattern. Conversely, provinces in the southern and Northern China witness larger relative
634 changes during IOD events, showing an opposing north-south pattern. For instance, the 2019
635 extreme pIOD led to relative changes of over 25% in certain provinces in the south and north.
636

637 **Author contributions**

638 Jun Wang designed the experiments. Ran Yan processed the data, carried out the analysis and wrote the
639 original manuscript. All the authors contributed to the writing of the paper.

640 **Acknowledgement**
