17 **Abstract.** Oceanic eddies are ubiquitous features of the circulation through to be involved in transporting water  
18 mass properties over long distances from their source region. Among these is a particular type with a core  
19 within the thermocline with little signature visible from space. Despite their significance, their role in the ocean  
20 circulation remains largely undocumented from observations. This study characterizes the variations in internal  
21 biogeochemistry, disparities with external properties, and processes influencing the dissolved oxygen budget  
22 of Poleward undercurrent eddies (PUDDIES) during their transit to oceanic waters. Employing a high-  
23 resolution coupled simulation of the Southeast Pacific, we scrutinize eddy dynamics and biogeochemical  
24 processes associated with the nitrogen cycle, including characteristic mechanisms of Eastern Boundary  
25 Upwelling Systems (EBUS) such as denitrification. Our findings reveal that Puddies capture a biogeochemical  
26 signal contingent upon their formation location, particularly associated with the core of the Peru-Chile  
27 Undercurrent at the core of the Oxygen Minimum Zone (OMZ). While permeability at the periphery facilitates  
28 exchange with external waters, thereby modulating the original properties, the core signal retains negative  
29 oxygen (O<sub>2</sub>) anomalies and positive anomalies of other biogeochemical tracers. These disturbances likely  
30 contribute to average properties that exceed the 90<sup>th</sup> percentile threshold in the open ocean, contrasting with  
31 the formation zone where they surpass 50<sup>th</sup> percentile levels. Suboxic cores are prevalent near the coast but  
32 decrease in abundance with distance from shore, giving way to a predominance of hypoxic cores, indicative of  
33 core ventilation during transit. The principal mechanism governing O<sub>2</sub> input into, or output from the eddy core  
34 entails lateral and vertical advection, with vertical mixing supplying O<sub>2</sub> to a lesser extent. Biological activity  
35 consumes O<sub>2</sub> for approximately 6 to 12 months more intensely the first 100 days, thereby facilitating the  
36 persistence of low O<sub>2</sub> conditions and extending the lifetime of biogeochemical anomalies within the core. The  
37 ammonium and nitrite depleted out of time in the eddy core with a decay rate greater than the nitrate and nitrous  
38 oxide, while these are accumulating in open sea. Our observations suggest that southern regions of the southeast  
39 Pacific OMZ undergo greater deoxygenation and nutrient enrichment due to Puddies compared to northern

40 regions. This underscores the significant role of Puddies in modifying biogeochemical conditions in the open  
41 ocean and in extending the boundaries of the Southern tip of the OMZ.

42

### 43 **1 Introduction**

44 Oxygen plays a fundamental role for life in the ocean, and numerous processes regulate its concentration in  
45 the water column. In subsurface waters (100-800 m depth), oxygen concentrations ( $O_2$ ) decrease significantly  
46 due to the abundance and decomposition of organic matter and limited ventilation, leading to the formation  
47 of oxygen minimum zones (OMZ) in eastern boundary upwelling systems (EBUS; Wyrki, 1962; Helly &  
48 Levin, 2004; Karstensen et al., 2008; Paulmier & Ruiz-Pino, 2009; Stramma et al., 2010). Under these  
49 conditions, heterotrophic metabolic processes prevail, dominated by activity of bacteria and archaea,  
50 resulting in significant shifts in biogeochemical cycles when  $O_2$  fall below 20  $\mu M$ .

51 The nitrogen cycle manifests in the oceans through various chemical species with different oxidation states.  
52 Outside the OMZ, where conditions are oxygenated, dinitrogen ( $N_2$ ) is transformed into ammonium ( $NH_4^+$ ),  
53 nitrite ( $NO_2^-$ ), and nitrate ( $NO_3^-$ ) through nitrification, with nitrous oxide ( $N_2O$ ) formed as a byproduct.  
54 However, within the OMZ, where  $O_2$  is depleted, nitrate becomes the primary oxidant, triggering  
55 denitrification. In this process, nitrate is reduced to gaseous forms ( $N_2$  and  $N_2O$ ), which can then be released  
56 into the atmosphere. This process has implications for primary production, carbon sequestration, and the  
57 release of  $N_2O$  into the atmosphere, a potent greenhouse gas (Goreau et al., 1980; Mantoura et al., 1993;  
58 Sarmiento & Gruber, 2006; Lam et al., 2009; Paulmier & Ruiz-Pino, 2009; Wright et al., 2012).

