9

10 **Abstract**

11 Globally, emissions from aviation affect Earth's climate via complex processes. Contrail cirrus and
12 carbon dioxide emissions are the largest factors contributing to aviation's radiative forcing on
13 climate. Contrail cirrus, like natural cirrus clouds, impacts Earth's climate. While contrail cirrus
14 enhances the influence of natural clouds on climate, uncertainties persist regarding their
15 characteristics and life cycle. Despite extensive research on contrails, significant uncertainties
16 remain. Contrail cirrus encompasses linear contrails and the associated cirrus clouds; these are
17 characterized by ice particle properties, e.g., size, concentration, mixing, extinction, ice water
18 content, optical depth, geometrical depth, and cloud coverage. The climate impact of contrails may
19 intensify due to projected increases in air traffic. The radiative forcing from global contrail cirrus
20 has the potential to triple and could reach as much as 160 mW m^{-2} by 2050. This projection is
21 based on anticipated growth in air traffic and a potential shift to higher altitudes. The future climate
22 impact of contrail cirrus is influenced by factors like the magnitude and geographical spread in air
23 traffic, advancements in fuel efficiency, the effects of the use of alternative fuels, and the effects
24 of the changing climate on the background atmosphere. This study reviews the microphysical
25 processes affecting contrail formation and the aging of contrails and contrail-cirrus. Furthermore,
26 the study explores global observational datasets for contrails, current analyses, and future
27 projections and will aid in evaluating the effectiveness and trade-offs associated with various
28 mitigation strategies. The research highlights gaps in knowledge and uncertainties while outlining
29 research priorities for the future.

42 **1 Introduction**

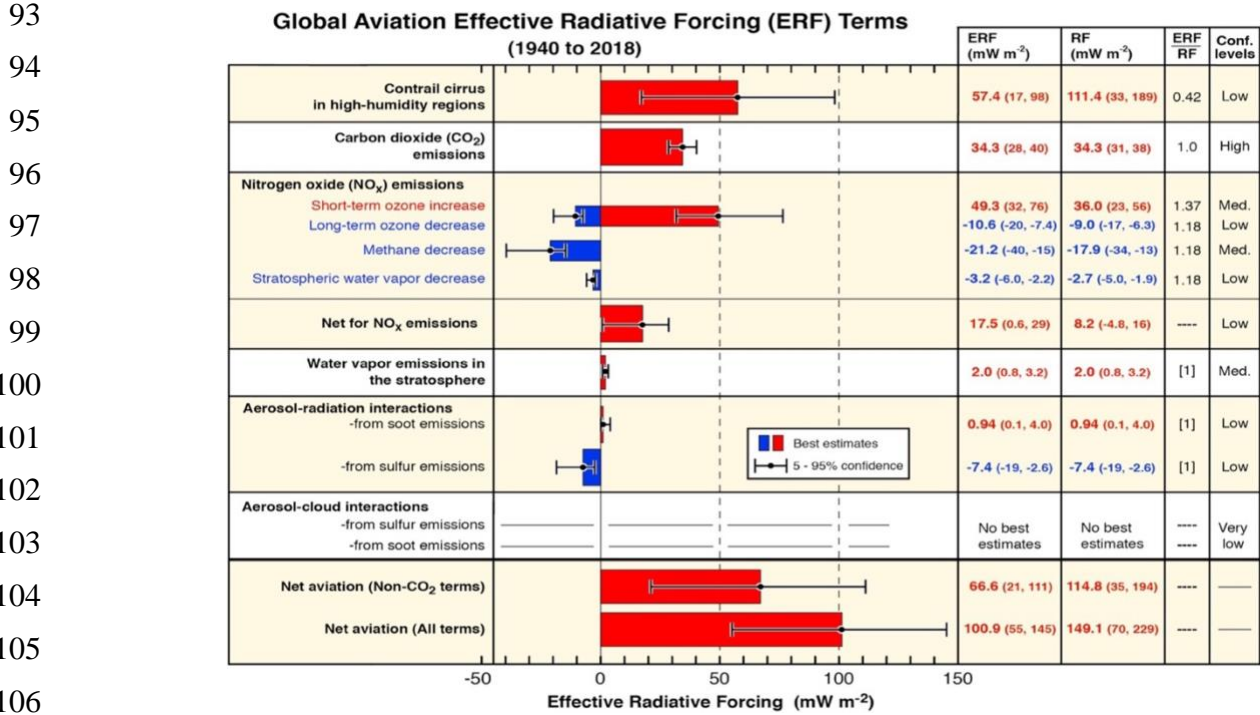

43 The increase in the atmospheric carbon dioxide (CO₂) concentration has had the most substantial
44 impact on human-induced climate change over recent decades (IPCC, 2021). Emissions from
45 aviation are a minor but significant contributor to these changes in climate, especially because of
46 emissions of CO₂ and the effects of contrail formation from emitted water vapor (H₂O). Aviation
47 expansion is outpacing economic growth, with projections indicating that over the next two
48 decades, the demand for aviation could grow to about 3 times its present level (Wuebbles et al.,
49 2007), with the International Civil Aviation Organization having previously projected a 4.3%
50 annual growth to 2050 (ICAO 2012). Recent analyses by Boeing and Airbus suggest slightly lower
51 rates of increase of 3.6-3.8% (Boeing, 2022; Airbus, 2023). These analyses suggest that aviation
52 could become an even more important contributor to climate change in the future. Taking both
53 CO₂ and non-CO₂ effects into account, The global aviation industry comprises about 3.5-4% of
54 the current human-made (anthropogenic) activities forcing on climate (Lee et al., 2020; Klöwer et
55 al., 2021; Grewe et al., 2021).

56 Aviation-induced cirrus is one of the most significant radiative forcing contributors from the
57 aviation sector. (IPCC, 1999; Lee et al., 2009, 2021; Brasseur et al., 2016). However, considerable
58 ambiguities persist, stemming from various origins, such as our incomplete understanding of cirrus
59 cloud characteristics, their geographical distribution, and their life span. (Kärcher 2018; Burkhardt
60 et al., 2018; Schumann and Heymsfield 2017). With current aircraft largely burning fossil fuel,
61 CO₂ emissions are the other major forcing. Additionally, NO_x (oxides of nitrogen) emission also
62 has a notable impact through the production of tropospheric ozone, but this is partially
63 counteracted by chemical feedback effects on concentrations of atmospheric methane (CH₄). Fig.
64 1 (Lee et al., 2021) provides the most current assessment of the climate-forcing effects resulting
65 from different aviation emissions on a global scale, spanning from 1940 to 2018; these effects are
66 shown in terms of radiative forcing (RF) and effective radiative forcing (ERF). Radiative forcing
67 in the context of contrails is due to the net radiative energy flux at the top of the atmosphere (TOA)
68 caused by the presence of contrails in the atmosphere (Fuglestedt et al., 2010). A positive
69 radiative forcing (RF) signifies an increase in atmospheric warming, as depicted by the red bars in
70 Figure 1. ERF, on the other hand, adjusts the RF by accounting for rapid responses occurring
71 within the Earth's climate system. While RF and ERF provide valuable insights, it's important to
72 acknowledge that these are global metrics. Contrails primarily affect the upper troposphere and
73 are short-lived, leading to potentially larger regional effects, particularly in densely populated
74 areas with high air traffic.

75 In the scientific literature, contrail cirrus is defined as encompassing both linear contrails and the
76 resulting formation of cirrus clouds. Figure 2 provides an overview of aviation exhaust plume
77 emissions and factors influencing contrail formation. The characteristics of contrail cirrus include
78 average ice particle sizes and concentrations, extinction, ice water content, optical depth,
79 geometrical depth, and contrail coverage. Integral contrail properties involve parameters such as
80 contrail cirrus volume, total number of ice particles, overall ice water content, and total extinction
81 (area integral of extinction) per contrail length.

82 Many global climate chemistry models used to study the physics and chemistry affecting the
83 Earth's climate system typically do not incorporate the impacts. Models that do account for
84 contrails estimate contrail cirrus coverage based on simplified treatments of contrail aging and
85 spreading mechanisms in ice-supersaturated regions (ISSRs) (Burkhardt et al., 2010; Burkhardt
86 and Kärcher, 2011; Bock and Burkhardt, 2016; Bier and Burkhardt, 2022; Chen and Gettelman

87 2013; Bickel et al., 2020; Schumann et al., 2015). The generation of persistent contrails depends
 88 on coming across ice-supersaturated conditions along a flight path, and these conditions show
 89 variability in both space and time within the troposphere and tropopause region (Irvine et al.,
 90 2013; Lamquin et al., 2012; Bier et al., 2017). Estimating the RF from contrail cirrus requires
 91 knowledge of complex microphysical processes, radiative transfer, and the interaction of contrails
 92 with background cloudiness (Burkhardt et al., 2010).

107 **Figure 1.** Current best evaluation of the climate forcing between 1940 and 2018 from commercial
 108 aviation for different types of emissions. ERF accounts for short-term feedback in the climate
 109 system not accounted for in the traditional RF evaluation. Adapted with permission from Lee et
 110 al. (2021).

114 **Figure 2.** Schematic overview of exhaust plumes (contrail formation in low temperature) and their
 115 composition. Adapted with permission from Lee et al. (2021).

116 This review article aims to provide a comprehensive overview of our understanding of contrails,
117 encompassing their formation, progression, and the consequent repercussions on Earth's climate
118 system. In the process, the microphysical processes underlying contrail formation are explored
119 along with their representation in the simulation of contrails in current climate-chemistry models
120 of the global atmosphere. Furthermore, we address the uncertainties surrounding this topic and
121 identify areas requiring further research in the future.

122 **2 Microphysics of Contrail Formation, Aging, And Transition to Contrail Cirrus**

123 Microphysical processes play a pivotal role in the formation of contrails and their evolution in the
124 atmosphere. This section is aimed at discussing these processes, their effects on the lifetime of
125 contrails, and the possible transition of contrails to contrail cirrus in the upper troposphere.

126 **2.1 The Physics of Contrail Formation and Aging**

127 The fundamental principles for determining the formation of contrails were independently
128 developed by E. Schmidt in 1941 and H. Appleman in 1953. Contrails appear when the hot and
129 moist exhaust from aircraft quickly mixes with the cold and humid surrounding air, causing the
130 humidity in the exhaust gases to exceed the saturation point for liquid water (Appleman, 1953;
131 Schmidt, 1941; Schumann, 1996). A schematic representation of the Schmidt-Appleman criterion
132 for contrail formation is shown in Figure 3. In this diagram, the two solid curves depict saturation
133 levels concerning liquid water (upper curve) and ice (lower curve). The phase trajectory of the
134 mixture, consisting of exhaust gases and ambient air, follows a straight line from the upper right
135 to the lower left in the e-T diagram, where 'e' represents the partial pressure of water vapor in the
136 mixture, and 'T' represents its absolute temperature (as denoted by the dashed lines). The path that
137 lines up with the water saturation curve (dotted) specifies the highest temperatures at which
138 contrail formation can take place. When the trajectory terminates in an ice-supersaturated state,
139 the persisting contrails have the potential to disperse and transform into contrail cirrus.

140 In cases where the conditions do not meet the criteria, the contrail formed will have a brief lifespan,
141 lasting only a few minutes. The mixing process is presumed to occur isobarically, resulting in a
142 straight-line mixing (phase) trajectory on an e-T diagram. The Schmidt-Appleman criterion
143 (SAC), which is primarily based on thermodynamics, establishes the threshold temperature for
144 contrail formation. This threshold is determined by several factors, such as ambient air pressure,
145 humidity, the amount of water and heat released by the aircraft per unit of fuel, and the overall
146 efficiency of the aircraft engine's propulsion system. (Jensen et al., 1998; Schumann, 1996).
147 Accurate assessments of contrails necessitate precise data on ambient meteorological conditions.
148 The persistence of contrails is contingent on meeting a specific humidity threshold, as defined
149 below.

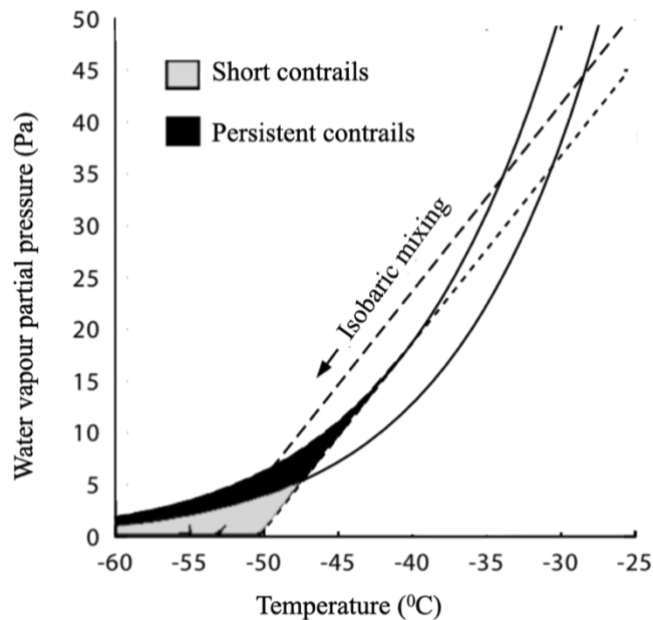

150 The persistence of contrails hinges on the atmospheric-specific humidity. Temperature and vertical
151 motions within the atmosphere play key roles in determining this humidity. Additionally, the
152 optical characteristics and lifespan of contrails are key aspects of contrail formation and are
153 influenced by various meteorological factors. These factors include turbulence, vertical motions,
154 wind shear, and the presence of ambient cirrus clouds. Furthermore, soot emissions from aircraft
155 engines can also influence these meteorological factors. The size and duration of the ice-
156 supersaturated region, the availability of water vapor for ice crystal growth, and consequently, the
157 sedimentation of these ice crystals within the contrail are also essential considerations (Bock and
158 Burkhardt, 2016). Crucially, the radiative forcing (RF) and the ensuing climate impacts depend on
159 a multitude of meteorological parameters. Additionally, factors such as the albedo and the

160 brightness temperature of the atmosphere in the absence of contrails play a significant role, as
161 outlined by Schumann et al. (2012).

162 Upon reaching the ambient temperature through the process of mixing with the surrounding air,
163 contrails undergo changes in size depending on the ambient humidity. When the ambient relative
164 humidity remains supersaturated concerning ice ($RH_{ice} > 100\%$), contrails experience growth in
165 ice water content and can remain detectable for up to 5 hours or even longer, as highlighted in
166 various studies (Gierens and Vázquez-Navarro, 2018; Schumann and Heymsfield, 2017; Bier et
167 al., 2017). This extended persistence contrasts with the mean lifetime of contrails, typically noted
168 to be around 2-3 hours (Schumann et al., 2015; Vázquez-Navarro et al., 2015; Tesche et al.,
169 2016; Sausen et al., 1998). Contrails, under such conditions, have the potential to disperse and
170 transform into thin cirrus layers. On the other hand, when the ambient relative humidity is not
171 supersaturated concerning ice, contrail ice particles sublime and dissipate. The timescale of this
172 sublimation and dissipation process is contingent on the sizes of the contrail ice particles and the
173 ambient air RH_{ice} (Schumann, 2012).

174 Combinations of satellite information and ground-based lidar measurements, such as in the Atlas
175 et al. (2006) case study, showed a lifetime of more than 2 hours and a mean optical thickness
176 (integrated extinction coefficient over a vertical column of unit cross section) of 0.35. Duda et al.
177 (2004) studied the development of contrail clusters over the Great Lakes and derived optical
178 thickness (optical depth, τ) from 0.1 to 0.6 for contrails that lasted several hours (Kärcher et al.,
179 2009). Graf et al. (2012) studied the cirrus cover cycle and observed timescales between 2.3 to
180 4.1 hours for contrail cirrus and 1.4 to 2.4 hours for linear contrails.

181

191

192 **Figure 3.** Phase diagram with mixing lines for aircraft exhaust Adapted from Gierens et al. (2008)
193 (Licensed under CC BY 4.0).

194 The critical factor influencing this contrasting behavior lies in the concept of ice supersaturation.
195 Ice supersaturation refers to conditions where the ambient humidity exceeds the saturation point

196 for ice, even at temperatures below freezing. These conditions are essential for the persistence and
197 growth of contrails. While the initial formation process might occur at varying humidity levels,
198 studies like Ovarlez et al. (2002) highlight the presence of ice supersaturation within cirrus clouds,
199 which can significantly impact contrail persistence. Jensen et al. (2001) revealed a surprisingly
200 high frequency of ice supersaturation in the upper troposphere, even in the absence of visible ice
201 clouds. This finding highlights the importance of considering ice supersaturation for accurate
202 assessments of contrail persistence and its potential transformation into cirrus clouds.

203 Upon reaching the ambient temperature through the process of mixing with the surrounding air,
204 contrails undergo changes in size depending on the ambient humidity. When the ambient relative
205 humidity remains supersaturated concerning ice ($RH_{ice} > 100\%$), contrails experience growth in
206 ice water content and can remain detectable for up to 5 hours or even longer. The microphysical
207 properties of contrails, including ice crystal size distribution and habit, significantly influence their
208 radiative effects and persistence. These properties are determined by the initial conditions during
209 contrail formation and subsequent processes. Ice crystal shapes in contrails are primarily randomly
210 oriented, small ice crystals, with a possibility of some horizontally oriented plates existing as well.
211 This finding is supported by Iwabuchi et al. (2012) who analyzed contrails using a combination of
212 MODIS and CALIPSO satellite data. Their study showed that contrails have larger backscattering
213 coefficients than neighboring cirrus clouds, indicative of smaller ice crystals. The analysis also
214 suggested a tendency for stronger depolarization when ice crystals are small, with a mean linear
215 depolarization ratio (LDR) of approximately 0.4-0.45 for young contrails and contrail cores
216 (Iwabuchi et al., 2012).

217 There has been ongoing uncertainty regarding whether persistent contrails exclusively form in
218 cloud-free supersaturated areas or if they can also develop within existing cirrus clouds (Burkhardt
219 et al. 2008). Subsequent modeling work (Tesche et al. 2016) suggested that persistent contrails
220 indeed have the potential to form within cirrus clouds. While the formation of contrails is
221 commonly observed in clear skies, they also emerge in conditions where the sky is covered with
222 thin or even subvisible cirrus clouds (Immler et al. 2008).

223 The temperature threshold for contrail formation, known as the SAC threshold, is slightly higher
224 in cirrus clouds compared to clear air (Gierens, 2012). This difference is attributed to the additional
225 humidity introduced by the ice water content (IWC) from cirrus clouds (Verma and Burkhardt
226 2022). In situ measurements have indicated high ice supersaturation both inside and outside cirrus
227 clouds (Comstock et al. 2004). Moreover, observational evidence suggests that contrails embedded
228 within cirrus clouds are not significantly thinner than contrails forming in clear air (Poellot et al.
229 1999).

230 A reliable estimation of the radiative effects stemming from contrail cirrus relies heavily on their
231 optical properties, which are intricately linked to their microphysical properties and age, as well
232 as their geographical distribution. The microphysical characteristics of contrail cirrus at various
233 plume ages, as observed in diverse airborne campaigns, have been systematically compiled and
234 detailed (Schröder et al. 2000; Schumann et al. 2017; Chauvigné et al. 2018). Fresh contrails,
235 typically observed in plumes around 2 minutes old, exhibit distinct features, including an ice
236 crystal number concentration reaching thousands per cubic centimeter and ice crystals measuring
237 up to a few micrometers in diameter. This characterization is consistent with observations (Märkl
238 et al., 2024, Bräuer et al., 2021a; Petzold et al., 1997). Contrails in their initial 2-5 minutes of
239 existence have been frequently measured (Voigt et al., 2011; Gayet et al., 2012). The distinctive
240 feature of these young contrails lies in their notably high ice crystal number concentration of small

241 ice particles, making them easily discernible from natural cirrus formations. However, contrails
242 often coexist with natural cirrus and may be incorporated into thin or subvisible cirrus (Kübbeler
243 et al., 2011; Gierens, 2012; Unterstrasser et al., 2017). This coexistence poses a challenge in
244 distinguishing between aged contrails and natural cirrus, complicating efforts to clarify the
245 contribution of contrail cirrus to the radiative balance. Contrail cirrus is characterized by a low ice
246 water content (IWC) ranging from 0.1 to about 10 mg m^{-3} , a feature it shares with natural cirrus
247 of in-situ origin, as observed by Schumann et al. (2017). Ice crystals within these clouds have
248 formed and enlarged in an ice-cloud environment (Luebke et al., 2016; Krämer et al., 2020). In
249 contrast to contrail cirrus and in situ-origin cirrus, cirrus clouds initiating from liquid often yield a
250 higher IWC since their ice crystals originally form as liquid drops (Krämer et al., 2016, 2020) in a
251 warmer atmosphere with an ambient temperature exceeding 235 K (-38°C), particles undergo
252 freezing as they are lifted into the cirrus temperature region of the atmosphere.

253 Chauvigné et al. (2018) applied a method based on principal component analysis to differentiate
254 between particles in contrail cirrus at various stages and those observed in natural cirrus during
255 the CONCERT 2008 campaign (Voigt et al., 2010). The success of the campaign stemmed from
256 the fact that contrails sampled during the CONCERT initiative were relatively young and exhibited
257 greater distinctiveness compared to natural cirrus formations. Despite this success, the
258 comprehensive acquisition of all necessary optical and microphysical parameters proved
259 challenging during single aircraft campaigns, limiting the widespread application of this method.
260 The CONCERT dataset is relatively small, encompassing approximately 4.0 hours of sampling
261 time in total (Kübbeler et al., 2011). A commonly held assumption regarding the formation and
262 evolution conditions of contrail cirrus is that it tends to persist particularly in ice-supersaturated
263 regions (ISSRs) (Kärcher, 2018).

264 The collective presence of commercial, military, and other aircraft contributes to a global increase
265 in cloudiness, primarily facilitated by the formation of persistent contrails when the surrounding
266 atmosphere reaches supersaturation. Contrail cirrus exhibits both cooling and warming effects,
267 with the nighttime impact being predominantly warming. Previous assessments of aviation's
268 influence on climate (IPCC, 1999; Lee et al., 2009; Brasseur et al., 2016) were limited by the
269 challenge of accurately quantifying the role of cloudiness arising from aging and spreading
270 contrails (Minnis et al., 2013). The formation of a persistent contrail necessitates ice-
271 supersaturated conditions along the aircraft's flight path. The life cycles of contrail cirrus are
272 contingent upon the temporal and spatial scales of ice-supersaturated regions, which exhibit high
273 variability in the troposphere and tropopause region (e.g., Lamquin et al., 2012; Irvine et al., 2013;
274 Bier et al., 2017). Estimating the impact of contrail cirrus on upper tropospheric cloudiness
275 requires the simulation of complex microphysical processes, contrail spreading, overlap with
276 natural clouds, radiative transfer, and interaction with background cloudiness (Burkhardt et al.,
277 2010).

278 Petzold et al. (2020) conducted a study investigating the frequency distribution of ice-
279 supersaturated regions (ISSRs) through regular in-situ observations made by passenger aircraft
280 across northern mid-latitude areas. Their research underscores the seasonal and geographical
281 variability of ISSRs, indicating a higher likelihood of occurrence during winter and in specific
282 geographic regions. This variability underscores the significance of considering the spatial and
283 temporal distributions of ISSRs when assessing the potential for contrail formation.

284 Reutter et al. (2020) delved into the characteristics of ice-supersaturated regions using a
285 combination of in-situ water vapor measurements obtained from the IAGOS research program and

286 data from ERA-Interim reanalysis. Their findings showcase the potential for validating reanalysis
287 data with high-resolution aircraft observations. This validation process is critical for enhancing the
288 accuracy of global models utilized in evaluating contrail formation and their subsequent climatic
289 impacts.

290 The ERF of contrail cirrus was estimated for 2011 (relative to an atmosphere without contrails) as
291 50 mWm^{-2} by Boucher et al. (2013), with uncertainty ranging from 20-150 mWm^{-2} . Lee et al.
292 (2021) presented a new estimate derived from the outcomes of global climate models
293 implementing process-based contrail cirrus parameterizations. Recent analyses by Lee et al. (2021)
294 of the current aviation fleet emissions evaluate the ERF through 2018 as 57 mWm^{-2} , with an
295 uncertainty range of 17-98 mWm^{-2} . Given the limited availability of independent estimates,
296 assessing uncertainty becomes crucial. This necessitates analyzing the sensitivities of relevant
297 processes and incorporating the uncertainties associated with the underlying parameters and fields.

298 Contrails are created in the early exhaust plumes of airplanes during cruise (Kärcher et al., 2015;
299 aufm Kampe, 1943, Weickmann, 1945; Schumann and Wendling, 1990; Schumann, 1996). This
300 occurs when a large number of supercooled water droplets are activated and freeze into ice
301 particles. At cruising altitudes, the atmospheric relative humidity (RH) typically falls too low to
302 support the presence of liquid water droplets. However, it is conducive to the existence of ice-
303 phase particles (Gettelman et al., 2006; Lamquin et al., 2012). Therefore, freezing must occur
304 shortly after droplet formation within the moist exhaust plume to produce persistent contrails.
305 Appleman (1953) proposed a critical requirement for contrail formation, suggesting that a
306 significant amount of aerosol particles in the plume act as centers for water condensation (referred
307 to as the "water-saturation constraint"). The formation of contrails also has a visibility constraint,
308 which estimates a minimum number of nucleated ice particles in the contrails at around 10^4 cm^{-3}
309 within a plume age of 0.3s for a small-scale research aircraft (Appleman, 1953; Kärcher et al.,
310 1996). These are the crucial constraints for contrail formation.

311 **2.2 Transition of contrails into contrail cirrus and contrail-cirrus-soot interaction**

312 Contrail cirrus consists of elongated contrails trailing high-altitude aircraft and thin cirrus patches
313 formed by the dispersion of persistent contrails. The morphology of contrails evolves based on
314 factors such as humidity, shear, stratification, waves, turbulence, and radiative heating. Contrails,
315 individually and collectively, interact with other cirrus formations, giving rise to what is termed
316 "contrail cirrus" (Schumann and Wendling, 1990). The total extinction is less pronounced when
317 contrails overlap due to humidity competition. Consequently, the climate impact does not always
318 exhibit a linear correlation with air traffic density (Unterstrasser and Sölch, 2012; Bickel et al.,
319 2020). The transformation of a single contrail into a contrail cirrus is observable during aircraft
320 spiral flights, as depicted in Figure 4 (Haywood et al., 2009). "Contrail outbreaks" describe
321 scenarios where numerous aged and young contrails coexist, often spanning expansive areas within
322 the same airspace (Duda et al., 2001).

323 Soot emissions, composed of black carbon particles from aviation, have the potential to alter cirrus
324 properties independently of contrail processing, leading to the formation of "soot cirrus" (Lee et
325 al., 2010). Climate impact assessments of aviation-induced soot cirrus remain inconclusive due to
326 uncertainties in soot abundance and their ice-nucleating properties (Gettelman and Chen, 2013;
327 Zhou and Penner, 2014; Righi et al., 2021). Increased concentrations of small-sized cirrus particles
328 resembling aviation soot emissions have been detected in cirrus regions with dense air traffic
329 (Kristensson et al. 2000). It remains uncertain whether the soot enters the ice during the initial

330 nucleation process or at a later stage through scavenging. The exact mechanism of soot
331 incorporation into cirrus ice remains unclear. Uncertainties persist regarding whether the soot
332 enters the ice during the initial nucleation process or at a later stage through scavenging.

333 A recent study by Testa et al. (2024) examines the processing of aviation soot within contrails and
334 offered further insights into the potential influence of soot on ice nucleation. They specifically
335 investigate the ice nucleation ability of contrail-processed soot particles at cirrus temperatures and
336 found that these particles were generally poor ice nucleating agents. This suggests that soot cirrus
337 formed from processed aviation soot may have a weaker influence on cirrus cloud formation than
338 previously thought.

339 Dischl et al. (2024) demonstrate a significant reduction in non-volatile particle emissions from
340 aircraft engines using sustainable aviation fuel (SAF) compared to traditional jet fuel. This finding
341 indirectly supports the notion that some soot particles might remain dry throughout contrail
342 formation or that some ice particles might sublime, as these processes could be influenced by
343 particle properties.

344 The sublimation of cirrus particles containing soot and sulfate may lead to the formation of soot
345 aggregates that can potentially act as efficient ice nuclei. A cirrus pattern observed near Munich,
346 Germany, on November 3, 2012, displayed characteristics suggesting an association with aged
347 soot plumes. The cirrus observed between 9.1 and 9.5 km in height, 8-10 km wide, and 35-50 km
348 long, exhibited a distinctive pattern resembling parallel line clouds. Back trajectories indicated that
349 soot was emitted upstream approximately 12 hours before the event by aircraft. The air ascended,
350 forming a cirrus about 4 hours before the event, lasting for about 1-2 hours before subsiding or
351 sublimating. Analyses propose that this could be cirrus formed on preactivated aircraft soot, but
352 certainty is limited, and it cannot be ruled out that the same pattern might have formed without air
353 traffic. (Schumann and Heymsfield, 2017).

354

Figure 4. Evolution of contrail cirrus over 1, 3, and 6.5 hours. Contrail cirrus is identified by bright white areas with low infrared (10.8 mm) brightness temperature. The satellite scenes are from NOAA AVHRR for 3 UTC times: (left) 1006 (age after emission = 1 hour), (middle) at 1202 (elapsed time: 3 hours), and (on the right) 1526 (elapsed time: 6.5 hours). Adapted with permission from Haywood et al. (2009).

355

356 A comprehensive understanding of the interplay between contrails, cirrus clouds, and aircraft
357 emissions is essential for accurate assessments of their combined effect on Earth's climate. Recent
358 investigations have illuminated this complex relationship, providing valuable scientific insights.
359 Notably, Urbanek et al. (2018) documented ice clouds exhibiting atypical characteristics over
360 Europe, suggesting potential deviations from standard ice crystal behavior. Additionally, these
361 clouds displayed lower ice supersaturation, hinting at a possible modification in the usual ice
362 formation processes (Urbanek et al., 2018). Intriguingly, the spatial distribution of these cloud
363 formations appeared to correlate with regions experiencing high air traffic. While a definitive
364 causal link between these observations and contrail cirrus formation remains elusive, they do
365 suggest a potential indirect influence stemming from aircraft emissions (Urbanek et al., 2018).

366 In contrast, Kärcher and colleagues (2021) examine the impact of soot particles emitted by aircraft.
367 Kärcher et al. (2021) use modeling to study how these soot particles influence the birth of new
368 cirrus clouds. they found that only a tiny fraction of the soot particles played a role in cloud ice
369 formation via the freezing of liquid aerosol droplets. Consequently, cirrus clouds affected by soot
370 displayed negligible deviations in overall cloud ice content and optical depth compared to their
371 naturally formed counterparts (Kärcher et al., 2021). These findings question the accuracy of
372 current climate models, suggesting they might be overestimating the global radiative impact of
373 interactions between aircraft soot and expansive cirrus clouds.

374 In a related study, Wolf et al. (2023) delve into the radiative effect (RE) of cirrus clouds, shedding
375 light on the pivotal role played by ice crystal properties. Their investigations unveiled that ice
376 crystal size and concentration are the linchpins dictating the overall RE of cirrus clouds.
377 Intriguingly, smaller ice crystals, often associated with contrails, wield a dual-edged radiative
378 effect, inducing both cooling and warming influences. This intricate interplay generally tips the
379 scale towards an overall warming effect exerted by cirrus clouds (Wolf et al., 2023).

380 Beyond the realm of ice crystal properties, Wolf et al. (2023) underscores the importance of other
381 variables. Surface albedo emerges as a contributing factor, with cirrus clouds potentially inducing
382 cooling effects over highly reflective surfaces, like ice, while warming effects over less reflective
383 ones. Additionally, the presence of underlying liquid water clouds and the solar zenith angle also
384 influence the radiative effect. Though their focus primarily centered on plane-parallel clouds, Wolf
385 et al. (2023) acknowledge the potential significance of three-dimensional scattering effects,
386 particularly under high sun angles.

387 **2.3 Evolution of contrails and stages of aviation-induced cloud evolution**

388 The review by Paoli and Shariff (2016) examined the primary physical processes and simulation
389 efforts involved in four distinct phases of contrail evolution. These phases are commonly
390 categorized as the jet, vortex, vortex dissipation, and diffusion phases. Contrail evolution is
391 conveniently divided into these four regimes for clarity (Gerz et al., 1998) (see Fig.5).

392 In the initial seconds after emission (the jet regime), the vortex sheet shed by the wings rolls up
393 into a pair of counter-rotating vortices known as the primary wake. Simultaneously, newly formed
394 ice crystals in the engine exhaust become entrapped around the cores of these vortices. Following
395 this, in the minutes that follow (the vortex regime), the vortices descend into the atmosphere due
396 to their mutually induced downward velocity.

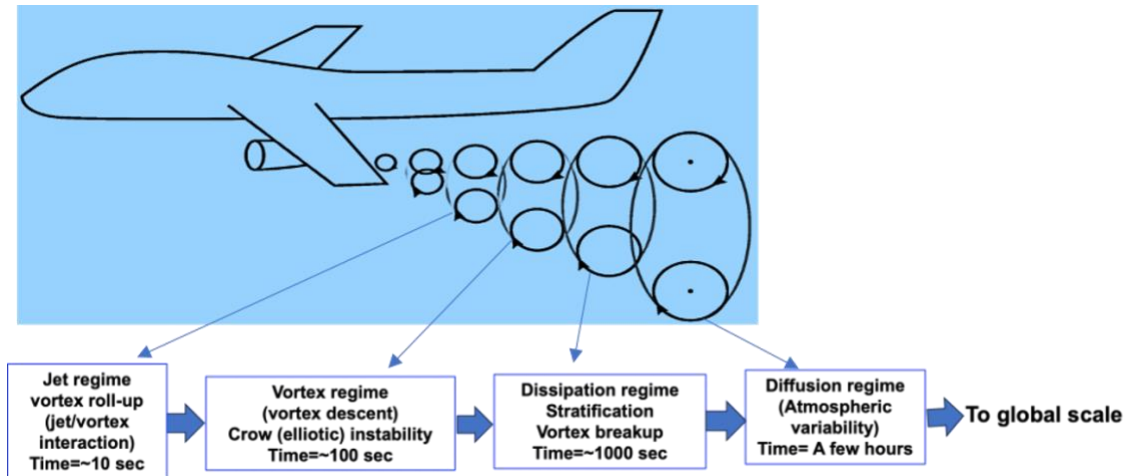

Figure 5. Schematic classification of aircraft wakes evolution into four regimes. Adapted from Paoli and Shariff (2016).

397 The descent of vortices effects in a contrast in density between the air contained within the vortices
 398 (within an oval-shaped region) and the ambient air. This process leads to the generation of vortices
 399 with opposite signs (in a stable stratified atmosphere) along the oval boundary. The vorticity shed
 400 in the upward direction gives birth to a "secondary wake." Within this secondary wake, a portion
 401 of the exhaust gases and ice particles becomes incorporated. Within the regime of vortex
 402 dissipation, the primary vortex pair and secondary vorticity disintegrate and disperse, releasing
 403 both exhaust and ice crystals that eventually endure sublimation. Ice crystals released in the
 404 secondary wake can endure for a longer duration due to the lower temperature. In the fourth
 405 regime, known as the diffusion regime, the horizontal and vertical spreading of the contrail is
 406 influenced by atmospheric turbulence, particle sedimentation, radiative processes, and wind shear
 407 until complete mixing takes place, typically within a few hours.

408 Figure 6 illustrates the processes that influence the various stages of contrail formation. Exhaust
 409 plumes, generated by burning fuel-air mixtures at high temperatures and pressure within turbofan
 410 jet engines, contain both gaseous and particulate matter. In the freely expanding and cooling
 411 plumes (jet regime), particle types include emitted soot particles and aqueous aerosol particles
 412 formed within the exhaust, along with entrained ambient aerosol particles. In scenarios where
 413 turbulent mixing occurs, leading to cooling and generating plume supersaturation over liquid
 414 water, a significant number of plume particles transform water droplets (depicted as gray circles
 415 in Fig. 6).

416 Water droplets rapidly freeze and increase in size by absorbing water vapor from their
 417 surroundings, eventually leading to the formation of a visible contrail. This occurs when the
 418 ambient temperature drops below the formation threshold. In exhaust rich in soot, most droplets
 419 contain soot inclusions. While droxtals, frozen water droplets with faceted surfaces, and hexagonal
 420 prisms and columns likely emerging from them may offer a realistic depiction of small ice crystals
 421 in fresh contrails, there is currently no direct observational evidence for their specific shapes.

422 Plumes from multiple aircraft engines combine with the two wingtip vortices, creating an
 423 inhomogeneous wake. The subsequent evolution of ice crystals is contingent upon fluid-dynamical
 424 processes, particularly in the vortex regime. The downward movement of the vortex pair warms

425 the surrounding air, resulting in the sublimation of ice crystals in the lower portion of the wake. A
 426 small fraction of contrail is amplified by the detrainment of air from the lower wake. Ice crystals
 427 present in the upper wake continue to grow by the uptake of entrained ice-supersaturated ambient
 428 water vapor. A few minutes past emission, the organized flow pattern collapses and mixes with
 429 ambient air (dissipation regime). Tables 1 and 2 summarize the qualitative and quantitative
 430 comparisons of contrail characteristics across different stages of evolution, including measurement
 431 techniques and modeling considerations.
 432

Figure 6. Processes influencing the contrail formation stage. Figure adopted with permission from Kärcher (2018). (Licensed under CC BY 4.0)

433 **Table 1.** Overview of qualitative comparison of contrail characteristics across different stages
 434 of evolution

Stage	Ice crystal size	Number density	Extinction properties	Width	Length	Optical depth
Jet	Large and concentrated	High	High	Wide	Long	High
Vortex	Smaller and more dispersed than jet	Moderate	Moderate	Variable	Variable	Moderate
Dissipation	Small and faint	Low	Low	Narrow	Short	Low
Diffusion	Very small and spread out	Very low	Very low	NA	NA	Extremely low

435
 436 **2.4 Contrail coverage**
 437 The radiative forcing (RF) for contrails, as determined by Lee et al. (2010), is defined by the
 438 product of contrail coverage and optical depth. For a single contrail segment, this product equates
 439 to total extinction. However, defining contrail coverage presents challenges for several reasons.
 440 Assessing contrail coverage separately from optical depth introduces difficulties. The
 441 identification of young contrails versus other cirrus clouds often relies on their distinctive line

442 shape. Yet, using geometric characteristics for contrail coverage classification introduces
 443 uncertainty, particularly when contrails undergo deformation or shape changes (Mannstein et al.,
 444 1999). Only a small fraction of all linear contrails is detectable from satellites (Kärcher et al., 2009;
 445 Mannstein et al., 2010; Minnis et al., 2013).