59 The southeast Pacific Ocean is the site of one of the most extensive and shallow OMZs (Paulmier & Ruiz-  
60 Pino, 2009), where anoxic conditions can even be observed (Ulloa et al., 2012). Several authors have  
61 determined the vertical and zonal extent of the OMZ, which exhibits significant seasonal variability,  
62 modulated both meridionally by subsurface currents towards the pole, and zonally by mesoscale processes  
63 (jets, eddies, fronts, filaments, etc.; Bettencourt et al., 2015; Chaigneau et al., 2011; Grados et al., 2016;  
64 Hormazabal et al., 2013; Morales et al., 2012; Stramma et al., 2013; Vergara et al., 2016; Pizarro-Koch et al.,  
65 2019). These processes result in changes in water mass properties, and together contribute up to a 25%  
66 reduction in  $O_2$  volume during spring (Pizarro-Koch et al., 2019).

67 Furthermore, future projections suggest the expansion of these  $O_2$  depleted zones through the global warming  
68 (Matear & Hirst, 2003; Stramma et al., 2010; Oschlies et al., 2018). Various mechanisms can potentially  
69 modify ventilation processes, leading to changes in subsurface water properties. The increase in sea surface  
70 temperature will affect  $O_2$  solubility, and enhanced water column stratification will impact a range of  
71 biological processes that influence  $O_2$  concentrations (Couespel et al., 2019; Keeling et al., 2010; Matear &  
72 Hirst, 2003; Oschlies et al., 2018; Schmidtko et al., 2017). The key role of turbulent dynamics in the  
73 functioning of OMZs is not considered in the current generation of climate models, limiting confidence in  
74 their projections, this is why understanding the role of mesoscale dynamics on the  $O_2$  and carbon cycles in  
75 EBUS has been a major concern of the community.

76 **'Poleward undercurrent eddies'** (Puddies) are types of subsurface or intrathermocline eddies characterized by  
77 coherent anticyclonic lenticular shaped vortices with cores located within the pycnocline and relatively  
78 homogenous interior waters (Dugan et al., 1982; McWilliams, 1985; Kostianoy and Belkin, 1989). Puddies  
79 originate in the Eastern Boundary Upwelling Systems (EBUS, Frenger et al., 2018) due to the interaction of  
80 the poleward-flowing current with the continental slope, generating submesoscale instabilities with  
81 anticyclonic vorticity, subsequently forming these characteristic mesoscale structures (Hormazabal et al.,  
82 2013; Combes et al., 2015; Molemaker et al., 2015; Thomsen et al., 2016; Contreras et al., 2019). These  
83 eddies represent 30-55% of the anticyclone eddies originating in the EBUS (Pegliasco et al., 2015; Combes  
84 et al., 2015) with cores that are warmer, saltier, O<sub>2</sub>-depleted, and nutrient-enriched relative to surrounding  
85 waters (Collins et al., 2013; Hormazabal et al., 2013; Morales et al., 2012; Johnson and McTaggart, 2010).  
86 Therefore, Puddies can play a crucial role in transporting these water properties hundreds or thousands of  
87 kilometers offshore to subtropical gyres, contributing to the expansion of the OMZ beyond the coastal region  
88 (Frenger et al., 2018). Observations of low O<sub>2</sub> events in open ocean regions provide support for this idea  
89 (Lukas and Santiago-Mandujano, 2001; Johnson and McTaggart, 2010; Schütte et al., 2016b; Stramma et al.,  
90 2013, 2014; Karstensen et al., 2015), with further evidence of biogeochemical processes typically observed  
91 only in the OMZ, such as N<sub>2</sub>O production (Cornejo et al., 2015; Arévalo-Martínez et al., 2016; Grundle et al.,  
92 2017) and nitrogen loss through denitrification (Altabet et al., 2012; Löscher et al., 2015). Additionally, the  
93 observed O<sub>2</sub> utilization rates within the eddy cores range from 0.29 to 44 nmol O<sub>2</sub> L<sup>-1</sup> d<sup>-1</sup>, which is up to 3 to  
94 5 times higher than in the surrounding waters (Cornejo et al., 2015; Karstensen et al., 2015). There is  
95 evidence of harboring microbial communities and metabolisms associated with low-oxygen environments  
96 that persist even when the eddies enter highly oxygenated waters, a phenomenon known as the "stewpot  
97 effect" (Löscher et al., 2015; Frenger et al., 2018).