446 Earlier studies examined global contrail coverage using regional satellite observations, estimating
 447 potential contrail coverage based on specific temperature and humidity data and traffic density
 448 (Sausen et al., 1998). The integration of observations to achieve hemispheric coverage has only
 449 recently become available (Duda et al., 2013). The coverage by contrail cirrus may be significantly
 450 higher than determined by line-shaped contrails, and uncertainty factors around an order of 10
 451 have been reported (Burkhardt and Kärcher, 2011). However, this ratio is highly uncertain due to
 452 detection issues. Burkhardt and Kärcher (2011) conducted a quantification of contrail cirrus using
 453 the ECHAM contrail cirrus global climate model (CCmod), which incorporates a subgrid-scale
 454 cloud class representing young contrails. This model captures the life cycle of artificial clouds and
 455 simulates their global coverage, along with the changes in natural cloudiness they induce. Their
 456 calculations revealed contrail cirrus coverage to be approximately 0.23%. Similar results were
 457 obtained from recent attempts to quantify contrail cirrus using MODIS data, accounting for more
 458 diffuse contrail contributions (Minnis et al., 2013).

459 **Table 2.** Estimated changes in contrail properties during different stages with measurement
 460 techniques and modeling consideration.

461 (This table presents estimated changes in contrail properties (ice crystal size, number density, etc.) during the
 462 different stages of their lifecycle. The values are not based on specific references but represent a general
 463 understanding derived from contrail studies.)
 464

Stage	Ice Crystal Size (µm)	Number Density (cm ⁻³)	Extinction Coefficient (km ⁻¹)	Width (m)	Length (km)	Optical Depth
Jet	1-10	10 ² -10 ⁴	10 ⁻² - 10 ⁻¹	10 - 20	10 - 100	0.01 - 0.1
Vortex	10 - 30	10 - 10 ²	10 ⁻³ - 10 ⁻²	10 ² -10 ³	1 - 10	0.001 - 0.01
Dissipation	30-100	1 - 10	10 ⁻⁴ - 10 ⁻³	10 ³ - 10 ⁴	0.1 - 1	0.0001 - 0.001
Diffusion (Early)	1000-3000	0.1 - 1	10 ⁻⁵ - 10 ⁻⁴	10 ⁴ - 10 ⁵	1 - 10	0.00001 - 0.0001
Diffusion (Mature)	3000-10000	0.01 - 0.1	10 ⁻⁶ - 10 ⁻⁵	10 ⁵ - 10 ⁴	NA	NA
Stage	Measurement Techniques		Modeling Considerations			
Jet	Lidar, satellite imagery		Microphysics, Ice Nucleation rates			
Vortex	Lidar, In-situ probes		Turbulence, Wind shear effects			
Dissipation	Lidar, Ground-based observations		Sedimentation, evaporation rates			
Diffusion (Early)	Lidar, satellite imagery		Radiative transfer, ice crystal habit			
Diffusion (Mature)	Lidar, Satellite imagery		Radiative transfer, cloud macrophysics			

465
 466 Observations during the COVID-19 pandemic lockdowns provide valuable insights into the
 467 relationship between air traffic and contrail coverage. Dauda et al. (2023) documented a significant
 468 decrease in contrail coverage (up to 41%) over the conterminous United States during the
 469 lockdown period compared to pre-pandemic levels. This decrease highlights the direct impact of
 470 air traffic on contrail formation and underscores the potential for mitigating climate impact through
 471 air traffic management strategies. However, the study also emphasizes the importance of
 472 considering environmental factors alongside air traffic when assessing contrail coverage. While

473 the reduction in air traffic was the primary driver of the observed decrease in contrail formation,
474 changes in atmospheric conditions at cruise altitudes likely played a secondary, but significant,
475 role.

476 In a modeling study, Huszar et al. (2013) adjusted the concentration of a tracer for contrails by
477 multiplying it with a specific factor and then adding it to the large-scale cloud ice mixing ratio.
478 They fine-tuned this factor through annual simulations spanning 2005 to achieve an appropriate
479 global value of the top-of-the-atmosphere radiative forcing attributable to contrails and contrail-
480 induced cirrus for that year, aiming for a target value of 31 mWm^{-2} as reported by Burkhardt and
481 Kärcher (2011). The distribution of this forcing aligns with Burkhardt and Kärcher (2011) findings,
482 showing peak values exceeding 300 mWm^{-2} over central Europe and the eastern U.S., with
483 significant parts of Europe and the U.S. experiencing a contrail-induced cirrus radiative forcing
484 above 100 mWm^{-2} . However, their estimates for eastern Asia surpass those of Burkhardt and
485 Kärcher (2011), with maximum values exceeding 300 mWm^{-2} , while ranging between 100 and
486 300 mWm^{-2} elsewhere. They suggested these differences could be attributed to how contrail cirrus
487 is handled (a simpler parameterization in this study versus the more complex contrail-cirrus
488 module used by Burkhardt and Kärcher), variations in simulated thermodynamic conditions over
489 East Asia, and differences in emission inventories.

490 Schumann (2012) developed the Contrail Cirrus Prediction (CoCiP) tool based on a Lagrangian
491 approach. In this model, global contrail coverage is computed by combining the optical depth (τ)
492 contributions from individual contrails and ambient cirrus, counting fractions of areas where
493 contrails cause the optical depth of the total cirrus to surpass a specific threshold (Schumann 2012).

494 Contrails not only augment cloud coverage but also thicken existing cirrus, consequently
495 influencing coverage (Minnis et al., 2013; Schumann and Graf, 2013). This thickening occurs by
496 generating more ice particles with smaller effective radii at constant ice water content (Kristensson
497 et al., 2000). While it is acknowledged that contrails consume humidity and may reduce natural
498 cirrus (Burkhardt and Kärcher, 2011; Unterstrasser and Görsch, 2014; Schumann et al., 2015;
499 Bickel et al., 2020), the prevailing evidence suggests that the thickening effect caused by numerous
500 additional small ice crystals tends to dominate.

501 **2.5 Contrail ice crystal nucleation**

502 Kärcher and Yu (2009) systematically investigated the relationship between nucleated contrail ice
503 crystal numbers and soot particle emissions. In exhaust rich in soot, there is a nearly proportional
504 increase in both ice crystal and soot particle numbers. Close to the contrail threshold, the formation
505 of ice crystals is limited as the low plume supersaturation hinders the activation of water on soot
506 particles, resulting in only a few ice crystals forming. Under conditions rich in soot, the quantity
507 of ice crystals reduces by about one hundred times compared to soot-poor conditions, reaching
508 constant low levels regulated by the number of particles present in the contrail environment. In
509 soot-poor exhaust at low ambient temperatures, there is an increase in ice crystal numbers due to
510 the activation of water and subsequent freezing of abundant aqueous plume particles. Figure 7
511 illustrates the ice crystal number emission index (per kilogram of fuel burnt) in the jet regime,
512 correlating with the number emission index of emitted soot particles as simulated by a parcel model
513 (Kärcher and Yu, 2009). Two sets of results are presented, one for an ambient temperature (T)
514 close to a contrail formation threshold temperature, $\Theta \approx 225 \text{ K}$ (-48°C), commonly encountered in
515 extratropical cruise conditions, and another for a lower temperature of $\Theta -12 \text{ K} \approx 213 \text{ K}$ (-60°C).

516 At intermediate ambient temperatures, nucleated ice crystal numbers increase due to enhanced
517 water activation of either soot or ultrafine aqueous plume particles.

518 The hatched area in Figure 7 represents the approximate range of current in-flight soot emission
519 indices. In exhaust rich in soot, the number of soot particles capable of water activation and
520 freezing increases with decreasing ambient temperature. This, in turn, raises plume cooling rates
521 and levels of plume supersaturation over liquid water. It's important to note that the primary driver
522 of the increased cooling and supersaturation is the decreasing ambient temperature, with soot
523 particles acting as additional ice nuclei under these cooler conditions. As the ambient temperature
524 (T) approaches the contrail formation threshold (Θ) in soot-poor exhaust, ambient aerosol particles
525 mixed into exhaust plumes become the sole source of contrail ice crystals. This is because fewer
526 plume particles can be activated due to declining plume supersaturation. The number
527 concentrations of ambient particles in contrails are significantly lower than current levels of soot
528 emissions.

529 The plume cooling rate plays a crucial role in determining the timing of water activation of
530 entrained ambient particles and, consequently, the number of ice crystals derived from them
531 (Kärcher 2015). In soot-poor exhaust, a substantial number of ultrafine aqueous plume particles
532 are formed in the fresh exhaust, especially if the fuel contains condensable vapors besides water
533 vapor. These small particles are anticipated to contribute significantly to ice crystal formation at
534 low ambient temperatures well below average values at cruise levels ($T \approx 218$ K in the extratropic
535 and $T \approx 228$ K in the tropics). If the formation of ultrafine particles cannot be mitigated, ice crystal
536 numbers are expected to be lowest in an intermediate range of soot emissions, specifically between
537 10^{13} and 10^{14} (kg-fuel)⁻¹.

538 The ice crystal number (Ni) holds significant importance in the context of contrail formation. Ni
539 quantifies the concentration of ice crystal particles present in the surrounding atmosphere. The
540 significance of Ni in contrail formation lies in its direct influence on various contrail properties.
541 Key aspects such as contrail persistence, the extent of spreading, and the optical characteristics of
542 contrails are closely tied to the ice crystal number (Ni). In essence, Ni serves as a fundamental
543 factor in understanding and characterizing contrail behavior and its impact on the atmosphere. A
544 higher Ni value implies a higher concentration of ice particles in the contrail, which can have
545 several implications, for instance, contrails with a higher Ni tend to persist for longer periods. This
546 means they remain visible in the sky for extended durations before dissipating or spreading. Higher
547 Ni values are associated with greater contrail spreading. As the ice particles in the contrail interact
548 with the surrounding atmospheric conditions, they can spread out and cover a larger area, which
549 may lead to contrail cirrus. The optical properties of contrails, for instance, their brightness and
550 ability to scatter sunlight, are affected by the ice crystal number. Higher Ni values can result in
551 brighter and more reflective contrails, which can contribute to increased cloudiness and affect the
552 Earth's energy balance.

553 The signs of variation in the number of ice crystals refer to the alteration in the ice particle
554 concentration within a contrail, such as increased ice particle concentration in the contrail, greater
555 persistence, and spreading of the contrail. Increased optical effects, such as increased brightness
556 and reflectivity. The decreased ice crystal particle concentration in the contrail leads to reduced
557 persistence and spreading of the contrail, and weaker optical effects. These variations in Ni may
558 occur due to several factors, comprising changes in atmospheric conditions, aircraft engine
559 emissions, and the presence of ice nuclei or other particles that impact ice particle formation.

560 Lewellen (2014) elucidates the pivotal role of initial ice crystal concentration (Ni) in contrail
561 dynamics through extensive simulations and the proposition of a simplified model. Their
562 simulations elucidate a discernible correlation between elevated Ni values and several significant
563 effects on contrails. First, contrails characterized by higher Ni values demonstrate prolonged
564 lifetimes, persisting for considerably extended durations, with simulations even indicating
565 lifetimes surpassing 40 hours (Lewellen, 2014). This protracted residence within the atmosphere
566 translates to amplified influence on radiative forcing, as contrails with higher Ni values possess
567 increased temporal opportunities for interaction with incident solar radiation. Second, heightened
568 ice particle concentration within the contrail leads to augmented contrail spreading. As Ni
569 escalates, interactions with atmospheric conditions become more conspicuous, potentially
570 precipitating the formation of contrail cirrus, a prevalent cirrus cloud type intimately associated
571 with contrail genesis (Lewellen, 2014). Finally, higher Ni values correlate with intensified optical
572 effects. A greater abundance of ice crystals within the contrail facilitates more efficient scattering
573 of incident sunlight, engendering brighter and more reflective contrails that perturb the radiative
574 equilibrium in the atmosphere (Lewellen, 2014).

575 Lewellen (2014) delineates a valuable framework for understanding the influence of Ni on contrail
576 significance through their simplified model: $S_{\Sigma} = \alpha N \times D$, where S_{Σ} represents the lifetime-
577 integrated ice crystal surface area, a metric for contrail impact, N is the total crystal number per
578 length of flight path (i.e., ice crystal concentration), and D represents the number-averaged fall
579 distance of ice crystals before sublimation. The coefficient 'α' is approximately constant in the
580 regime of interest. This equation underscores the critical role of Ni (N) in determining the overall
581 radiative forcing exerted by contrails. A higher Ni value translates to a larger S_{Σ} , indicating a more
582 significant impact on the atmosphere due to increased light scattering and longer contrail
583 persistence.

584 **2.6 Stages of aviation-induced cloud evolution and spreading stage**

585 The microphysical and optical characteristics of ice crystals within contrails undergo alterations
586 as they disperse or transform into contrail cirrus, contingent upon the prevailing meteorological
587 conditions and microphysical processes (Fig. 8). Over time, persistent contrails undertake a
588 transformation from their initial linear form to become contrail cirrus. In regions of heavy air
589 traffic, these contrail cirrus formations overlap and merge, giving rise to extended layers of ice
590 clouds characterized by alterations in shape, depth, and longevity. These patterns differ from
591 natural cirrus clouds in terms of microphysical, and optical, additionally, geometric properties also
592 play a role. The ice-supersaturated layers that sustain these properties exhibit variations in both
593 vertical structure and horizontal extent, impacting the exchange of water molecules between vapor
594 and ice phases within them. Collectively, these factors contribute to the radiative forcing (RF)
595 potential of aviation-induced cirrus (AIC). Figure 8 illustrates the augmentation in cloud coverage
596 area attributed to the vertical shear of horizontal wind components.

597 The turbulent mixing or entrainment processes result in a gradual reduction (dilution) of ice crystal
598 concentrations over time. The sizes of ice crystals grow through the absorption (deposition) of
599 water vapor from layers that are supersaturated with ice. Continuous deposition growth causes
600 deviations in the shapes (habits) of ice crystals from their initial isometric forms.

613

614 **Figure 7.** Nucleation of ice crystals in jet aircraft exhaust plumes. Figure adapted with permission
615 from Kärcher (2018). (Licensed under CC BY 4.0)

616 The shapes and sizes of ice crystals in cirrus clouds significantly impact their growth rates, fall
617 speeds, and optical properties. Larger ice crystals (>30 micrometers) tend to settle due to gravity
618 with fall speeds exceeding 100 meters per hour and are more likely to sublimate in warmer or drier
619 environments. Smaller ice crystals remain suspended around the flight levels due to their negligible
620 fall speeds, provided that some degree of supersaturation can be maintained, which depends on the
621 prevailing meteorological conditions.

622 The efficiency of sedimentation, the process by which ice crystals fall from clouds, is influenced
623 by the depositional growth rate, which in turn is affected by ice supersaturation, the rate of air
624 cooling, and the characteristics of the ice crystals themselves, including their size, shape, and
625 number concentration. Sedimentation increases the vertical extent of cirrus clouds, enhancing their
626 spreading rate and coverage under sheared flow conditions.

627 The settling of ice crystals, known as sedimentation, is a critical factor in determining the lifespan
628 of contrails. As the contrail ages, larger ice particles, due to their increased mass, fall out of the
629 plume more rapidly. This phenomenon can be explained by the concept of terminal velocity
630 (Spichtinger and Gierens, 2009). Researchers have explored methods to calculate this velocity,
631 considering the distribution of ice crystal sizes within the plume (Spichtinger and Gierens, 2009).
632 This approach provides a more comprehensive understanding of the sedimentation process.

633 The size of an individual ice crystal directly influences its falling speed. Larger crystals, typically
634 associated with persistent contrails, descend from the plume quicker than their smaller counterparts
635 found in ephemeral contrails. This sedimentation process significantly impacts the vertical
636 distribution of ice crystals within the contrail and affects its overall persistence. Ice crystals lofted
637 higher, potentially due to weaker updrafts, may experience slower sedimentation and persist for
638 longer durations, especially in colder atmospheric regions.

639

640 2.7 Lessons learned from observations of contrails and their properties

641 Contrails, as well as cirrus clouds, are frequently observed in air that lacks saturation (Kübbeler et
642 al., 2011; Krämer et al., 2009). The prevailing explanation suggests that these clouds consist of
643 large ice particles formed under supersaturated conditions, which then descend to lower and drier
644 levels, undergoing slow sublimation. Notably, instances of contrails and contrail cirrus have been
645 documented in ice-sub-saturated air across various scenarios, extending beyond dedicated contrail
646 research flights (Schumann et al., 2017; Voigt et al., 2011; Kübbeler et al., 2011; Gayet et al.,
647 2012; Chauvigné et al., 2018). Such observations have been derived not only from contrail-specific
648 research endeavors but also from In-service Aircraft for a Global Observing System (IAGOS)
649 commercial aircraft data collected in the North Atlantic region (Petzold et al., 2017).

650 Apart from a high number of small contrail ice particles, large particles (ice particle diameter
651 greater than 100 μm) were also detected but at relatively low concentrations (Voigt et al., 2010).
652 Such large ice crystals were also observed in contrail cirrus during the ML-CIRRUS (Midlatitude
653 Cirrus experiment) campaign (Voigt et al., 2017). However, attention to contrail cirrus in ice-sub-
654 saturated environments and the role that large ice particles play in contrail cirrus was raised by
655 Kübbeler et al. (2011) and Schumann (2012).

667 **Figure 8.** Influential factors in aircraft-induced cloud formation. Figure adopted with permission
668 from Kärcher (2018). (Licensed under CC BY 4.0)

669 Kübbeler et al. (2011) suggested that the subsaturation observed in contrail cirrus during the
670 CONCERT campaign is caused by the sublimation of large ice particles that may have fallen from
671 higher altitudes after forming under ice supersaturated regions (ISSRs). However, due to the
672 limited contrail cirrus data available, it is difficult to confirm whether contrail cirrus commonly
673 occurs in ice-sub-saturated environments.

674 Li et al. (2023) explored an extended dataset derived from 14.7 hours of cirrus cloud sampling
675 conducted at a frequency of 1 Hz, with a maximum speed of approximately 290 m s^{-1} , obtained
676 during the ML-CIRRUS 2014 campaign. Utilizing readily available parameters that characterize
677 cirrus microphysical properties—including ice number concentration, ice crystal sizes, and ice water
678 content (IWC)—they employed a more straightforward statistical method to distinguish aviation-
679 induced cirrus from natural cirrus, in contrast to the approach adopted by Chauvigné et al. (2018).

680 It consists of the SAC, covering the most common aircraft cruising altitude range, and a recently
681 developed algorithm for detecting aircraft exhaust plumes to identify matured contrail cirrus (>0.5
682 h lifetime; Voigt et al., 2017; Schumann et al., 2017), and natural cirrus. Contrail cirrus showed
683 sharp differences from natural cirrus during the stages of formation and in the corresponding
684 microphysical properties and occurrence conditions.

685 **Observational Constraints**

686 While there is growing evidence regarding contrail observations in ice-subsaturated
687 environments, it is imperative to acknowledge the inherent limitations associated with measuring
688 contrail properties. These limitations stem from various factors, including:

689 *Spatial and temporal resolution of instrumentation:* The comprehensive depiction of contrail
690 phenomena may be impeded by the restricted range or sampling frequency of instruments
691 employed for in-situ or remote sensing observations. For instance, satellite-based observations
692 might fail to capture minute-scale contrail features, while in-situ measurements conducted via
693 research aircraft may not fully encompass the spatial extent of a contrail layer.

694 *Discriminating contrails from natural cirrus formations:* The differentiation between contrails
695 and natural cirrus clouds, particularly in ice-subsaturated conditions, presents a significant
696 challenge and often necessitates sophisticated analytical techniques. Both varieties of ice clouds
697 can exhibit comparable characteristics concerning size and ice crystal properties, rendering the
698 definitive identification of their origin based on limited observations a challenging endeavor.

699 *Restricted data availability:* Observational datasets, particularly those focusing on fully
700 developed contrail cirrus, may be scarce. This scarcity impedes the ability to draw definitive
701 conclusions regarding the prevalence of contrails in sub-saturated environments and their
702 enduring influence on the climate system.

703

704 **3 Modeling of Contrails and their Impacts**

705 Understanding the multifaceted impacts of contrails necessitates employing models at various
706 scales. Local-scale process and fluid-dynamic models offer valuable insights into how plume
707 turbulence and wake dynamics influence the nucleation and properties of contrail ice crystals.
708 These simulations can then be validated against in-situ aircraft measurements of nucleated ice
709 crystal concentrations and sublimation losses (Kärcher, 2018). For broader-scale analysis, cloud-
710 resolving and regional models are utilized. These models incorporate meteorological boundary
711 conditions and leverage optical parameterizations to capture the shortwave radiative response of
712 micron-sized ice crystals. By co-locating these simulations with data from aircraft and satellite
713 observations, scientists can gain a more comprehensive understanding of the radiative forcing (RF)
714 exerted by contrail cirrus and its potential influence on pre-existing cirrus clouds (Kärcher, 2018).

715 The limitations of current instrumentation in measuring the microphysical and optical properties
716 of contrail cirrus elevate the importance of models (Table 3) for estimating their RF. To provide
717 robust predictions of climate change driven by aircraft emissions, models simulating ice nucleation
718 and sublimation must effectively translate the current understanding of contrail formation and
719 evolution processes into frameworks that lack the spatial or temporal resolution to explicitly
720 capture the formation stage. This objective can be achieved by synergistically integrating findings
721 from observations with local-scale, process-oriented models.

722

723

724 **Table 3.** Modeling the complexities of aircraft-induced cloud radiative effects (Adapted from
 725 Kärcher 2018).

Model scale	Spatial resolution		Contrail stages	Major challenges	Approach/solution
	Horizontal	Vertical			
Local	<10 m	<10 m	Formation stage	Ice crystal number and size distribution	Turbulence microphysics coupling
Regional	<1000 m	<100 m	Spreading stage	Radiative flux changes and interaction with natural clouds	Contrail to contrail cirrus transition
Global	<1000km	<1km	Full life cycle	Ice crystal formation and ice supersaturation	Parameterization and high resolution

Improvements in a hierarchy of local- to global-scale models to be realized in conjunction with observations providing data for cloud and radiation parameterization development and overall model validation.

726 3.1 Modeling of individual contrails

727 Individual contrails have been studied by various authors through approaches ranging from
 728 simplified parameterizations to more complex numerical models. Parameterization approaches
 729 normally depend on simplified assumptions to estimate contrail properties based on simplified
 730 atmospheric and emission conditions. On the contrary, more sophisticated numerical models, such
 731 as the Contrail Cirrus Prediction model (CoCiP), utilize detailed representations of atmospheric
 732 processes, ice particle growth, and radiative transfer to simulate the formation and evolution of
 733 contrails.

734 3.1.1 Contrail Cirrus Prediction Tool (CoCiP) for individual contrails

735 Schumann et al. (2017) compiled a dataset of contrail properties from various sources, including
 736 previous publications, additional information gathered from experimenters, reanalysis of existing
 737 data, and comparisons with the CoCiP database. The dataset expands upon the work of Schumann
 738 and Heymsfield (2017) by incorporating data from the ML-CIRRUS campaign (Voigt et al., 2016).
 739 The data includes both in-situ measurements of contrails, such as ice particle size spectra obtained
 740 using optical particle spectrometers (Baumgardner et al., 2011; Wendisch and Brenguier, 2013),
 741 and remote sensing data from ground-based and airborne lidar, spectroradiometers, satellites,
 742 cameras, and visual observations. Remote sensing data provides information on contrail properties
 743 such as width and optical depth (Spinhirne et al., 1998; Duda et al., 2004).

744 3.1.2 MIT Aircraft Plume Chemistry, Emissions, and Microphysics Model (APCEMM)

745 APCEMM is applied to assess the impact of non-linear plume chemistry and to deliver an initial
 746 estimate of the effects of contrails on atmospheric chemistry. Accurately determining the intricate
 747 relationship between contrail microphysics and chemistry often necessitates the use of costly large
 748 eddy simulations (LESs). APCEMM, through simplified assumptions about plume dynamics,
 749 strives to close the disparity between Gaussian plume models and LESs, as outlined by Fritz et al.
 750 (2020). APCEMM simulates the growth and chemical progression of an individual aircraft plume.
 751 It computes chemical concentrations and aerosol characteristics for a two-dimensional cross-
 752 section of the plume, angled perpendicular to the flight path. Dynamics, chemistry, and
 753 microphysics are explicitly modeled within the plume, using two different approaches depending
 754 on the age of the plume.

755

756 **3.1.3 NASA's global model for evaluation of individual linear contrails**

757 The NASA Ames Research Center developed a computationally efficient aircraft contrail model
758 designed to simulate aircraft-induced contrail formation. This model relies on the Appleman
759 criterion and operates under static atmospheric conditions (Sridhar et al., 2010; Neil et al., 2010).
760 Subsequently, researchers from NASA Ames extended this model to simulate the dynamic
761 transport of contrails by incorporating a Lagrangian dispersion model and a cloud microphysics
762 model (Li et al., 2013). The computational methods employed are grounded in well-established
763 approaches utilized in other aircraft contrail models (Pruppacher and Klett, 2000; Schumann et al.,
764 1995).

765 In comparison with models from Stanford (Naiman et al., 2009; Naiman et al., 2011; Jacobsen et
766 al., 2011) and DLR (Burkhardt and Kärcher, 2009; Burkhardt and Kärcher, 2011; Bier and
767 Burkhardt, 2022), this dynamic contrail model diverges primarily in two aspects: (1) It excludes
768 the initial contrail ice particles down-wash process caused by airplane wake vortex turbulence.
769 This process, typically lasting less than a minute, is crucial in determining contrail ice nucleation,
770 initial contrail ice particle sizes, and displacements through a complex fluid dynamic process
771 dependent on atmospheric, aircraft, and fuel parameters. In this model, the average initial ice
772 particle size is predefined, and the initial contrail location is set based on the cell where contrail
773 formation conditions are met. (2) The results from this model do not yet include additional
774 radiative forcing caused by aircraft contrails. The researchers are in the process of adding a contrail
775 radiative forcing module capable of computing the total aircraft contrail radiative forcing using
776 inputs from the model, such as ice particle size and linear contrail cloud cover area.

777 **3.1.4 DLR's ICON-LEM regional model**

778 Verma and Burkhardt (2022) developed and implemented a model for contrail formation into the
779 ICON-LEM (ICOsahedral Non-hydrostatic Large-Eddy Model; Zängl et al., 2014; Dipankar et al.,
780 2015). This model includes parameterizations for ice nucleation in the jet phase and ice crystal
781 loss during the contrail's vortex phase. It facilitates the investigation of modifications to cirrus
782 clouds resulting from contrail formation. ICON is the new German Numerical Weather
783 Prediction/Climate Model co-developed by DWD and MPI. It solves a set of equations on an
784 unstructured triangular grid based on successive refinement of a spherical icosahedron (Zängl et
785 al., 2014).

786 The model asserts high horizontal resolution coupled with a vertical resolution of approximately
787 150 m in the upper troposphere, enabling the resolution of pertinent cloud processes. Within
788 ICON-LEM, a contrail scheme has been developed and implemented, incorporating the
789 parameterization of contrail ice nucleation as proposed by Kärcher et al. (2015) and accounting
790 for the survival of ice crystals within the vortex phase. (Unterstrasser, 2016), to study changes in
791 cloud variables due to contrail formation within cirrus. Contrail formation, dependent on
792 atmospheric as well as aircraft and fuel parameters, is calculated, and contrail ice nucleation and
793 ice crystal loss in the contrail's vortex phase are estimated.

794 **3.1.5 Large-eddy simulations covering the entire life cycle, from initiation to termination**

795 Lewellen et al. (2014) outlined the utilization of large-eddy simulations with size-resolved
796 microphysics to model persistent aircraft contrails and the resulting contrail-induced cirrus clouds.
797 These simulations aim to depict the dynamic evolution of contrails, spanning from a few wing
798 spans behind the aircraft to their dissipation over an extended period. The emphasis of the study
799 lies in the modeling approach, discussing the development of schemes for efficient numerical
800 computation. The authors introduced dynamic local ice binning and updating, along with coupled
801 radiation, to accurately capture microphysical processes and radiative properties within individual
802 columns. The paper also addresses the challenge of maintaining realistic ambient turbulence over
803 extended simulation times, proposing a "quasi 3D" approach as a computationally feasible
804 approximation of the full dynamics, allowing for exploration across a broader parameter space.

805 Lewellen (2014) provides an extensive analysis encompassing over 200 instances of long-lived
806 contrails, spanning from their formation at several seconds old to their termination. The study
807 investigated the complete lifespan of long-lived contrails originating from a single aircraft. Various
808 factors were explored, including the effective ice crystal number emission index, temperature,
809 relative humidity concerning ice, stratification, shear, supersaturated-layer depth,
810 uplift/subsidence, and coupled radiation. The analysis delved into the scaling behaviors of contrail
811 lifetime, width, ice mass, and surface area. The simulations unveiled contrail lifetimes exceeding
812 40 hours, widths surpassing 100 kilometers, and ice masses exceeding 50 kg per meter of the flight
813 path. The paper identified distinct behavioral regimes influenced by radiative forcing and proposed
814 a simplified model to predict these regimes.

815 Key insights from the simulations highlight the notable impact of ice crystal number loss resulting
816 from competition among different crystal sizes, influencing both young contrails and aging contrail
817 cirrus. The sensitivity of contrail properties to the initial number of ice crystals decreases over
818 time, highlighting the importance of uncertainties in ice crystal deposition coefficients and the
819 Kelvin effect. The influence of atmospheric turbulence on contrail properties and lifetime is also
820 emphasized. Additionally, the paper discusses the effects of ice crystal shape, coupled radiation,
821 precipitation dynamics, and the role of water from fuel consumption in reducing ice crystal loss in
822 colder contrails.

823 Lewellen's simulations provide valuable insights into contrail behavior, shedding light on the
824 significance of crystal number loss mechanisms, the interaction between shear and ice
825 sedimentation, the depth of the supersaturated layer, and the potential impact of "cold" subvisible
826 contrails. The findings from these simulations contribute to estimating the effects of intricate
827 contrail scenarios, formulating mitigation strategies, and enhancing our comprehension of the
828 dynamics of natural cirrus clouds.

829 **3.2 Treatment of contrails in global models**

830 The consideration of contrail cirrus in global climate models has greatly improved in recent years.
831 Despite these advancements, notable uncertainties persist, particularly in the depiction of contrail
832 microphysics and the interaction between contrail-cirrus and cirrus-radiation. As mentioned
833 earlier, the characteristics of young contrail cirrus diverge from those of natural cirrus primarily
834 due to the elevated ice crystal number concentration typical in contrails. Consequently,
835 microphysical process rates in contrail cirrus, influencing its lifespan, can exhibit significant
836 deviations from those observed in natural cirrus. In this section, we examine the treatments of
837 contrail and contrail cirrus in global models. Very few models account for contrails, so our focus

838 is on those models that have been published extensively on contrail impacts, including modeling
839 studies done by the Institute for Atmospheric Physics (DLR), the National Center for Atmospheric
840 Research (NCAR), and Stanford University. The focus is on their modeling approaches and
841 findings. We start with a description of the approach used to treat contrails in these models.

842 **3.2.1 DLR Contrail Cirrus Prediction Model (CoCiP)**

843 CoCiP can be implemented within a GCM and used to study the global distributions of contrails
844 and contrail cirrus (Schumann et al., 2015). The model is specifically crafted for the estimation of
845 contrail cirrus coverage and the analysis of contrail climate impact, particularly in the context of
846 aviation system optimization processes. It is engineered to simulate the entire life cycle of
847 contrails. Contrail segments arise between waypoints along individual aircraft tracks in air masses
848 that are cold and humid enough. The initial characteristics of contrails are contingent upon the
849 specific aircraft involved. The advection and progression of contrails adhere to a Lagrangian
850 Gaussian plume model. This model treats the contrail life cycle using bulk contrail ice physics,
851 incorporating several simplifying assumptions. Notably, the model demonstrates efficiency in
852 handling mixing and cloud processes in a quasi-analytical manner (Schumann, 2012). Contrails
853 become extinct when the bulk ice content endures sublimation or precipitation.

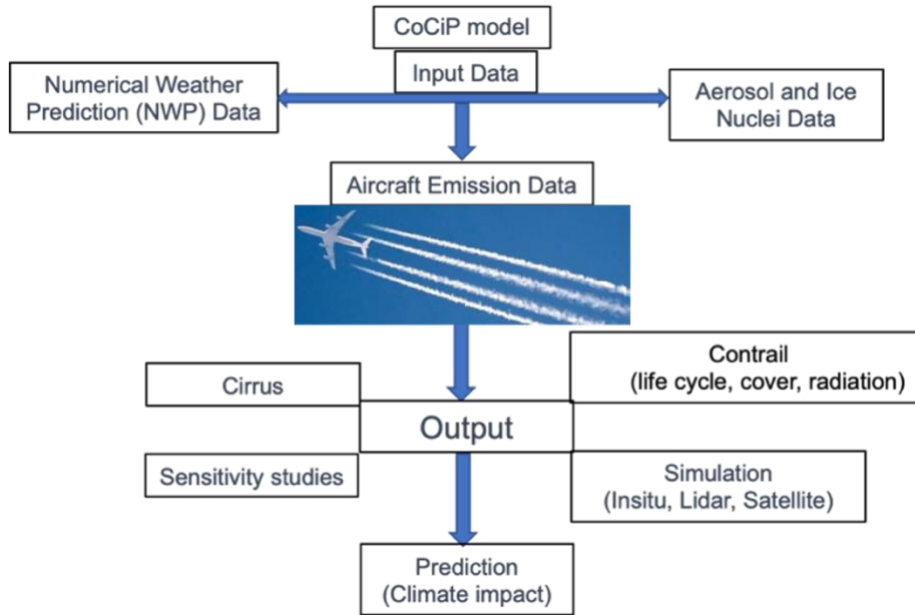

854 The model takes into consideration the impact of both aircraft properties and ambient
855 meteorological conditions. This encompasses established contrail formation thresholds, the effects
856 of advection, turbulent mixing, and the formation of ice mass from both emitted and ambient
857 humidity. The number of ice crystals is contingent upon the quantity of soot particles emitted. The
858 model incorporates simplified approximations for the survival of ice particles in adiabatically
859 sinking wake vortices and the loss of particles in aged contrails (Schumann, 2012).

860 CoCiP (Contrail Cirrus Prediction) depicted in Figure 9 simulates the formation of contrails under
861 specific meteorological conditions, either regionally or globally. Numerical weather prediction
862 data are utilized to determine ambient meteorological conditions through linear interpolation at
863 given positions and times. The model has been effectively employed to simulate contrails in both
864 global and specific cases, and its results have been compared with outcomes from other models
865 and in-situ measurements (Schumann, 2012).

866 **3.2.2 DLR version of the ECHAM5-HAM model**

867 The global climate model ECHAM5-HAM (European Center for Medium-Range Weather
868 Forecasts (ECMWF) and Hamburg) was developed at the Max Planck Institute (MPI) for
869 Meteorology in Hamburg, Germany (Roeckner et al., 2003, 2006; Stier et al., 2005), and adapted
870 to study of aviation effects on climate, including the modeling of the effects from contrails. The
871 aerosol-climate modeling system ECHAM5-HAM is based on a flexible microphysical approach,
872 and it predicts the evolution of an ensemble of microphysically interacting internally and externally
873 mixed aerosol populations as well as their size distribution and composition. Bier and Burkhardt
874 (2022) applied the ECHAM5-HAM model, incorporating a two-moment microphysical scheme
875 that was expanded to introduce a novel cloud category-contrail cirrus. The contrail cirrus scheme
876 encompasses a parameterization addressing contrail ice nucleation, the loss of ice crystals during
877 the vortex phase, plume dilution, the spreading of contrails influenced by vertical wind shear, and
878 inclusive microphysical and macrophysical processes aligned with the natural cloud scheme.

894 **Figure 9.** Schematic of the CoCiP model. Adapted from Schumann (2012). Contrail Image
895 (Credit: Adrian Pingstone (public domain))

896 The contrail cirrus parameterization implemented in ECHAM5-HAM follows the framework
897 established by Burkhardt and Kärcher (2009), who introduced contrail cirrus as a distinct cloud
898 class alongside natural cirrus clouds within the model's natural cloud scheme. The water and heat
899 budgets are balanced, with natural cirrus and contrails competing for available water vapor.
900 Prognostic variables, including ice water content, contrail coverage, and the length of contrail
901 cirrus, are computed based on factors such as persistence, advection, spreading, and
902 deposition/sublimation.

903 Bock and Burkhardt (2016) extended this parameterization (CCMod) by incorporating a
904 microphysical two-moment scheme (Lohmann et al., 2008). This enhancement significantly
905 improved the representation of microphysical processes by introducing contrail cirrus ice crystal
906 number concentration and volume as additional prognostic variables. This advancement is crucial
907 for studies investigating the impact of aircraft particle number emissions on contrail cirrus
908 properties and their overall climate influence.

909 Bier and Burkhardt (2022) describe the initialization of contrails within the model. However, the
910 chosen initialization time of 450 seconds (7.5 minutes) warrants further discussion. This value
911 represents half of a model time step, potentially suggesting computational efficiency as a factor in
912 its selection. Nevertheless, a 450-second delay in contrail formation might be too long for accurate
913 simulations, especially for studies focusing on the early stages of contrail evolution. Future
914 investigations need to explore the sensitivity of model results to this initialization time and
915 potentially refine it for a more realistic representation of contrail formation processes.

930 ECHAM5-CCMod. [Adapted from Bier and Burkhardt (2022). Contrail Image (Credit: Adrian
931 Pingstone (public domain)

932 In instances of contrail cirrus volumes exhibiting very low ice crystal number concentrations, as
933 observed in aged contrails associated with heightened ice crystal sedimentation, the deposition of
934 ice water is constrained, aligning with the depositional growth of ice crystals (Bock and Burkhardt,
935 2016). In more recent iterations of the model, specifically, ECHAM5-CCMod, Bier and Burkhardt
936 (2019) incorporated the contrail ice nucleation parameterization proposed by Kärcher et al. (2015).
937 In their model approach, they suggest that the plume cools over time due to continuous mixing of
938 the exhaust with ambient air, eventually becoming water-supersaturated when the SAC criterion
939 is met. The number of activated aerosol particles, stemming from soot and ambient particles, is
940 computed based on ambient conditions, fuel/engine characteristics, and exhaust particle properties.
941 Additionally, Bier and Burkhardt (2022) introduced a parameterization for ice crystal loss during
942 the vortex phase and conducted a thorough evaluation of their model.

943 3.2.3 NCAR CAM6 model with Contrails

944 In the first NCAR study of the radiative forcing of linear contrails and contrail cirrus, Chen and
945 Gettelman (2013) used the Community Atmosphere Model version 5 (CAM5), the atmospheric
946 component of the National Center for Atmospheric Research (NCAR) Community Earth System
947 Model (CESM). More recently, they have used the updated atmospheric component from the new
948 version of CESM2 (Danabasoglu et al., 2020). The current atmospheric model implemented in
949 CESM2 is CAM, version 6.2 (CAM6; Gettelman et al., 2020). CAM6 incorporates a detailed two-
950 moment cloud microphysics scheme (Gettelman and Morrison, 2015) coupled with an aerosol
951 microphysics and chemistry model (Liu et al., 2016; Gettelman et al., 2019). The latest version of
952 the contrail parameterization (Chen et al., 2012) was utilized with CAM6 (Gettelman et al., 2021).
953 While the ice cloud microphysics and aerosols exhibit minimal differences between CAM5 and
954 CAM6, the aerosol activation in CAM6 significantly differs, impacting natural cirrus clouds but

955 not contrails. The assumed emission ice particle diameter was adjusted from the original
956 parameterization (10 μm) to 7.5 μm to better align with observations (e.g., Lee et al., 2021).