98 The Southeast Pacific (SEP) is characterized by extensive subsurface mesoscale eddy activity with radii  
99 ranging from ~25 to ~50 km and cores of ~500 m of vertical extent (Chaigneau et al., 2009; Hormazabal et  
100 al., 2013; Combes et al., 2015, Frenger et al., 2018). They transport a total volume of approximately 1 Sv (1  
101 Sv = ~1x10<sup>6</sup> m<sup>3</sup> s<sup>-1</sup>) westward with an average velocity of ~2 km d<sup>-1</sup> (Hormazabal et al., 2013). The cores of  
102 these eddies exhibit homogenous salinity profiles (>34.5) and low O<sub>2</sub> concentrations (< 1.0 mL L<sup>-1</sup>), linking  
103 them to Equatorial Subsurface Water (ESSW) transported poleward by the Peru-Chile Undercurrent (PCUC;  
104 Hormazabal, 2004; Colas et al., 2012; Hormazabal et al., 2013). Generally, the low values of O<sub>2</sub> in  
105 subsurface eddies is related to higher concentrations of nitrate, phosphate, and silicate (Czeschel et al.,  
106 2015). However, under suboxic conditions (O<sub>2</sub> < 20 μM), the prevailing anaerobic metabolism is  
107 denitrification, where nitrate is utilized as an electron acceptor, leading to increased production of NO<sub>2</sub><sup>-</sup> and  
108 N<sub>2</sub>O (Goreau et al., 1980; Mantoura et al., 1993; Lam et al., 2009; Wright et al., 2012). Within these eddies,  
109 various biogeochemical processes coexist that are highly sensitive to O<sub>2</sub> variations, while physical processes  
110 modulate biogeochemical patterns through mixing, submesoscale effects, or mass exchange with water  
111 masses from different origins through turbulent advection (José et al., 2017; Kartensen et al., 2017; Loveccio  
112 et al., 2022).

113 This complexity of processes involved during the life cycle of a Puddy, along with the lack of continuous in  
114 situ measurements, results in a limited understanding of nutrient recycling throughout their lifetime, and the

115 balance between processes controlling the rate of change of O<sub>2</sub> and nutrients. In the present study, we aim to  
116 characterize the internal biogeochemistry of eddies formed under various low-oxygen conditions in the SEP.  
117 We then analyze factors generating natural variability during the lifespan of bioelements associated with the  
118 nitrogen cycle during the trajectory of Puddies from the OMZ to better ventilated oceanic waters.  
119 Specifically, we document the evolution of water mass properties and processes inside puddies with  
120 contrasting initial characteristics in terms of O<sub>2</sub> concentration (suboxic versus hypoxic) in order to evaluate  
121 the role of these properties in OMZ maintenance. Our aim is also to fill in knowledge gaps in the  
122 biogeochemical dynamics of this type of eddy due to the lack of observational data, especially in the SEP. To  
123 quantify the changes that Puddies undergo as a result of their complex dynamics, we use a regional  
124 biogeochemical coupled model simulation. Two approaches are employed: 1) robust statistical analysis of  
125 contrasting water masses properties and rates within and outside the Puddies, and 2) case studies focusing on  
126 determining temporal changes in eddy properties along their trajectory. The organization of this study is as  
127 follows: Section 2 presents the details of the model and methods used for the identification and  
128 characterization of Puddies, Section 3 describes the biogeochemical characterization inside and outside the  
129 Puddies, temporal changes to the O<sub>2</sub> budget and the biogeochemical properties, Section 4 discusses the  
130 results and Section 5 presents the main conclusions and future projections.