957 For contrail studies at NCAR, the standard version of CESM with 32 levels (to 3 hPa) vertical and
958 $\sim 1^\circ$ horizontal resolution was employed. Winds and optional temperatures were relaxed to
959 NASA's data assimilation analyses, specifically the Modern-Era Retrospective analysis for
960 Research and Applications, version 2 (MERRA2; et al., 2015), with wind nudging (Gettelman et
961 al., 2020, 2021). CESM2 features a fully interactive land surface model (the Community Land
962 Model, version 5; et al., 2020). Sea surface temperatures (SSTs) are fixed to MERRA2 SST, and
963 there is no interactive ocean.

964 These simulations allow for adjustments in atmospheric and surface temperatures, resulting in
965 radiative flux perturbations representing an Effective Radiative Forcing (ERF). Sensitivity tests
966 were conducted, with temperatures nudged to MERRA2. The results were compared with previous
967 contrail simulations using this model and others, as well as observational data. The pattern of
968 contrail-induced changes to cloud fraction closely resembled the previous model documented in
969 CAM5 (Chen and Gettelman 2013), with peak effects observed in the Northern Hemisphere at
970 mid-latitudes. The radiative forcing in the CAM6 simulations exceeded that of the earlier Chen
971 and Gettelman (2013) study due to a smaller initial contrail area (100 vs. 300 m) and smaller initial
972 ice crystal sizes (7.5 vs. 10 μm diameter). The radiative forcing pattern and magnitude were
973 qualitatively and quantitatively consistent with the analysis conducted by Lee et al. (2021),
974 aligning with the intercomparison between contrail simulation models.

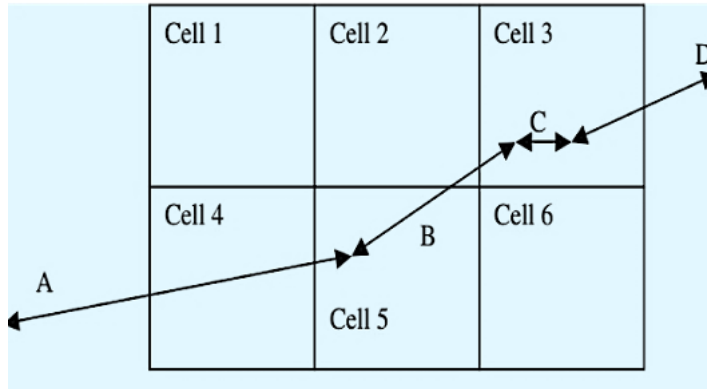

975 **3.2.4 Stanford global model for contrail evaluation**

976 Although it is no longer actively utilized in aviation studies, Stanford University developed a low-
977 order contrail model and a Large Eddy Simulation (LES) model (Naiman et al., 2009; Naiman et
978 al., 2011; Jacobsen et al., 2011). In their work, Jacobsen et al. (2011) assessed mass-conservative,
979 positive-definite, unconditionally stable, and non-iterative numerical techniques for simulating the
980 evolution of discrete, size, and composition-resolved aerosol and contrail particles within
981 individual aircraft exhaust plumes. This simulation was conducted in a global or regional 3-D
982 atmospheric model, incorporating the coupling of subgrid exhaust plume information to the grid
983 scale (see Fig. 11). This approach represents a distinct method for simulating the impacts of aircraft
984 on climate, contrails, and atmospheric composition.

985 The microphysical processes addressed within each plume include size-resolved coagulation
986 among and between aerosol and contrail particles, aerosol-to-hydrometeor particle ice and liquid
987 nucleation, deposition/sublimation, and condensation/evaporation. Each plume is characterized by
988 its own emission and supersaturation, and the spreading and shearing of each plume's cross-section
989 are calculated over time. Aerosol and contrail-particle core compositions are tracked for each size
990 and affect optical properties within each plume. When linear contrails sublimate or evaporate, their
991 size and composition-resolved aerosol cores and water vapor are introduced to the grid scale,
992 where they influence large-scale clouds. The model's algorithmic properties were analyzed, and
993 the final model was evaluated against in situ and satellite data. Table 4 summarizes the cross-
994 model intercomparison of contrail simulation models covered in this study.

1014 **4 Radiative Forcing for Contrail Cirrus in Global Models**

1015 **4.1 Contrail radiative forcing and efficacy**

1016 Contrails during the day can warm or cool depending on optical depth, zenith angle, and ice crystal
1017 shape (Meerkötter et al., 1999; Stuber et al., 2006; Newinger and Burkhardt, 2012). Stuber et al.
1018 (2006) suggested that moving all air traffic to the day decreases RF. Newinger and Burkhardt
1019 (2012) stated that we need to consider the lifetime of the contrails since daytime air traffic can
1020 cause a large contrail coverage at night. After all, it is the long-lived contrail cirrus outbreaks that

1021 are responsible for a large part of the climate impact (Burkhardt et al., 2018). As illustrated in Fig.
1022 1, the overall effect reveals a positive net radiative forcing (RF), signifying a warming impact. The
1023 examination of this phenomenon is undertaken here in contrast to the comprehensive RF, the local
1024 RF (RF') can be defined as the instantaneous change in net incoming radiation for 100% contrail
1025 coverage in a specific location.

1026 Contrail RF comprises both a long-wave (LW) and a short-wave (SW) component, with each
1027 influenced by flight characteristics and the time of day. Unlike the systematic dependency on
1028 optical depth (τ), the relationship between RF and ice water path (IWP) is less consistent (De Leon
1029 et al., 2012; Schumann et al., 2012). The LW RF is positive both day and night, with the largest
1030 impact observed for a cold contrail (located near the tropopause) over a warm, cloud-free Earth
1031 surface. The shortwave radiative forcing (RF) is predominantly negative, with the greatest impact
1032 observed for contrails over darker surfaces, such as cloud-free oceans (Meerkötter et al., 1999).
1033 Studies conducted by Schumann et al. (2012), utilizing both their model and observational
1034 evaluations, suggest the existence of substantial regional RF' values. The calculation of contrail
1035 RF within a global model is contingent on factors such as the representation of contrails, the
1036 atmospheric conditions, and the radiation transfer model employed (Myhre et al., 2009).

1037 While radiative forcing (RF) provides a valuable measure of the impact of contrails on the radiative
1038 balance, it doesn't fully account for the efficacy of different forcing agents in driving surface
1039 temperature changes. Recent studies by Bickel et al. (2020) and Ponater et al. (2021) highlight the
1040 importance of effective radiative forcing (ERF) as a superior metric. ERF considers feedback
1041 mechanisms that can influence the ultimate climate impact of a forcing agent.

1042
1043 Bickel et al. (2020) analyzed the feedback processes and quantified the effective radiative forcing
1044 (ERF) of contrail cirrus, which refers to the cloud formations produced by aircraft engine exhaust.
1045 They highlighted that feedback analysis is a valuable tool for understanding climate sensitivity and
1046 the differences in efficacies between various climate-forcing agents. Previous climate model
1047 simulations have suggested a relatively low efficacy of contrails in forcing global mean surface
1048 temperature changes. They employed a climate model that incorporates a state-of-the-art
1049 representation of contrail cirrus and conducted the simulations with fixed sea surface temperatures
1050 to determine the ERF resulting from contrail cirrus.

1051 Bickel et al. (2020) noticed that significant scaling up of aviation density is necessary to obtain
1052 statistically significant results from the simulations. Their study found that the ERF of contrail
1053 cirrus is less than 50% of the respective instantaneous or stratosphere-adjusted radiative forcings.
1054 The best estimate of contrail cirrus ERF is approximately 35%. In comparison, the reduction of
1055 ERF is more substantial for contrail cirrus than for a similar magnitude increase in CO₂
1056 concentrations. They identified the main factor contributing to the reduction in contrail cirrus ERF
1057 as a compensating effect of natural clouds that provide negative feedback. Additionally, they
1058 observed that the combined water vapor and lapse rate adjustment, which affects the distribution
1059 of water vapor in the atmosphere and the lapse rate (temperature decrease with altitude), has a less
1060 positive impact on contrail cirrus ERF compared to the reference case of CO₂ forcing.
1061 Nevertheless, the negative feedback provided by natural clouds has a more pronounced effect in
1062 reducing contrail cirrus ERF compared to these adjustments.

1063 Overall, Bickel et al. (2020) suggested that contrail cirrus has a lower climate impact than initially
1064 thought, with the reduction in ERF attributed to the compensating effect of natural clouds.
1065 Understanding the specific feedback processes and quantifying the ERF of different climate

1066 forcing agents, such as contrail cirrus, is crucial for accurately assessing their contributions to
1067 surface temperature changes and overall climate dynamics.

1068 While radiative forcing (RF) provides a measure of contrail impact on radiative balance, it doesn't
1069 fully account for the efficacy of different forcing agents in driving surface temperature changes.
1070 Recent studies by Ponater et al. (2021) emphasize the importance of effective radiative forcing
1071 (ERF) as a superior metric. ERF considers feedback mechanisms that influence a forcing agent's
1072 ultimate climate impact. Their findings suggest a potentially lower climate impact from contrail
1073 cirrus than previously assumed based on ERF calculations. However, as acknowledged by Ponater
1074 et al. (2021), further research is needed to confirm the efficacy of ERF in assessing the complete
1075 surface temperature response to contrail cirrus. Direct simulations of this response would be
1076 crucial for validating ERF as a reliable metric for contrail cirrus impact.

1077 Similar to findings by Bickel (2023), this study highlights the potential limitations of using RF
1078 alone to estimate contrail cirrus impact. Here, climate model simulations revealed a significant
1079 reduction in the effective radiative forcing (ERF) of contrail cirrus compared to its conventional
1080 RF. This suggests a potentially lower climate impact from contrail cirrus than previously assumed
1081 based solely on RF calculations. The primary contributor to this reduced ERF is likely a negative
1082 cloud adjustment, where contrail cirrus formation leads to a decrease in natural cirrus cover.
1083 Further research is needed to confirm these findings across different climate models and refine our
1084 understanding of contrail cirrus efficacy in driving surface temperature changes.

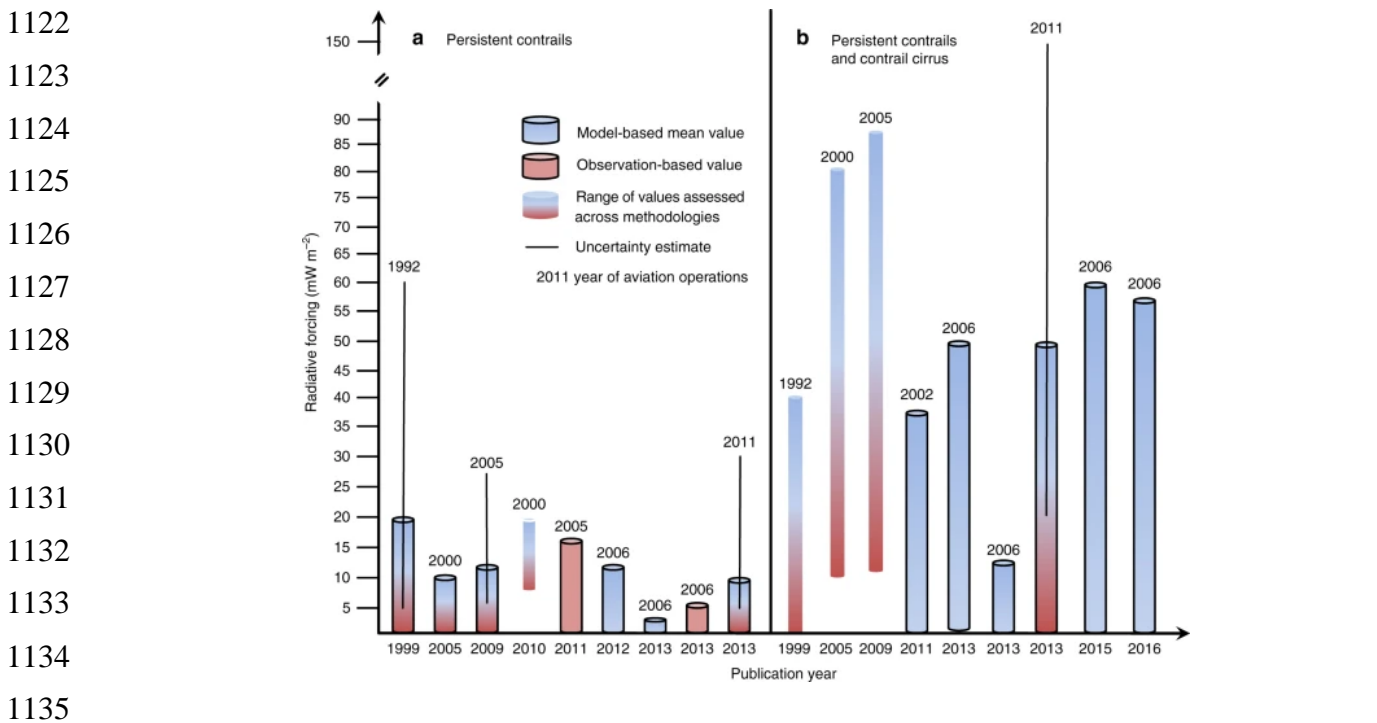

1085 Long-lasting contrails contribute to global climate change. These contrails can form cirrus clouds,
1086 which are a type of high-altitude cloud that can trap heat in the atmosphere. This trapping of heat
1087 is known as radiative forcing. While the exact contrail contribution to radiative forcing remains
1088 uncertain, it is thought to be a significant factor in climate change (Brasseur et al., 2016). The RF
1089 metric is a backward-looking measure of the effect of emissions on the radiative flux balance and
1090 is commonly used to compare changes in climate forcings (Wuebbles et al., 2010). The RF linked
1091 to non-CO₂ aviation emissions arises from processes occurring over different time scales. Contrails
1092 generally exist for a few hours after an aircraft emissions occur, but other emissions can last much
1093 longer. Effects on the distribution of aerosols and on ozone produced from NO_x emissions can
1094 remain for a few days to months, while changes in CH₄ can be affected for longer than a decade.
1095 The limitations of using RF as a comprehensive metric for global non-CO₂ aviation climate
1096 impacts are well-recognized due to such associated spatiotemporal variations (Wuebbles et al.,
1097 2007). The nonlinear interactions involved make it imprecise to represent the sum of RF for various
1098 non-CO₂ components as a single value. Similarly, distinct climate responses are observed for
1099 different forcing mechanisms.

1100 In 2016, Brasseur et al. investigated the radiative forcing (RF) through analyses involving seven
1101 global models (CAM4, CAM5, IGSM, GISS-E2, GEOSCCM, GATOR-GCMOM, and GEOS-
1102 CHEM) as part of the Federal Aviation Administration's (FAA) Aviation Climate Change
1103 Research Initiative (ACCRI) program. The assessment covered climate impacts for 2006, and the
1104 initial five models projected impacts for 2050 scenarios, specifically focusing on selected aircraft
1105 emission components. In a separate study, Chen and Gettelman (2016) used the CAM5 model to
1106 estimate RF for contrails and contrail cirrus in the 2050 future scenario, employing the 2006 AEDT
1107 dataset. Notably, the research highlighted the tendency to overestimate global linear contrail (LC)
1108 net RF when using the natural ice cloud optical property parameterization as a stand-in for contrail
1109 counterparts in modeling studies. Furthermore, the distribution of regional RF indicated that in

1110 densely trafficked airspaces, such as the United States, RF could be up to ten times higher than the
 1111 global average (Brasseur et al., 2016).

1112 Schumann and Graf (2013) determined a more significant AIC impact by using both observational
 1113 data and the contrail cirrus prediction model (CoCiP; Schumann, 2012). They found an "aviation
 1114 fingerprint" ascribed to a daily air traffic cycle within the diurnal cycle of cirrus properties in the
 1115 North Atlantic region (NAR), associating with the annual mean diurnal patterns of cirrus cover
 1116 and outgoing longwave radiation (OLR) derived from Meteosat data (Graf et al., 2012).

1117 Figure 12 shows the global average annual radiative forcing (RF) values and uncertainty ranges
 1118 for persistent contrails alone and together with contrail cirrus. The values are compiled from
 1119 selected studies and assessments published since 1999 and include a recent development by
 1120 Kärcher (2018). Over time, early assessments of contrail RF have been confirmed and the range
 1121 of uncertainty has been narrowed down considerably.

1136 **Figure 12.** Global annual average amount of radiative forcing caused by aircraft-induced clouds
 1137 Figure adapted with permission from Kärcher (2018). (Licensed under CC BY 4.0)

1138 The figure shows that the RF due to persistent contrails alone is -0.01 W/m^2 (with an uncertainty
 1139 range of $0.005\text{-}0.03 \text{ W/m}^2$), and the RF due to persistent contrails together with contrail cirrus is
 1140 $\sim 0.05 \text{ W/m}^2$ (with an uncertainty range of $0.02\text{-}0.15 \text{ W/m}^2$). (Kärcher, 2018). Figure. 12 shows
 1141 that analyses accounting only for linear contrails underestimate the total RF for contrails. More
 1142 recent analyses tend to show an overall warming of around $\sim 45 \text{ mWm}^{-2}$ (Bier and Burkhardt, 2022).

1143 The models applied by DLR and NCAR's groups are summarized in Table 5 (updated from. Bock
 1144 and Burkhardt, 2016). Bock and Burkhardt (2016) evaluated the year 2002 using the AERO2k
 1145 inventory and for year 2006 using the AEDT 2006 slant distance inventory. The corrected NCAR
 1146 analyses and their more recent results are consistent with those from the DLR modeling studies
 1147 (Lee et al., 2021). These findings further amplify the conclusions from Fig. 12.

1148 **Table 5.** Summary of existing contrail cirrus simulations and RF from the DLR and NCAR
 1149 models. Adapted from of Bock and Burkhardt (2016).

1151 4.2 Future RF projections

1152 4.2.1 DLR’s study for future RF projections

1153 Bock and Burkhardt (2019) investigated how changes in air traffic between 2006 and 2050,
 1154 including both volume increase and upward shift in flight altitudes (0.3-1.5 km), would impact
 1155 contrail cirrus properties and radiative forcing. Table 6 shows their simulations considering this
 1156 combined scenario. It projects a fourfold increase in air traffic and a maximum flight density at a
 1157 lower altitude (200 hPa in 2050 compared to 240 hPa in 2006), which has climate implications.

1158 In Table 6, the air traffic distance is specified as the ground-projected track distance. The coverage
 1159 is sketched out for all contrail cirrus, and the visibility of contrail cirrus (visible optical depth >
 1160 0.05) is indicated in brackets (Bock and Burkhardt, 2016). Radiative forcing estimates exist for
 1161 both track distance and slant distance within brackets (Table 6). Remarkably, Bock and Burkhardt
 1162 (2019) determined that the projected future increase in air traffic, coupled with a minor shift to
 1163 higher altitudes, outcomes in a substantial rise in contrail cirrus coverage, optical depth, and
 1164 radiative forcing. Particularly, air traffic contrail cirrus radiative forcing is estimated to increase
 1165 threefold, from 49 to 159 mW m⁻² (Fig. 13). The findings are a result of a future air traffic
 1166 inventory, where the measurement of air traffic is signified in terms of track distance (ground
 1167 projected) rather than slant distance (3-D). Declining the initial contrail ice particle number by
 1168 50% results in a substantial drop in the climate impact of contrail cirrus, leading to a global decline
 1169 in radiative forcing for the year 2050. The reduction is significant, amounting to a 14% reduction
 1170 from 160 to 137 mWm⁻² (Fig. 13).

1171 4.2.2 RF projections from the NCAR model

1172 The study conducted by Chen and Gettelman (2016) investigated the radiative forcing curbing
 1173 from aviation-induced cloudiness, using the Community Atmosphere Model Version 5 (CAM5)
 1174 for both present (2006) and future (up to 2050) scenarios. The researchers found a projected four-

1175 fold increase in global flight distance from 2006 to 2050. Despite this, the simulated radiative
 1176 forcing from contrail cirrus in 2050 is predicted to reach 87 mWm^{-2} , representing a seven-fold rise
 1177 compared to 2006. This underlines a non-linear correlation between radiative forcing and fuel
 1178 emission mass, accredited to non-uniform regional escalations in air traffic and changes in contrail
 1179 radiative forcing sensitivity through different regions.

1180 **Table 6.** Overview of the model simulations: Air traffic distance exists as ground-projected track
 1181 distance. Coverage is furnished for all contrail cirrus, with coverage for visible contrail cirrus
 1182 (visible optical depth > 0.05) shown in brackets (Bock and Burkhardt, 2016). The radiative
 1183 forcing is represented for both track distance and slant distance, with values enclosed in brackets.
 1184 (Adapted from Bock and Burkhardt (2019))

Background	Inventory	Air traffic volume (km yr^{-1})	Propulsion efficiency	Initial ice number concentration (cm^{-3})	Coverage (%)	RF (mW m^{-2})
2006	2006	3.7×10^{10}	0.3	150	1.1 (0.7)	49 (56)
2006	2050 Baseline	15.4×10^{10}	0.3	150	2.9 (2.0)	159 (182*)
2050 (RCP6)	2050 Baseline	15.4×10^{10}	0.3	150	2.8 (2.0)	160 (183*)
2050 (RCP6)	2050 Scenario1	15.4×10^{10}	0.42	75	2.98(1.7)	137 (157*)

RCP6-Representative Concentration Pathway 6.0

*Asterisks denote extrapolated values resultant from the factor resolute by the radiative forcing in 2006, which is connected to air traffic volume and computed using slant distance and track distance (Bock and Burkhardt, 2016).

1185 The CAM5 simulations also indicate that the negative radiative forcing resulting from the indirect
 1186 effect of aviation sulfate aerosols on liquid clouds in 2050 could be as large as -160 mWm^{-2} , a
 1187 four-fold increase from 2006. Consequently, when considering both aviation aerosols and contrail
 1188 cirrus, the total radiative forcing in 2050 could possibly employ a cooling impact on the planet.
 1189 Aerosols, particularly aviation sulfate aerosols distributed at cruise altitudes, may be transferred
 1190 to the lower troposphere. This procedure raises aerosol concentrations and consequently enhances
 1191 the cloud drop number concentration and persistence of low-level clouds. On the other hand, the
 1192 study suggests that aviation black carbon aerosols have an insignificant net forcing affect globally,
 1193 both in 2006 and 2050.

1194 The researchers focus on specific regions, for instance, Central Europe, eastern North America,
 1195 and East Asia, and recommend quantitative evaluations of the forcing in each region for several
 1196 scenarios. For example, in Central Europe, the predicted contrail cirrus radiative forcing in 2050
 1197 is anticipated to locally peak at 2 Wm^{-2} , marking a 2 to 3-fold increase compared to 2006. In the
 1198 eastern United States, the contrail cirrus radiative forcing could reach 800 mWm^{-2} in 2050,
 1199 revealing a higher percentage increase compared to 2006. The most prominent rise in contrail
 1200 cirrus radiative forcing is estimated in East Asia, where a 6-fold increase is projected for 2050,
 1201 associated with the region's anticipated significant rise in consumption of aviation fuel. The
 1202 inclusion of aviation aerosols in the simulations suggests a slight reduction in positive forcing over
 1203 land, as compared to the forcing solely caused by contrail cirrus. On the other hand, over the ocean,
 1204 a negative forcing rising from aviation emissions is measured. This can be accredited to the lower
 1205 surface albedo and cleaner environment (fewer aerosols) in comparison to land areas. In the three

1206 regions with the highest projected air traffic in 2050 (eastern United States, Central Europe, and
 1207 East Asia), aviation aerosols reduce the regionally averaged positive radiative forcing induced by
 1208 contrail cirrus by approximately 50%, as indicated by the blue boxes in Fig. 14. The peak positive
 1209 forcing within each of these regions is also reduced by 50% due to aviation aerosols. The study
 1210 provides detailed regional estimates of these effects (Table 7).

1211 The negative radiative forcing result from aviation aerosols, as detected in this study, supports the
 1212 inferences represented by Righi et al. (2013). The extent of the cooling effect is estimated to be
 1213 affected by the background cloud drop number concentration.

1245 4.3 Issues representing cloud-contrail and contrail-contrail overlaps in modeling studies

1246 A thorough examination of past methodologies for modeling cloud layer overlaps and several
 1247 modeling studies recommends that overlapping with other cloud layers is prone to reduce both the
 1248 shortwave (cooling) and longwave (warming) radiative forcing linked to contrails (Sanz-Morère
 1249 et al., 2021). However, there is inadequate agreement on how the overlap between clouds and
 1250 contrails might modify the net radiative forcing due to uncertainties regarding whether it would
 1251 more strongly mitigate the shortwave or longwave components. Particularly, the precise impact of
 1252 contrail-contrail overlap on global contrail radiative forcing has yet to be measured. In this section,
 1253 we review previous literature referring to the treatment of multiple-layer overlap in the context of
 1254 contrail radiative forcing calculations.

1255 Schumann et al. (2012) determined that the net radiative forcing may augment if contrails overlap
 1256 with low-level clouds but could go through significant variations when passing under natural cirrus
 1257 clouds. This underscores the significance of precisely modeling natural clouds in contrail
 1258 simulations. Nevertheless, when utilizing this method to simulate single contrails, accounting for
 1259 the radiative interactions among multiple contrails turns into a challenging task. In prior examples
 1260 of modeling contrail-contrail overlap, when simulating contrails in global climate models, various
 1261 treatments have been utilized, as outlined in Table 8. Contrail parametrizations have been
 1262 formulated for ECHAM4 (Ponater et al., 2002; Burkhardt and Kärcher, 2009), where maximum-
 1263 random overlap is presumed between contrail and cloud layers, as well as among different contrails
 1264 (Burkhardt and Kärcher, 2011; Marquart et al., 2003; Bock and Burkhardt, 2016; Frömming et al.,
 1265 2011). Rädcl and Shine (2008) and Rap et al. (2010) also use this parameterization, calibrating
 1266 the outcomes by using satellite observations.

1267

1268 **Figure 14.** Ensemble of the average regional radiative forcing in $W m^{-2}$, utilizing the baseline
 1269 emission scenario for the year 2050 with RCP8.5 meteorology, focusing on contrail cirrus alone
 1270 (a–c) and contrail cirrus combined with aviation aerosols (d–f). The term "RESTOM" represents
 1271 the alteration in the net residual radiative flux at the top of the model. The plot includes only
 1272 ensemble-mean perturbations that surpass 2 standard deviations of the averaged control
 1273 simulations. (Figure adopted with permission from Chen and Gettelman, 2016) (Licensed under
 1274 CC BY 4.0)

1275

1276

1277

1278

1279

1280 **Table 8.** Existing methods for modeling contrail–contrail overlap when estimating global contrail
 1281 RF. MRO: maximum-random overlap, defined by Geleyn and Hollingsworth (1978) as assuming
 1282 that clouds in adjacent layers maximally overlap, while clouds separated by one or more clear
 1283 layers randomly overlap (Adapted from Sanz-Morère et al. 2021).

Source	Model used to represent contrail–contrail overlap
Minnis et al. (1999)	No overlap considered (fractional coverage from observations)
Marquart et al. (2003)	MRO in the vertical for each column
Rädel and Shine (2008)	Random overlap
Rap et al. (2010)	Random overlap
Frömming et al. (2011)	MRO in the vertical for each column
Burkhardt and Kärcher (2011)	MRO in the vertical for each column
Chen and Gettelman (2013)	Zero contrail–contrail overlap in grid box
Schumann and Graf. (2013)	Linear RF addition
Bock and Burkhardt (2016)	MRO in the vertical for each column

1284
 1285 Chen and Gettelman (2013) included contrails in the CAM5 model by portraying them as an
 1286 increase in the 3-D cloud fraction, where the model presumes maximum-random overlap.
 1287 Nevertheless, in their method, they considered zero overlaps between newly formed contrails when
 1288 placed at the same vertical level (approximately 1 km). Finally, the CoCiP Lagrangian contrail
 1289 model (Schumann, 2012) reports contrail-contrail overlaps indirectly by linearly summing the
 1290 radiative forcing of all contrails, taking into consideration any observed cirrus present above the
 1291 simulated contrail. Nonetheless, this method does not clearly consider the overlap between
 1292 simulated contrails. Inconsistencies rise in how contrail-contrail overlaps are modeled across
 1293 various studies. The most efficient approach remains uncertain, and as of now, no analysis has
 1294 measured the impact of contrail-contrail overlaps on global contrail RF. Since further expansion
 1295 of the aviation sector is expected, it is anticipated that an increased number of instances of contrail
 1296 overlap will occur. Hence, a more inclusive understanding of the degree and dynamics of contrail-
 1297 contrail overlap is a necessity. Table 9 summarizes the agreement and disagreement between
 1298 climate models on contrail cirrus radiative forcing.

1299 **5 Observation Datasets for Contrail Studies**

1300 The vast majority of observations, comprised of airborne, satellite, and ground-based approaches,
 1301 encompass jet aircraft exhaust contrails from 1972 onward. Nevertheless, it is remarkable that
 1302 records of contrail observations date back to as early as 1915, as published by Ettenreich in 1919.

1303 Early measurements performed behind a propeller-driven aircraft offered data supporting the
 1304 concept that contrail ice formation requires liquid saturation to originate, associating with the
 1305 Schmidt-Appleman criterion that is now well-established (Schmidt, 1941, Appleman,1953 and
 1306 Schumann, 1996.). These remarks, which encompassed the collection of ice particles on impactors
 1307 and halo observations, also furnished initial insights into the size and shape of both contrail and
 1308 cirrus ice particles (Weickmann, 1945).

1309

1310

1311

1312 Table 9 Agreement and disagreement between climate models on contrail cirrus radiative forcing
 1313

Aspect	Agreement	Disagreement	Potential Causes	Recommendations for Future Research
Net Radiative Forcing (RF)	Likely positive net RF, signifying warming			
Longwave vs. Shortwave RF		Models show some variation in the relative contribution of longwave (warming) and shortwave (cooling) components to the net RF depending on factors like ice crystal shape and optical depth.	Complexity of ice crystal parameterizations Treatment of solar radiation transfer	Improve ice crystal parameterizations in models to better capture the variation in radiative properties. Conduct studies to refine the treatment of solar radiation transfer in contrail simulations.
Regional Variations	Models concur on significant regional variations in RF			
High-traffic vs. Low-traffic areas		Models show discrepancies in the magnitude of the regional variations.	Input data on air traffic patterns	Improve the quality and resolution of air traffic data used in climate models.
Future RF Projections	Models predict a significant increase in contrail cirrus RF by 2050 due to rising air traffic and flight altitude			
Impact of aviation aerosols		Models show variations in the projected net effect (warming vs. cooling) due to the counteracting impact of aviation aerosols on low-level clouds.	Uncertainties in how models represent aviation aerosol properties and their interactions with clouds.	Conduct dedicated studies to improve the representation of aviation aerosols and their interactions with clouds in climate models.
Cloud Overlap	Overlap with other clouds (natural cirrus, low-level clouds) can affect RF, but the extent of impact (shortwave vs. longwave dominance) is uncertain.	Contrail-contrail overlap is not well understood and might be more frequent in the future.	Need for a better understanding of cloud-contrail and contrail-contrail overlap and their impact on global RF.	Develop improved methods for simulating cloud-contrail and contrail-contrail overlap in climate models. Conduct observational studies to quantify the frequency and radiative effects of contrail overlap.

1314
 1315 The precise testing of models necessitates reliable quantitative data, covering not only information
 1316 on contrail and plume properties but also on contrail age, the generating aircraft, atmospheric
 1317 conditions during contrail formation, and the observational methods employed (Schumann et al.,
 1318 2017). Mean properties of individual contrails are characterized for a wide range of jet aircraft as
 1319 a function of age during their life cycle from seconds to 11.5 h (7.4-18.7 km altitude, -88 to -31°C

1320 ambient temperature), based on a compilation of about 230 in-situ and remote sensing
1321 measurements (Schumann et al., 2017). Contrails from individual aircraft can remain visible for
1322 extended periods, as reported in analyses by Minnis et al. 1998, 2013) and Vázquez-Navarro et al.
1323 (2015). Schumann et al. (2017) furnished a brief description of individual datasets, integrating new
1324 analyses for their study, and combined them to create a "contrail library" (COLI). This dataset was
1325 then compared with the outcomes of the Contrail Cirrus Prediction (CoCiP) model. The
1326 observations corroborate that the quantity of ice particles in contrails is controlled by both the
1327 engine exhaust and the formation process in the jet phase. Some particle losses ensue in the wake
1328 vortex phase, with succeeding gradually diminishes over time.

1329 Publicly available air traffic data are usually limited, but certain projects have gathered flight data
1330 from sources such as air traffic control or ground-based observations (Schumann et al., 2013;
1331 Schumann et al., 2017). Distinguishable projects with air traffic subsets since 2005 are accredited.
1332 Garber et al. (2005) compiled traffic data for the United States and southern Canada for the years
1333 2000-2005. In Germany, the Deutsche Flugsicherung (DFS) has been gathering and filing away
1334 traffic data from 2006 onwards for more new projects. The Aviation and Climate Change Research
1335 Initiative (ACCRI; Brasseur et al., 2016) furnished a global waypoint dataset for the year 2006 to
1336 researchers included in the ACCRI project.

1337 The existing observation datasets on contrail properties and formation conditions are constantly
1338 expanding with the inclusion of innovative resources. The recently developed Global Aviation
1339 Emissions Inventory based on ADS-B (GAIA) (Teoh et al., 2024). leverages historical flight paths
1340 derived from Automatic Dependent Surveillance-Broadcast (ADS-B) technology, coupled with
1341 reanalyzed weather data from 2019 to 2021. GAIA paints a detailed picture of global aviation
1342 activity, encompassing the spatial and temporal variations in flight patterns, fuel consumption, and
1343 emissions of key pollutants like CO₂, NO_x, and particulate matter. This information proves
1344 particularly valuable for contrail research by offering insights into the connections between aircraft
1345 types, flight routes, and the potential for contrail formation in diverse regions. For example, by
1346 analyzing short-haul versus long-haul flight emissions within GAIA, researchers can glean insights
1347 into the contribution of various aircraft categories to contrail formation patterns across different
1348 geographical areas.

1349 By seamlessly integrating GAIA with existing observation datasets like COLI (Schumann et al.,
1350 2017), researchers can cultivate a more nuanced understanding of the interplay between aviation
1351 activity, atmospheric conditions, and contrail occurrence. This enhanced knowledge ultimately
1352 empowers the improvement of contrail prediction models and informs strategies to mitigate their
1353 impact on climate.

1354 Particulars about aircraft assets, including size, mass, speed, fuel consumption, and propulsion
1355 efficiency, were tracked from various references, including the BADA (EUROCONTROL, 2009).
1356 Added engine properties, such as fuel consumption and emissions at surface pressure, can be
1357 attained from the ICAO Aircraft Engine Emissions Databank (EASA, 2023) and the 2006 AEDT
1358 emissions inventory (Barrett, 2010; Wilkerson, 2010).

1359 Poll (2018) devised a straightforward model to estimate fuel burn for commercial aircraft, offering
1360 a transparent, publicly accessible option apart from the BADA and PIANO codes (Piano-X,
1361 software, Lissys Ltd., 2008)). Utilizing this method necessitates understanding the Mach number
1362 and flight level where an aircraft, under specific conditions, achieves its absolute minimum fuel

1363 burn rate. Yet, acquiring this data proves challenging, although an initial effort is outlined in Poll
1364 and Schumann (Poll, 2018), where input files are supplied for 53 aircraft types.

1365 Two sets of observational-based capabilities exist that can provide the coverage needed to help
1366 evaluate the global modeling analyses for treating the effects of contrails, the Contrail Library
1367 (COLI) and the satellite-based record. The Contrail Library results are useful for evaluating limited
1368 areas of contrails but not for global analyses.

1369 **5.1 Contrail Library (COLI)**

1370 The COLI database includes 236 entries describing properties of contrails with known ages,
1371 including mean data for one hundred cases of in-situ measurements, more than 70 cases from
1372 ground-based and airborne lidar observations, 50 cases from satellites, and a few camera
1373 observations. The data come from 33 observation projects during the last 45 years. The comparison
1374 of the data from various measurements shows notable differences among the various instruments
1375 utilized across the dataset. Nevertheless, a notable accord endures among each approach, as well
1376 as uniformity between in-situ and remote sensing results, along with agreement with Schumann et
1377 al (2017) model outcomes. Moreover, in-situ data resultant from contrail measurements, the
1378 investigation integrates remote sensing data found from ground-based or airborne lidar and
1379 spectroradiometer, satellites, cameras, and visual interpretations. Table 10 summarizes some of
1380 the projects that contributed to the COLI database, including the aircraft used and the primary
1381 location, the mode of reference, and the primary reference of the study.

1382 Accurate forecasting of contrail occurrence and persistence holds significant importance in
1383 addressing their potential climate impact. For this purpose, research conducted by Gierens et al.
1384 (2020) underscores the limitations of reanalysis data, primarily due to their coarse vertical
1385 resolution. This study shows the necessity for high-resolution observational data, especially
1386 concerning temperature and relative humidity in the upper troposphere and tropopause region, to
1387 understand contrail formation and behavior better. Initiatives such as the In-service Aircraft for a
1388 Global Observing System (IAGOS) (Gierens et al., 2020) are pivotal in providing such data by
1389 utilizing advanced instruments installed on passenger aircraft. The assessment of contrail
1390 formation models demands dependable data encompassing both contrail characteristics and
1391 atmospheric conditions during their formation. While the study by (Gierens et al., 2020) evaluates
1392 the predictability of contrails using the Schmidt-Appleman criterion based on reanalysis data, it
1393 underscores the critical role of high-resolution data in assessing more advanced contrail prediction
1394 models. The availability of observational datasets containing parameters such as temperature,
1395 relative humidity, and air traffic data, as discussed in this section, is indispensable for such model
1396 assessments.

1397

1398 **5.2 Satellite-based datasets**

1399 Over the past two decades, the detection of contrail in satellite imagery has primarily depended on
1400 the algorithm developed by Mannstein et al. (2003) (e.g., Palikonda et al., 2005; Vazquez-Navarro
1401 et al., 2010). This algorithm contains a series of convolution and thresholding operations related
1402 to brightness temperature images and, subsequently the detection of linear associated components
1403 of fitting size. While the algorithm has been fine-tuned to attain either high precision or high
1404 remembrance in contrail detections, no single model has simultaneously surpassed in both aspects.
1405 Subsequently, empirical observations of contrail coverage often need broad lower-bound/upper-
1406 bound approaches (Duda et al., 2013). Minnis et al. (2013) reported the properties of contrail cirrus

1407 clouds formed during 11 different contrail outbreaks, in the context of objectively determined
1408 linear contrails and their properties. It was observed that the ratio of contrail cirrus to linear
1409 contrails is substantially affected by the satellite analysis algorithm utilized to allocate linear
1410 contrails. Furthermore, this ratio seems to be affected by the presence of overlapping contrails,
1411 which can obscure individual contrails.