131

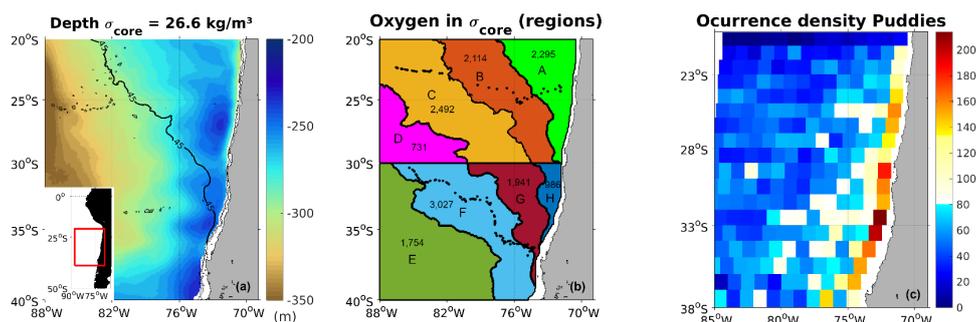

## 132 **2 Methods**

### 133 **2.1 Regional biogeochemical coupled model**

134 We used a high-resolution, coupled physical-biogeochemical model simulation of the SEP that considers the  
135 main processes involved in the transformation of the water masses relevant to the OMZ variability and the  
136 dynamics of the Peru-Chile Undercurrent (PCUC). This current plays a significant role in generating Puddies  
137 and in the southward extension of the OMZ in the Peru-Chile Eastern Boundary Upwelling System (EBUS).

138 The physical dynamics were simulated using the Regional Ocean Modelling System (ROMS), a regional  
139 ocean circulation model that solves the primitive equations with free surface and sigma coordinates  
140 (Shchepetkin and McWilliams 2005, 2009). ROMS was coupled with the biogeochemical model BioEBUS,  
141 specifically developed for Eastern Boundary Upwelling Systems (EBUS) and based on the nitrogen cycle  
142 using N<sub>2</sub>P<sub>2</sub>Z<sub>2</sub>D<sub>2</sub> model formulation (Koné et al., 2005; Gutknecht et al., 2013a). We adopted the same  
143 configuration as specified in several other studies in the region (Dewitte et al., 2012; Montes et al., 2014;  
144 Vergara et al., 2016; Pizarro-Koch et al., 2019) using a spatial resolution of 1/12°, 37 vertical levels, with  
145 outputs every three days, suitable for resolving mesoscale features. The overall domain covers the latitudinal  
146 range of 12°N to 40°S from the coast to 95°W, although the present study focuses on latitudes off the coast  
147 of Chile between 20° and 40°S (Figure 1a). The simulated period was from 2000 to 2008.

148

149

150 **Figure 1.** Depth of the OMZ core, modeled dissolved O<sub>2</sub> climatology offshore of the Chilean coast, and spatial  
 151 distribution of the occurrence density of the Puddies identified over the nine year period. (a) The OMZ core was  
 152 considered as being in the isopycnal layer 26.6 kg/m<sup>3</sup> (defined with  $\sigma_{core}$  layer; see Section 2.2). The study area  
 153 covers 20° - 40°S and from the coast to 88°W. The black contour shows the traditional OMZ limit ([O<sub>2</sub>]=1mL/L or  
 154 ~ 45 μM) at -300 m. Black lines represent isobaths of -1000 m and -500 m. (b) Subregions are defined by the  
 155 following O<sub>2</sub> contours using the  $\sigma_{core}$  layer: Region A (O<sub>2</sub> < 20 μM), Region B and Region H (20 μM < O<sub>2</sub> < 45 μM),  
 156 Region C and Region G (45 μM < O<sub>2</sub> < 90 μM), Region D and Region F (90 μM < O<sub>2</sub> < 120 μM) and Region E (120  
 157 μM < O<sub>2</sub>). Yellow dots indicate the path of the tracking of two Puddies for the case studies. Numbers are the total  
 158 profiles counted in each region. The same colors will be used in the following figures to refer to the subregions. (c)  
 159 Occurrence density (colormap) is quantified by the total number of Puddies identified in each 1°x1° area for each  
 160 snapshot ( $\Delta t = 3$  days), with the possibility that the same eddy may be counted more than once if remaining in the  
 161 same area. Numbers refer to the total occurrence density by region.