1412 The contrail cirrus optical depths were found to be 2-3 times greater than their linear contrail
1413 counterparts and the associated ice crystal particle diameters were 20% greater than the contrail
1414 particle sizes. The analyses of such satellite datasets are likely to be useful for evaluating global
1415 models of contrail radiative effects.

1416 An exception to the application of the Mannstein et al. (2013) algorithm is prominent in Kulik
1417 (2019) and Meijer et al. (2021). These analyses employed a deep learning model for pixel-level
1418 contrail detection using GOES-16 satellite imagery. Upon detecting a contrail, these studies
1419 facilitate the assessment of its lifetime impact and the ascription of potentially relevant flights
1420 (Vazquez-Navarro et al., 2010; Vazquez-Navarro et al., 2013; Vazquez-Navarro et al., 2015.
1421 Mutually, these practices furnish a means to evaluate the efficacy of flight diversions in avoiding
1422 contrail formations. McCloskey et al. (2021) officially released the first large dataset of pixel-level
1423 contrail locations in Landsat-8 satellite imagery labeled by humans. Labelers should be able to
1424 accurately differentiate contrails from naturally occurring cirrus due to Landsat-8's high spatial
1425 resolution and the advected flight history information provided. This dataset will be useful in
1426 benchmarking contrail detection models and validating contrail research in collocated
1427 geostationary satellite imagery.

1428 Satellite-based datasets offer valuable insights into global contrail occurrence and variability,
1429 although challenges arise when estimating contrail radiative forcing. Retrieving contrail optical
1430 thickness, a crucial parameter for such calculations, from current satellite observations, is
1431 particularly difficult. Moreover, distinguishing contrails from overlapping features and natural
1432 cirrus clouds remains challenging, especially with limited spatial resolution. Addressing these
1433 challenges is essential for enhancing the contribution of satellite observations to contrail radiative
1434 forcing estimations. Advancements in retrieval algorithms for contrail optical thickness and
1435 methods to differentiate contrails from overlapping features are necessary for more accurate
1436 assessments.

1437
1438 Despite these challenges, satellite-based contrail datasets have significant potential for monitoring
1439 contrail occurrence and coverage over time. This information is valuable for evaluating the
1440 effectiveness of flight diversion strategies aimed at minimizing contrail formation. Furthermore,
1441 the emergence of human-labeled contrail datasets like McCloskey et al. (2021) provides a valuable
1442 resource for training and validating future advancements in contrail detection using deep learning
1443 and machine learning algorithms. Continuous collaboration among satellite data providers,
1444 atmospheric scientists, and AI researchers is vital for realizing the full potential of satellite-based
1445 contrail datasets for contrail mitigation and climate impact assessments.

1446
1447 Ng et al. (2023) presented a human-labeled dataset named open contrails to train and evaluate
1448 contrail detection models based on GOES-16 Advanced Baseline Imager (ABI) data. Ng et al.
1449 (2023) proposed and evaluated a contrail detection model that incorporates temporal context for
1450 improved detection accuracy. The human-labeled dataset and the contrail detection outputs are
1451 publicly available on Google Cloud Storage at gs://goes_contrails_dataset.

1452 Persuading policymakers and airlines about the climate benefits of flight diversions becomes more
 1453 reasonable with the availability of satellite corroboration capabilities. Geostationary satellites like
 1454 GOES-16 and low-earth orbit satellites such as Landsat-8 present both complementary strengths
 1455 and weaknesses when employed for the task of contrail detection (i.e., coverage versus persistence
 1456 of the observations). An automated contrail detection system is essential for developing and
 1457 evaluating contrail avoidance systems. Deep neural networks can be employed as an automated
 1458 contrail detection system, a form of artificial intelligence (AI) and machine learning (ML), that
 1459 has been advanced to connect and categorize contrails in satellite imagery or other relevant data
 1460 sources. This system can effectively analyze complex patterns and features associated with
 1461 contrails, by leveraging the competencies of deep neural networks. By utilizing deep neural
 1462 networks and machine learning techniques, the automated contrail detection system offers an
 1463 efficient and reliable solution for detecting and monitoring contrails, facilitating further research
 1464 and analysis of their impact on climate and aviation.

1465 **Table 10.** Observations from the year 2000 to 2014 were incorporated into the COLI for the study
 1466 of contrail (Adapted from Schumann et al. 2016).

Year	Project name	Source aircraft	Carrier/location	Measurement	Reference
2000	Cluster	airliners	Great Lakes	satellite	Duda et al.,(2004)
2001	Shutdown	B747+C fighters	Northwestern USA	satellites	Minnis et al.,(2002)
2002	CRYSTAL-FACE	WB-57	NASA WB-57	in situ	Gao et al.,(2006)
2003	Fallstreaks 2003	airliners	Goddard	lidar	Atlas and Wang (2010)
2005	PAZI-2	airliners	DLR Falcon	in situ	Febvre et al.,(2009)
2006	CR-AVE	WB-57	NASA WB-57	in situ	Flores et al.,(2006)
2008	CONCERT	airliners	DLR Falcon	in situ	Voigt et al.,(2010)
2008	ACTA	airliners	Europe andNorth Atlantic	satellite	Vázquez-Navarro et al.,(2015)
2011	CONCERT2011	airliners	DLR Falcon	in situ	Kaufmann et al.,(2014)
2011	COSIC	Bae 146	FAAM Bae-146	in situ	Jones et al.,(2012)
2012	Cameras	airliners	Munich	cameras	Schumann et al.,(2013)
2014	ML-CIRRUS	B772 or F900	HALO	in situ	Voigt et al.,(2016)

1467
 1468 Siddiqui (2020) conducted a study where a neural network was used to distinguish contrail cirrus
 1469 clouds from regular cirrus clouds on TSI images. The study found that the neural network
 1470 triumphed with a high accuracy of 98.5% on the validation set, implying that the model was able
 1471 to learn significant visual features of contrails that differentiate them from regular cirrus clouds.
 1472 The success of this model opens various practical applications for studying contrails. For instance,
 1473 the model can be used to analyze images from different months of data, agreeing for researchers
 1474 to investigate the frequencies of contrail occurrences. This can impart valuable insights into air
 1475 traffic trends, as well as how physical conditions like temperature and humidity vary seasonally
 1476 and their potential impact on contrail formation. Researchers can better understand contrail
 1477 behavior and their relationship with various environmental factors by leveraging the neural
 1478 network’s ability to detect and classify contrails accurately. This knowledge can be used to refine
 1479 models and predictions related to contrail formation and persistence and contribute to a more
 1480 comprehensive understanding of aviation’s impact on the atmosphere.

1481 **6 Supersonic contrails**

1482 Contrail studies have primarily focused on subsonic aviation due to the predominance of subsonic
 1483 air traffic since the retirement of the Concorde in 2003. Contrail formation and persistence for

1484 supersonic commercial aircraft pose challenges -- persistent contrails are unlikely to form in the
1485 stratosphere when these aircraft are flying at supersonic speeds but societal requirements for flying
1486 at subsonic speeds over land to avoid noise issues would still potentially produce persistent
1487 contrails. The importance of understanding the global climate effect of contrails linked to
1488 supersonic aviation is well-established (Stenke et al., 2008). Matthes et al. (2022) recently
1489 published a comprehensive review on the climate effects of supersonic aviation, encompassing
1490 non-CO2 effects like contrail formation. Their work highlights the need for a thorough
1491 understanding of existing research in this area and uncertainties persist regarding parameters
1492 controlling contrail ice crystal distribution evolution for these aircraft. Consequently, the presence
1493 or absence of contrails becomes a discernible marker of the aircraft's speed regime. Additionally,
1494 limited research, such as observations by Schumann et al. (2017) suggested the possibility of
1495 contrail formation even at high altitudes (18.7 km) under specific atmospheric conditions. These
1496 factors highlight the need for a comprehensive understanding of contrail formation and persistence
1497 for future supersonic aircraft.

1498

1499 **7 Uncertainties and Research Gaps**

1500 **7.1 Uncertainties**

1501 There are several crucial areas of uncertainty and research gaps that require focused investigation
1502 to achieve a more comprehensive understanding of contrail formation, evolution, and their effects:

- 1503 • *Humidity Observations and Predictions:* An important uncertainty lies in the accuracy and
1504 reliability of humidity observations and predictions at different altitudes. Improved
1505 measurements and modeling of humidity are critical for assessing the conditions conducive to
1506 persistent contrail formation and their subsequent behavior. Addressing this uncertainty will
1507 lead to more precise insights into contrail persistence and its associated radiative impacts.
- 1508 • *Aircraft Plume Mixing:* Uncertainty persists in referring to how ambient air mixes with the
1509 aircraft plume during contrail formation, comprising uncertainties associated with the rate and
1510 extent of mixing.
- 1511 • *Interaction with Natural Cirrus Clouds:* The interplay between natural cirrus clouds and
1512 contrails initiates an additional level of uncertainty, fostering obscuring the understanding of
1513 their individual and mutual effects on radiative forcing (RF).
- 1514 • *Regional Variations in Atmospheric Conditions:* The sensitivity of contrail radiative impacts
1515 to regional variations in atmospheric conditions is not well understood and remains uncertain.
- 1516 • *Aerosols and Aircraft Emissions:* Uncertainties persist in understanding the role of aerosols
1517 and particles from aircraft emissions in contrail formation and properties.
- 1518 • *Uncertainties and Soot Particles:* The role of soot particles in contrail formation remains
1519 subject to uncertainties, particularly regarding their ability to nucleate ice. Despite the presence
1520 of numerous ice particles in fresh contrails, ongoing debates, as highlighted in recent studies
1521 such as Righi et al. (2021), question whether soot particles directly facilitate ice nucleation.
1522 Clarifying this relationship is essential for comprehending the impact of soot emissions on
1523 contrail formation and subsequent evolution. To address this knowledge gap, further research
1524 efforts are imperative to explore the influence of soot particles on ice nucleation processes
1525 within contrails.
- 1526 • *Radiative Transfer Scheme:* Schumann and Graf (2013) further highlight these complexities
1527 by demonstrating an observed "aviation fingerprint" in cirrus cover and outgoing longwave

1528 radiation (OLR) that aligns with air traffic patterns. Their study estimates a regional longwave
1529 radiative forcing of 600-900 mWm⁻², emphasizing the impact of aviation on cirrus cloud
1530 formation. Additionally, their analysis of the shortwave/longwave forcing ratio underscores
1531 the model's dependence on the global net forcing. These findings resonate with our discussion
1532 on radiative transfer scheme uncertainties, as variations in how models handle radiative
1533 processes can significantly influence the estimated impact of contrails on Earth's energy
1534 balance.

1535
1536 Significant uncertainties persist regarding the radiative forcing caused by aircraft contrails. These
1537 uncertainties arise from numerous factors, starting with uncertainties in the background
1538 meteorology and specific aircraft emissions. When assessing the climate impact of contrail cirrus,
1539 the primary uncertainties lie in (1) determining upper tropospheric water vapor concentrations and
1540 regions of supersaturation; (2) adequately representing contrail cirrus processes in global models;
1541 and (3) understanding the radiative response resulting from the contrail cirrus presence, typically,
1542 only approximate assessments of uncertainties associated with these processes are furnished.

1543 Assessing the radiative response of contrail cirrus involves handling several crucial uncertainties,
1544 including:

1545 *Uncertainties in Contrail Cirrus Radiative Forcing:* Estimating the radiative forcing (RF) of
1546 contrail cirrus clouds is inherently uncertain. Lee et al. (2021) categorizes these uncertainties into
1547 two main areas: (A) uncertainties related to the radiative response of contrail cirrus and (B)
1548 uncertainties associated with the upper-tropospheric water budget and the contrail cirrus scheme
1549 within climate models.

1550 (A) *Uncertainties in Radiative Response*

1551 Radiative Transfer Scheme (A1): Myhre et al. (2009) estimated an uncertainty of approximately
1552 35% arising from the radiative transfer scheme employed in climate models. This scheme
1553 simulates how different wavelengths of radiation interact with various atmospheric components,
1554 including contrail cirrus.

1555 *Cloud Heterogeneity (A2):* The inhomogeneity of ice crystals within a model grid box, vertical
1556 cloud overlap, and limitations of plane-parallel geometry contribute an estimated uncertainty of
1557 35% (Carlin et al., 2002; Pomroy and Illingworth, 2000; Gounou and Hogan, 2007).

1558 *Ice Crystal Habit (A4):* Variations in the shape and form (habit) of ice crystals within contrail
1559 cirrus can significantly impact how they interact with radiation. Markowicz and Witek (2011)
1560 suggest an uncertainty of 20% due to this factor.

1561 *Soot Core Impact (A5):* The radiative transfer uncertainty associated with soot cores embedded
1562 within contrail cirrus ice crystals is significant, particularly for shortwave albedo (reflectivity), but
1563 remains unquantified (Liou et al., 2013). Soot cores can absorb radiation, potentially leading to a
1564 warming effect that is not currently accounted for in models.

1565 (B) *Uncertainties in Water Budget and Contrail Cirrus Scheme*

1566 *Ice Supersaturation (B1):* Uncertainties in the representation of upper-tropospheric ice
1567 supersaturation (Lamquin et al., 2012) contribute an estimated 20% uncertainty.

1568 *Ice Crystal Number Density (B2):* and Radiative Transfer for Young Contrails (A3): Uncertainties
1569 in ice crystal number densities (Karcher et al., 2015, 2018) are linked to factors like water vapor
1570 saturation and soot emissions. Lee et al. (2021) recognized the dependence between A3 (radiative

1571 transfer for young contrails) and B2 (ice crystal number density). Consequently, they included the
1572 uncertainty from A3 within their overall category B uncertainty estimate.

1573 *Contrail Cirrus Lifetime* (B3): The effect of contrail cirrus lifetime on estimated RF is relatively
1574 small, with an associated uncertainty estimated at 5-10% (Chen and Gettelman, 2013; Newinger
1575 and Burkhardt, 2012). While Lewellen (2014) highlights the potential importance of lifetime
1576 through large-eddy simulations demonstrating contrail cirrus lifetimes exceeding 40 hours and
1577 widths exceeding 100 km, several factors contribute to the seemingly counterintuitive finding in
1578 this context of estimated RF. Lewellen's (2014) simulations highlight the potential significance
1579 of contrail cirrus with extended lifetimes, particularly for their ice crystal surface area and overall
1580 radiative impact. However, the study focuses on the integrated effect over the entire lifetime,
1581 whereas the uncertainty estimate (5-10%) pertains to the impact of variations in lifetime on the
1582 average RF. Further research is needed to better understand the complex interplay between contrail
1583 cirrus lifetime, ice crystal growth processes, atmospheric conditions, and their combined effect on
1584 radiative forcing.

1585 *Air Traffic Data Resolution* (B4): Sensitivity studies suggest an uncertainty of about 10% arising
1586 from the temporal resolution of air traffic data used in climate models (Lee et al., 2021).

1587 *Natural Cloud Feedback* (B5): The feedback mechanism by which contrail cirrus alters the upper
1588 tropospheric water budget, affecting natural clouds, introduces a significant uncertainty that
1589 remains unquantified (Burkhardt and Karcher, 2011; Schumann et al., 2015). Lee et al. (2021)
1590 assumed an uncertainty of 15% for this factor.

1591 *Initial Ice Crystal Assumptions* (B6): The estimation of RF by Chen and Gettelman (2013) is
1592 subject to uncertainties associated with assumptions about initial ice crystal radii and contrail
1593 cross-sectional areas, leading to an estimated uncertainty of 33%.

1594 Overall Uncertainty

1595 Following Lee et al. (2021), the uncertainty in the radiative response to contrail cirrus (excluding
1596 soot cores) is estimated to be around 55%, assuming independence of different uncertainties. This
1597 aligns with their findings and highlights the dominance of radiative response uncertainties
1598 (category A) in the overall uncertainty budget. Category B uncertainties (water budget and contrail
1599 cirrus scheme) remain significant and require further investigation, particularly the combined
1600 effect of ice crystal number density and radiative transfer for young contrails.

1601 **7.2 Research needs and gaps**

1602 In the pursuit of a comprehensive understanding of contrail impacts on climate, there is a critical
1603 need to establish clear research needs and requirements.

1604 Improving weather models demands better predictions of humidity and clouds with enhanced
1605 resolution in time, space, and altitude. The models must also adapt to evolving weather conditions.
1606 Accurate water vapor data during cruise altitudes is crucial, emphasizing the need for small, cost-
1607 effective humidity sensors. To achieve this, there is a need for the production, testing, and
1608 evaluation of precise sensors. Lidar technology and weather model assessments play a key role in
1609 advancing observational capabilities for more accurate predictions. Enhancing cirrus cloud
1610 forecasts requires a dual focus on data and artificial intelligence. Ensemble simulations are vital
1611 for estimating uncertainties in cirrus cloud predictions. Additionally, there is an urgent need for
1612 more climate and contrail models, ensuring a comprehensive understanding and evaluation of these
1613 complex atmospheric processes. Furthermore, research by Ovarlez et al. (2000) highlights

1614 discrepancies between measured water vapor content and data from weather forecasts. Their
1615 findings emphasize the importance of accurate humidity measurements, particularly for studies on
1616 contrail formation and persistence. Weather forecasts might underestimate actual humidity,
1617 potentially leading to inaccurate assessments of contrail behavior. This underlines the need for
1618 ongoing research to improve the accuracy of humidity data in weather models.

1619 Furthermore, high-quality observations, effectively integrated into weather models, are crucial for
1620 setting accurate starting points for forecasts (Bauer et al., 2015). This highlights the need for robust
1621 data collection strategies that combine information from diverse sources. These sources can
1622 include in-situ measurements taken directly within the atmosphere, radar systems that track
1623 precipitation patterns, and satellite sensors that provide a global view. Advanced data assimilation
1624 techniques then play a vital role by merging these observations with model outputs. This combined
1625 approach creates a more precise picture of the initial atmospheric state, ultimately leading to
1626 improved weather forecasts (Bauer et al., 2015).

1627 Sun and Roosenbrand (2023) reported the limitations in traditional computer vision approaches
1628 for contrail detection, particularly in handling the complexity of satellite images under varying
1629 conditions. Earlier machine learning methods relied on simpler convolutional neural network
1630 models, primarily demanding extensive labeled data for contrail presence determination. Notably,
1631 there is a gap in the existing literature, lacking research specifically tailored to machine learning
1632 approaches for contrail detection, setting it apart from other image segmentation or detection tasks.
1633 A significant challenge lies in the absence of adequate loss functions optimized for linear features
1634 like contrails during training, making detection notably difficult at lower resolutions, especially
1635 when multiple contrails are close. Addressing these gaps is crucial for advancing the efficacy of
1636 contrail detection methods (Sun and Roosenbrand, 2023).

1637 While a complete understanding of contrail effects on climate may not be achievable, further
1638 research is crucial to reduce uncertainties and improve our ability to predict and mitigate their
1639 impact. Here are some of the key areas of research gaps that should be explored to address existing
1640 uncertainties:

- 1641 ▪ *Properties of Contrail Particles:* Understanding contrail effects on climate requires
1642 reflection of key factors such as particle size, layer height, cloud overlap, and optical
1643 properties. Larger particles tend to have a different radiative impact than smaller ones. The
1644 altitude of contrail formation impacts their interaction with solar and terrestrial radiation.
1645 Precise climate modeling requires proper accounting for cloud overlap, impacting radiative
1646 calculations. Contrail optical properties, comprising albedo and emissivity, determine their
1647 reflective and trapping abilities for solar and terrestrial radiation. The concentration and
1648 size distribution of contrail particles affect their formation and radiative impact. Accurate
1649 estimation of contrail forcing, important for climate modeling and policy decisions,
1650 depends on understanding particle number, size, and layer height.
- 1651 ▪ *Assessment of Effective Radiative Forcing:* Effective Radiative Forcing (ERF) is a valuable
1652 tool for evaluating the global mean radiative impact of contrail cirrus on climate. However,
1653 it's important to recognize that ERF primarily focuses on this average effect and may not
1654 fully capture regional variations or complex feedback mechanisms associated with contrail
1655 formation and persistence.
- 1656 ▪ *Emissions and Alternative Fuels:* Corroborating a precise connection between soot and
1657 contrail ice crystal numbers is important for understanding the environmental impact of
1658 sustainable aviation fuels, such as biofuels. Biofuels are being studied as a more sustainable

1659 alternative to conventional aviation fuels, and evaluating their impact on contrail formation
1660 is crucial for assessing environmental benefits. Scientific research, notifying regulatory
1661 decisions, relies on the interpretation of the correlation between soot and ice crystal
1662 numbers. This connection is integral for complete visions of the environmental
1663 implications of alternative aviation fuels. Precise data on contrail formation, containing the
1664 impact of biofuels, is crucial for climate models predicting the impact of aviation emissions
1665 on climate. The experimental establishment of the soot-ice crystal connection gives this
1666 understanding.

1667 ■ *Properties of Soot Particle:* A study into the bimodal size distributions of soot particles in
1668 aircraft emissions is critical for focusing uncertainties on contrail formation and properties,
1669 with inferences for climate science and aviation practices. In-flight measurements uncover
1670 that freshly emitted soot particles usually exhibit a single peak in number-size distributions,
1671 but some cases play a second, larger particle mode in near-field contrails and dry plumes.
1672 The source of this larger mode remains uncertain, signifying that the bimodal distribution
1673 may survive in unrefined jet engine emissions rather than be caused by contrail processing
1674 or coagulation during plume development. Precise data on soot particle properties is
1675 essential for climate models incorporating contrail outcomes, and resolving the origin of
1676 bimodal size distributions is crucial to improving model representations of contrail
1677 properties. Policymakers and regulatory bodies rely on scientific research for progressing
1678 aviation-related environmental policies, making an understanding of soot particle size
1679 distributions significant for up-to-date decision-making.

1680 A study into the bimodal size distributions of soot particles in aircraft emissions is critical
1681 for focusing uncertainties on contrail formation and properties, with inferences for climate
1682 science and aviation practices (Schumann et al., 2002). In-flight measurements typically
1683 show a single peak in the number-size distribution of freshly emitted soot particles
1684 (Schumann et al., 2002). However, some cases reveal a second, larger particle mode in
1685 near-field contrails and dry plumes. The source of this larger mode remains uncertain,
1686 suggesting that the bimodal distribution might be present in unrefined jet engine emissions
1687 rather than being solely caused by contrail processing or coagulation during plume
1688 development (Schumann et al., 2002). Precise data on soot particle properties, including
1689 any potential bimodal size distribution, is essential for climate models incorporating
1690 contrail effects. Resolving the origin of this bimodal distribution is crucial to improving
1691 model representations of contrail properties. Policymakers and regulatory bodies rely on
1692 scientific research for progressing aviation-related environmental policies, making an
1693 understanding of soot particle size distributions significant for up-to-date decision-making.

1694

1695 ■ Examining the microphysical interaction between soot particles and contrail ice crystals
1696 emerges as a critical research priority. Laboratory experiments simulating contrail
1697 formation conditions offer valuable insights into the ice nucleating potential of soot
1698 particles under controlled environments. Moreover, field measurements focusing on the
1699 in-situ characterization of soot particles and ice crystals within nascent contrails provide
1700 indispensable data for validating models. By integrating these methodologies, researchers
1701 can advance their understanding of the role of soot particles in contrail formation and
1702 refine climate models accordingly.

1703

1704 ▪ *Remote Sensing for Contrail-Cirrus*: Organized regional campaigns are important for
1705 estimating key variables in aging contrail-cirrus and aircraft plumes. This contains in-situ
1706 and remote sensing to portray the growth, decay, and trajectories of contrail ice particles,
1707 delivering essential data for interpretation of transformation and radiative effects.
1708 Estimation of contrail particles, ambient aerosols, and gaseous aerosol precursors notifies
1709 climate modeling and environmental assessments, connecting emissions to contrail
1710 properties. Gathered data validates climate models, enhancing their accuracy and
1711 improving the representation of contrail-cirrus effects. Understanding contrail-cirrus
1712 development supports developing mitigation strategies, informing contrail avoidance, and
1713 reducing aviation's climate impact.

1714 In addition to these research issues, there is a need to bridge the gaps with the assessment of the
1715 above-reported uncertainties and to investigate and improve the understanding of contrail
1716 avoidance and climate tradeoffs. Research should explore how to mitigate the climate impact of
1717 contrails without compromising aviation safety and efficiency.

1718 **7.3 Contrail avoidance and climate tradeoffs**

1719 While existing studies explore contrail avoidance strategies and their impact on fuel burn and
1720 climate, a comprehensive large-scale evaluation remains elusive. Ideally, such an evaluation would
1721 encompass a significant number of routes, account for weather variations, enable full flight level
1722 optimization, quantify contrail impacts on individual flights, and compare results to a fuel-optimal
1723 baseline to isolate the specific effects of contrail avoidance. This comprehensive approach would
1724 provide a more definitive understanding of the fuel-climate tradeoffs associated with contrail
1725 avoidance strategies.

1726 Recent studies investigating targeted contrail avoidance strategies offer promising results. Teoh et
1727 al. (2020) suggest that focusing on a small percentage of flights with the highest contrail impact
1728 could be an effective approach, minimizing the overall increase in fuel consumption and CO₂
1729 emissions. Additionally, advancements in engine design hold promise as a long-term solution for
1730 reducing contrail formation.

1731 Molloy et al. (2022) address a critical step towards implementing effective contrail avoidance
1732 strategies in practice. Their work outlines the practical considerations for conducting large-scale
1733 trials, which are essential for evaluating the feasibility and effectiveness of these strategies in real-
1734 world conditions. The proposed deployable options based on existing air traffic management
1735 processes offer a promising path forward for initiating such trials.

1736 Frias et al. (2024) present a compelling case for the practicality and economic viability of contrail
1737 avoidance. Their findings demonstrate that significant reductions in contrail climate impact can be
1738 achieved with minimal operational burdens. This study provides strong motivation for airlines and
1739 air traffic controllers to embrace contrail avoidance strategies as a means to reduce aviation's
1740 overall climate footprint.

1741 Gierens et al. (2008) proposed several potential ways to mitigate the impact of contrails,
1742 encompassing both technical and operational approaches. Regarding the technical aspect, they
1743 recognized the challenge of completely preventing contrail formation due to its primarily
1744 thermodynamic nature. However, they suggested the exploration of new engine cycles and
1745 technical infrastructures that might help suppress contrails. Additionally, reducing the number of
1746 emitted particles was considered to mitigate contrail formation. While such evaluations would not

1747 eliminate contrails completely, they would produce thinner contrails with rarer but larger crystals.
1748 These heavier ice crystals would incline more rapidly on average, causing shorter contrail
1749 lifetimes. The analysis also investigated operational mitigation options. Striking strict constraints,
1750 such as fixed maximum flight levels, was studied unreasonably due to the significant challenges it
1751 would pose for air traffic controllers and the resulting safety concerns. Their proposed strategies
1752 focused on addressing contrail formation both at the technical level through engine and
1753 infrastructure improvements and at the operational level by implementing flexible measures that
1754 consider real-time weather conditions. These approaches aimed to strike a balance between
1755 contrail reduction and the practical needs of aviation.

1756 In a recent study, Sausen et al. (2023) presented an experiment that aimed to avoid contrail
1757 formation during real-world operations. This experiment took place in the Maastricht Upper Area
1758 Control region, covering parts of Germany, the Benelux countries, and the North Sea, in the year
1759 2021. The researchers highlighted that contrail avoidance could serve as an effective method for
1760 mitigating the climate impact of aviation. To conduct their trial experiment, air traffic was
1761 deliberately diverted every other day by adjusting the flight altitude, either increasing or decreasing
1762 it by up to 2000 ft, whenever potential persistent contrails were predicted. The effectiveness of
1763 these deviations was assessed by analyzing satellite images of high clouds and employing a
1764 contrail detection algorithm that utilized contrail properties. Despite the ongoing challenge of
1765 accurately forecasting persistent contrails, the trial achieved a significant level of success, reaching
1766 97.5%, suggesting that on average, persistent contrails can be avoided during regular flights in the
1767 real world through minor adjustments in the vertical flight path. Contrail avoidance through minor
1768 adjustments in flight paths represents a practical approach to mitigate the formation of persistent
1769 contrails. It demonstrates the feasibility of implementing such measures within air traffic
1770 management to reduce the environmental impact of aviation. The study highlights the potential for
1771 real-world applications of contrail avoidance as a means of addressing the climate effects of
1772 contrails. The findings of this experiment mark an important milestone in implementing
1773 operational measures in air traffic management to decrease the impact of climate from aviation.

1774 The limitations of simply avoiding all contrails become evident when we consider their diverse
1775 climate effects. While some contrails can have a net cooling effect, others contribute to warming.
1776 This distinction necessitates a more nuanced approach to contrail avoidance. We should focus on
1777 mitigating the formation of contrails that contribute to warming, while potentially allowing or even
1778 encouraging the formation of those with a net cooling effect. This distinction requires reliable
1779 methods for differentiating between the two contrail types.

1780 *Future considerations: optimizing contrail avoidance.*

1781 The Sausen et al. (2023) study represents a significant step forward, demonstrating the feasibility
1782 of operational contrail avoidance through minor flight adjustments. To optimize this approach for
1783 maximum climate benefit, future research should focus on three key areas:

1784 *Distinguishing warming from cooling contrails:* Developing robust methods to differentiate
1785 between these contrail types is crucial. Improved weather forecasting models and contrail
1786 prediction algorithms that consider factors like altitude, atmospheric conditions, and cirrus cloud
1787 cover can contribute to this goal.

1788 *Large-scale implementation:* Evaluating the broader applicability of contrail avoidance strategies
1789 necessitates conducting large-scale trials across diverse airspace with varying weather patterns.

1790 This will provide a more comprehensive understanding of the effectiveness and potential trade-
1791 offs associated with contrail avoidance in different operational contexts.

1792 *Integration with air traffic management:* For widespread adoption, efficient protocols for
1793 integrating contrail avoidance measures within existing air traffic management systems are
1794 essential. This may involve developing streamlined decision-making tools and communication
1795 channels for air traffic controllers and pilots.

1796 By addressing these considerations, contrail avoidance can evolve from a general strategy to a
1797 targeted approach that maximizes its potential for mitigating aviation's climate impact. This
1798 approach would focus on reducing the formation of warming contrails while allowing for or even
1799 encouraging the formation of cooling contrails.

1800 In a recent Ph.D. thesis, Elmourad (2023) evaluated the fuel-climate tradeoffs arising from contrail
1801 avoidance strategies applied on a large scale. This study raises several key questions about
1802 contrails avoidance: What fraction of aviation's global total contrail length can be avoided using
1803 vertical re-routing exclusively? What is the fuel penalty of such an avoidance strategy? How does
1804 the fuel penalty or contrail reduction vary between flights or seasons? Can the fuel penalty be
1805 constrained? What effect does that have on the ability to do contrail avoidance? What net climate
1806 benefit can be achieved from contrail avoidance strategies? How does this differ from avoiding all
1807 contrails or only nighttime contrails? What are the relative orders of magnitude between the
1808 climate benefits from contrail avoidance and the climate damages from additional fuel burn? How
1809 does this difference compare with the uncertainties associated with contrail impacts?

1810 As the global volume of air traffic continues to rise, the aviation industry grapples with a
1811 significant challenge in mitigating its environmental impact on climate change. Contrails, which
1812 contribute to global warming by trapping terrestrial radiation, have the potential to counteract the
1813 benefits of reduced emissions resulting from optimized flight paths. In a study by Roosenbrand et
1814 al. (2023), the authors conducted a global assessment of flights that contribute to contrail formation
1815 and assessed the altitude adjustments required to avoid these contrail-prone areas. This analysis
1816 utilized a combination of data from the Integrated Global Radiosonde Archive (IGRA), which
1817 provides measurements from weather balloons with global coverage and high vertical resolution,
1818 and flight data from OpenSky. The study identified Mid-Western Europe, the Eastern United States
1819 of America, and Japan as regions characterized by both high air traffic volumes and a substantial
1820 percentage of flights forming contrails. Importantly, these regions offer opportunities for altitude
1821 adjustments of less than one kilometer to minimize contrail formation. The research also
1822 pinpointed other regions where relatively minor operational interventions could yield significant
1823 climate benefits.

1824 *Fuel-climate tradeoffs:* While there have been numerous studies on operational contrail avoidance,
1825 there are still some research gaps in the field when it comes to understanding the fuel-climate
1826 tradeoffs that would follow a large-scale global application of contrail avoidance strategies.

1827 *Sustainable Aviation Fuel (SAF):* Much still needs to be understood about what SAF will look like
1828 as it becomes the dominant fuel of the future. The emissions of soot and other particles from SAF
1829 are still not well understood and will have a significant effect on future contrail production and
1830 lifetimes. According to Bräuer et al. (2021b), sustainable aviation fuels have been identified as
1831 capable of reducing both contrail ice numbers and the radiative forcing caused by contrail cirrus.
1832 Their study involved the measurement of apparent ice emission indices across different fuels with
1833 varying aromatic content at altitudes ranging from 9.1 to 9.8 km and 11.4 to 11.6 km. The data

1834 were collected during the ECLIF II/NDMAX flight experiment in January 2018, encompassing a
1835 variety of fuels differing in aromatic quantity and type. A comparison between a sustainable
1836 aviation fuel blend and a reference fuel Jet A-1 revealed a maximum reduction of 40% in apparent
1837 ice emission indices, highlighting the potential impact of sustainable aviation fuels on mitigating
1838 contrail-related environmental effects.

1839 Moore et al. (2017) investigated the effects of using a biofuel blend, as opposed to traditional jet
1840 fuel, on these aircraft emissions. Their findings revealed a notable decrease in both the quantity
1841 and weight of particles discharged from aircraft engines when the biofuel blend was employed.
1842 This discovery implies that integrating biofuels into aviation practices could offer a viable
1843 approach to mitigating the environmental footprint of air travel on climate change.

1844 Moore et al. (2017) utilized measurements of particle size distributions to examine the variations
1845 between the reductions in number and mass emissions indices for the two types of fuels. A
1846 significant decrease in both total and non-volatile particle number and volume was observed with
1847 the biofuel blend, accompanied by a slight shift towards smaller sizes in the peak diameter of the
1848 mode, ranging from 3 to 5 nm for number distributions and 9 to 12 nm for volume distributions.
1849 This shift appears to be driven by a more substantial reduction in the number of larger soot-mode
1850 aerosols, which act as condensation nuclei for organic species and sulfuric acid. Since gas-to-
1851 particle condensation is proportional to particle size (specifically, to the square of the diameter in
1852 the free molecular regime), the reduced emission of the soot size mode from the biojet fuel blend
1853 decreases the condensational sink, thereby enhancing the nucleation of new particles in a
1854 compensatory manner. This interplay is evident in the size-dependent reductions in number
1855 emissions. Their study found that blending petroleum-based fuels with a HEFA biojet fuel leads
1856 to a reduction in both volatile and non-volatile particle emissions by 50%–70% under atmospheric
1857 cruise conditions. However, the emissions indices for soot particle numbers remain in the soot-
1858 rich regime (around 10^{14} kg^{-1}) for the biofuel blend. Theoretical calculations suggest that the initial
1859 number of contrail ice particles increases linearly with the soot number emissions index in the
1860 soot-rich regime, and that ambient and ultrafine particles are unlikely to contribute significantly to
1861 contrail formation.

1862 *Alternative aircraft and new fuels:* There is a lot of ongoing discussion about the potential
1863 development of aircraft using hydrogen as fuel. Such an aircraft engine would still emit water
1864 vapor and therefore could produce contrails. However, the major reduction in particulates, e.g., no
1865 soot, could affect the lifetime of the contrail and whether it could result in contrail cirrus. Research
1866 is needed to evaluate the potential for contrail production and resulting lifetimes. Other alternative
1867 fuels would also need to be evaluated.

1868 There is a necessity for government research organizations as well as industry partners to venture
1869 into the investigation and establishment of sensor prototypes. An example is a humidity sensor
1870 prototype with a range of great precision covering 20 parts per million by volume to more than
1871 10,000 ppmv. The purpose is to improve the accuracy of measurements, especially on parameters
1872 like temperature and relative humidity, at altitudes preserved during flight to counteract contrail
1873 mitigation. Additionally, improving measurement at lower altitudes is vital for improving the
1874 precision of weather forecasting. This accumulated data will play a pivotal role in evaluating and
1875 integrating these insights into forecast models, enhancing the robustness of these calculations. An
1876 additional area of focus is the refinement of model calculations on the impact of contrails,
1877 necessitating improved handling of variables such as clouds, aerosols, and specific aircraft
1878 characteristics.

1879 Tackling the pressing challenge of climate change requires the exploration and adoption of
1880 effective contrail mitigation strategies. Recent studies show promise in the utilization of alternative
1881 fuels, particularly sustainable aviation fuels (SAFs), which boast lower soot particle emissions
1882 compared to conventional jet fuel. Initial flight trials have shown a marked decrease in contrail
1883 formation when SAFs are used, potentially attributed to the reduced concentration of ice nucleation
1884 particles in SAF exhaust. Moreover, ongoing research focuses on optimizing flight path planning
1885 and air traffic management (ATM) to minimize contrail formation and persistence. Research
1886 conducted by Sausen et al. (2023) demonstrates the feasibility of contrail avoidance through minor
1887 adjustments in flight paths during real-world operations. Continued progress and application of
1888 these strategies, coupled with advancements in contrail observation technologies such as high-
1889 precision humidity sensors, offer significant potential to mitigate the climate impact of aviation.
1890

1891 **8 Conclusions**

1892 This study reviews the current understanding of the impacts of contrail formation by aircraft on
1893 the Earth's climate system; it provides insights into the current state of contrail research, offering
1894 perspectives on contrail formation, characteristics, life cycle, and potential future impacts. The
1895 study underscores the importance of confronting uncertainties in climate models and emphasizes
1896 the need for further research to enhance our understanding of contrail effects.

1897 Aviation emissions, encompassing both contrail cirrus clouds and carbon dioxide emissions, exert
1898 an important influence on the Earth's climate. Extensive research efforts have significantly
1899 improved our understanding of contrail formation and aging; however, key microphysical
1900 processes remain a subject of ongoing investigation. Our examination of global observational data
1901 and projections highlights the potential for a significant increase in contrail cirrus radiative forcing
1902 by the mid-21st century, driven by factors such as anticipated growth in air traffic, potential
1903 improvements in fuel efficiency, and evolving atmospheric conditions. While uncertainties
1904 regarding the precise magnitude of this increase exist, the potential consequences necessitate
1905 proactive mitigation strategies. Several promising approaches are being explored, including
1906 operational measures to optimize flight paths, the development of new contrail suppression
1907 technologies, and the adoption of sustainable aviation fuels. Implementing a combination of these
1908 strategies, while continuously refining our understanding of contrail effects, is crucial for
1909 minimizing the overall climate impact of aviation.