162 The model uses atmospheric forcing data from NCEP-NCAR (2.5° x 2.5°, Goubanova et al., 2011). Latent  
 163 heat flux and other variables –for estimating other air-sea fluxes– such as air temperature and humidity are  
 164 provided by monthly climatology with a resolution of 1° x 1° from COADS (da Silva et al., 1994). The  
 165 boundary conditions for temperature, salinity, and horizontal velocity were provided by the SODA 1.4.2  
 166 reanalysis (Smith et al., 1992). The BioEBUS model consists of 12 compartments interacting through  
 167 advection-diffusion equations and source-minus-sink (SMS) processes. The considered components include  
 168 inorganic dissolved nutrients (NO<sub>3</sub><sup>-</sup>, NO<sub>2</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup>), large and small phytoplankton (“small” representing  
 169 nanophytoplankton; mainly small flagellates between 2 and 20 μm and “large” representing  
 170 microphytoplankton; mainly diatoms between 20 and 200 μm), large and small zooplankton (“small”  
 171 representing microzooplankton; mainly heterotrophic ciliates between 20 and 200 μm, and “large”  
 172 mesozooplankton; mainly copepods between 200 μm and 2 mm), and detritus (small and large). Dissolved  
 173 organic nitrogen (DON) was considered following the formulation of Dadou et al. (2001, 2004) and Huret et  
 174 al. (2005), O<sub>2</sub> including its ocean-atmosphere interaction according to Peña et al. (2010) and Yakushev et al.  
 175 (2007), and the production of N<sub>2</sub>O using the parameterization of Suntharalingam et al. (2000, 2012). The  
 176 boundary and initial conditions for the BioEBUS model were obtained from the CARS2006 climatology  
 177 (CSIRO Atlas of Regional Seas) for O<sub>2</sub> and NO<sub>3</sub><sup>-</sup>, with constant vertical profiles adopted for NH<sub>4</sub><sup>+</sup>, NO<sub>2</sub><sup>-</sup>, and  
 178 dissolved organic nitrogen (DON) (based on Koné et al., 2005). Phytoplankton biomass was estimated based  
 179 on chlorophyll concentration (Chl-a) –obtained from SeaWiFS climatological satellite data– and then  
 180 extrapolated vertically using the method of Morel and Berthon (1989). Detailed information on simulation

181 and validation of the physical model (ROMS) is given by Dewitte et al. (2012) and Vergara et al. (2017). The  
182 parameter configuration of BioEBUS is the same as used in Montes et al. (2014) for the Peruvian region,  
183 Vergara et al. (2016) for the northern region of Chile, and Pizarro-Koch et al. (2019) for the central-southern  
184 region of Chile.

185 The time rate of change of the concentration of each component is governed by the advection-diffusion  
186 equation (Equation 1, see Gutknecht et al., 2013a). For instance, the  $O_2$  balance is given

$$187 \quad \frac{\partial O_2}{\partial t} = -\nabla \cdot (uO_2) + K_H \nabla^2 O_2 + \frac{\partial}{\partial z} \left( K_z \frac{\partial O_2}{\partial z} \right) + SMS(O_2) \quad (1)$$

188 where  $u = (u, v, w)$  represents the fluid velocity, with component  $u$  for zonal,  $v$  for meridional, and  $w$  for  
189 vertical. The first term on the right-hand side represents the advection ( $ADV = -\nabla \cdot (uO_2)$ ), which is an  
190 scalar, but can also be decomposed in the sum of zonal ( $XADV = -u \frac{\partial O_2}{\partial x}$ ), meridional ( $YADV = -v \frac{\partial O_2}{\partial y}$ ),  
191 and vertical ( $VADV = -w \frac{\partial O_2}{\partial z}$ ) components. The second and third terms correspond to horizontal (HMIX)  
192 and vertical (VMIX) diffusion, where  $K_H$  is the horizontal eddy diffusion coefficient (set to  $100 \text{ m}^2 \text{ s}^{-1}$  in this  
193 version of the model), and  $K_z$  is the turbulent diffusion coefficient calculated using the K-profile  
194 parameterization mixing scheme (Large et al., 1994). The last term  $SMS(O_2)$  represents the effect of  
195 sources and sinks associated with the relevant biogeochemical processes. For  $O_2$ , the source process is  
196 primary production, and sink processes include remineralization, nitrification, and zooplankton excretion.

## 197 2.2 Characterization of the study area

198 The study area extends from  $20^\circ$  to  $40^\circ\text{S}$  and from the Chilean coast to  $88^\circ\text{W}$ . In this region the OMZ core  
199 ( $O_2 < 45 \mu\text{M}$  or  $\sim 1 \text{ mL/L}$ ) is centered at a density surface of  $\sigma_\theta = 26.6 \text{ kg m}^{-3}$  whose depth varies, being  
200 shallower in the coastal area and deepening in the oceanic region (Figure 1a). Near the slope, a deepening in  
201  $S_{\text{core}}$  is observed north of  $30^\circ\text{S}$ , where the slope is narrower. South of  $30^\circ\text{S}$ , it widens, as indicated by the  
202 1000 m and 500 m depth isobaths.

203 All variables were interpolated from the original sigma vertical coordinate to depth every 5 meters from 800  
204 m to the surface. In the deep ocean ( $\sim 4000 \text{ m}$  depth) typically 13 of the 37 vertical levels fall within this  
205 depth range. Two main zones were considered: the northern zone ( $20^\circ$ – $30^\circ\text{S}$ ), where the OMZ is zonally  
206 wider and characterized by suboxic conditions ( $O_2 < 20 \mu\text{M}$ ); and the southern zone ( $30^\circ$ – $40^\circ\text{S}$ ), where the  
207 OMZ is mostly hypoxic ( $O_2 < 45 \mu\text{M}$ ) and much narrower (Figure 1b). Subsequently, we adopted additional  
208 criteria to subdivide those regions, using ranges that define the various metabolic niches for organisms:  
209 region A with  $O_2 < 20 \mu\text{M}$ , region B and H with  $20 \mu\text{M} < O_2 < 45 \mu\text{M}$ , region C and G with  $45 \mu\text{M} < O_2 < 90$   
210  $\mu\text{M}$ , region D and F with  $90 \mu\text{M} < O_2 < 120 \mu\text{M}$  and region E with  $120 \mu\text{M} < O_2$ . This subdivision was based  
211 on  $O_2$  concentrations observed on a density surface that represent the core of the Puddies ( $S_{\text{core}} = 26.6 \text{ kg m}^{-3}$ ,  
212 the  $S_{\text{core}}$  depth is shown in Figure 1a).

213 The region within the first  $\sim 100 \text{ km}$  off the coast was considered as a formation zone for Puddies where a  
214 large number of surface and subsurface eddies are typically generated (e.g., Chaigneau et al., 2009; Figure

215 1c). Along the coast, approximately 1° of latitude x 1° longitude boxes were selected to characterize the  
216 biogeochemical properties of the source water that the Puddies eventually enclose upon formation.

### 217 2.3 Definition of “mean state” and mesoscale contribution

218 To estimate the physical and biogeochemical perturbations from the mean field associated with the eddies,  
219 we use a Reynolds-like decomposition, which for the field of  $\text{NO}_3^-$  concentration is written as follows Eq.  
220 (2):

$$221 \quad \text{NO}_3(x, y, z, t) = \underline{\text{NO}_3} + \text{NO}_3'(x, y, z, t) \quad (2)$$

222 where  $\underline{\text{NO}_3}(x, y, z)$  is the “mean state” of  $\text{NO}_3^-$  over the period 2000-2008, with fluctuations of this “mean  
223 state” corresponding to  $\text{NO}_3'(x, y, z, t)$ . Similarly, for other variables involved,  $\underline{S}$ ,  $\underline{N_2O}$ , etc., denoted the  
224 “mean state”, whereas  $S'$ ,  $N_2O'$  etc., correspond to anomalies, which includes eddy fluctuations and changes  
225 associated with annual and interannual variability. This decomposition method was used for all variables  
226 analyzed in each subregion of study. To evaluate the impacts of the Puddies on the various fields, we used an  
227 algorithm to identify subsurface eddies (See details in Section 2.5) and then compared the perturbed fields  
228 inside the Puddies with the total field. This procedure is further explained in section 2.6.

### 229 2.4 Calculation of AOU, $\Delta\text{NO}_3^-$ and $\Delta\text{N}_2\text{O}$

230 The apparent oxygen utilization (AOU),  $\text{NO}_3^-$  production ( $\Delta\text{NO}_3^-$ ), and  $\text{N}_2\text{O}$  production ( $\Delta\text{N}_2\text{O}$ ) provide an  
231 estimate of how much has been produced/consumed by biological processes since the water mass was  
232 formed. These estimates are associated with the time the water mass has spent without coming into contact  
233 with the ocean surface or being ventilated.

234 The AOU calculation was derived from the García & Gordon (1992) algorithm, based on the  $\text{O}_2$  saturation  
235 concentration at any temperature and salinity, and using the following Eq. (3):

$$236 \quad \text{AOU} = [\text{O}_2]_{\text{sat}} - [\text{O}_2]_{\text{obs}} \quad (3)$$

237 The  $\text{N}_2\text{O}$  saturation ( $\Delta\text{N}_2\text{O}$ ) was calculated using the Gruber & Sarmiento (2002) methodology and the  
238 following relationship Eq. (4):

$$239 \quad \Delta\text{N}_2\text{O} = [\text{N}_2\text{O}]_{\text{obs}} - [\text{N}_2\text{O}]_{\text{sat}} \quad (4)$$

240  $\text{NO}_3^-$  production ( $\Delta\text{NO}_3^-$ ) is defined as follows Eq. (5):

$$241 \quad \Delta\text{NO}_3^- = [\text{NO}_3^-]_{\text{obs}} - [\text{NO}_3^-]_{\text{preformed}} \quad (5)$$

242 The value of  $[\text{NO}_3^-]_{\text{preformed}}$  in subsurface waters considered for the above calculation was that of Equatorial  
243 Subsurface Water (ESSW) in all regions except E, where the value for Antarctic Subsurface Water (SAAW)

244 was taken from Llanillo et al. (2012). The assessment of the modeled surface  $\text{NO}_3^-$  is provided in Appendix  
245 1.

## 246 **2.5 Puddy Identification and Tracking**

247 For the identification of Puddies, the algorithm proposed by Faghmous et al. (2015) (see:  
248 <https://www.nature.com/articles/sdata201528>) was adapted to deal with subsurface eddies that have a weak  
249 dynamical signature at the surface of the ocean. The original algorithm is based on the presence of local  
250 extreme values (minimum in the case of cyclonic eddies and maximum in the case of anticyclonic eddies,  
251 considering a neighborhood defined a priori around it) of sea level anomalies (SLA). Because the SLA signal  
252 from subsurface eddies may be rather weak or absent, the present study used anomalies in the layer thickness  
253 ( $\delta h$ ). This layer is bounded by the density surfaces  $S_{\text{upper}} = 26.0 \text{ kg m}^{-3}$  and  $S_{\text{lower}} = 26.9 \text{ kg m}^{-3}$ . Thus,  
254 positive anomalies ( $\delta h > 0$ ) indicate the presence of subsurface anticyclonic eddies due to their convex shape  
255 (for our case, Puddies). When  $\delta h$  is at its maximum ( $\delta h_{\text{max}}$ ), the largest closed contour around the  
256 geographical location of  $\delta h_{\text{max}}$  is considered as the edge of the eddy, as  $\delta h_{\text{max}}$  is associated with the center of  
257 the eddy and the points contained within the eddy edge are the body of the eddy (Faghmous et al., 2015).  
258 Starting from  $\delta h_{\text{max}}$ , a gradual decrease of 0.1 m was used to establish the size and amplitude of the eddy.  
259 Only eddies that reached a minimum horizontal area of 30 grid points ( $A_{\text{min}} \sim 1.95 \times 10^9 \text{ m}^2$ , equivalent to a  
260 radius of  $\sim 25 \text{ km}$ ) were considered here because eddies below that threshold size are not well identified. For  
261 the present analysis, only eddies that did not exceed a radius of 150 km were considered. The identification  
262 of eddies was conducted every three days over the entire period. Subsequently, all  $\delta h_{\text{max}}$  positions were  
263 classified by subregion and in  $1^\circ \times 1^\circ$  cells for their enumeration (Figure 1b, 1c) and for characterizing the  
264 average properties of these Puddies (statistical analyses are shown in section 3).

265 For the case studies, two Puddies formed in zones with contrasting biogeochemical properties (i.e., zones A  
266 and G) were selected and followed. The algorithm kept track of both eddies, although tracking was lost at  
267 certain times. In the case of the eddy formed in region A, the track was lost for up to 87 days (29 time steps),  
268 whereas for the eddy formed in region G, the maximum number of days without tracking was 27 days (9 time  
269 steps). Long gaps were manually corrected with  $\delta h_{\text{max}}$  search, the verification of the trajectory was carried  
270 out under visual inspection of the vertical sections of vorticity fields and  $\text{O}_2$  contours. Finally, short gaps  
271 (shorter than 3-time steps) in the Puddy trajectories were filled using linear interpolation.

272

## 273 **2.6 Compound Formation**

### 274 **2.6.1 Average Profiles**

275 To understand the typical conditions within Puddies identified in the formation zone and each subregion,  
276 average profiles were constructed as follows: i) all eddy centers (i.e.,  $\delta h_{\text{max}}$  positions) were classified  
277 according to the regions defined in Figure 1 ii) for each eddy center, vertical profiles were extracted between

278 the density surfaces  $S_{\text{upper}}$  and  $S_{\text{lower}}$  for all variables, for each corresponding region iii) then, these profiles  
279 were time-averaged to obtain typical profiles for each variable. The analysis of these results is presented in  
280 sections 3.1 and 3.2.

281

## 282 **2.6.2 Puddy evolution**

283 As a case study, we characterize the evolution of several variables within two Puddies. The selected eddies  
284 exhibited a long trajectory toward the open ocean with a lifetime  $> 1$  year. For these Puddies, we estimate  
285 characteristics inside the entire eddy volume as follows: i) an average radius ( $r_{\text{mean}}$ ) during its entire trajectory  
286 was calculated, ii) a circular polygon (eddy mask) with a  $r_{\text{mean}}$  was drawn around the Puddy center to extract  
287 all the grid points within the circumference. The same mask was applied to all depths (every 5 meters)  
288 creating a cylinder between  $S_{\text{upper}}$  and  $S_{\text{lower}}$ . From the total volume enclosed by the cylinder, an average  
289 vertical profile was obtained at each time step for each variable. The temporal evolution of these two Puddies  
290 is presented in sections 3.4 and 3.5.

## 291 **2.7 Calculation of percentiles**

292 To quantify the significance of the internal contribution of Puddies compared to the average state, a random  
293 sampling of positions ( $> 200$ ) was conducted for each region to extract variables in the  $S_{\text{core}}$  at approximately  
294 100 different time points. Subsequently, the 50th, 75th, and 90th percentiles (P50, P75, P90) were calculated  
295 from these samples and compared to results obtained in Section 3.2.3 (Table 4).

296

## 297 **3 Results**

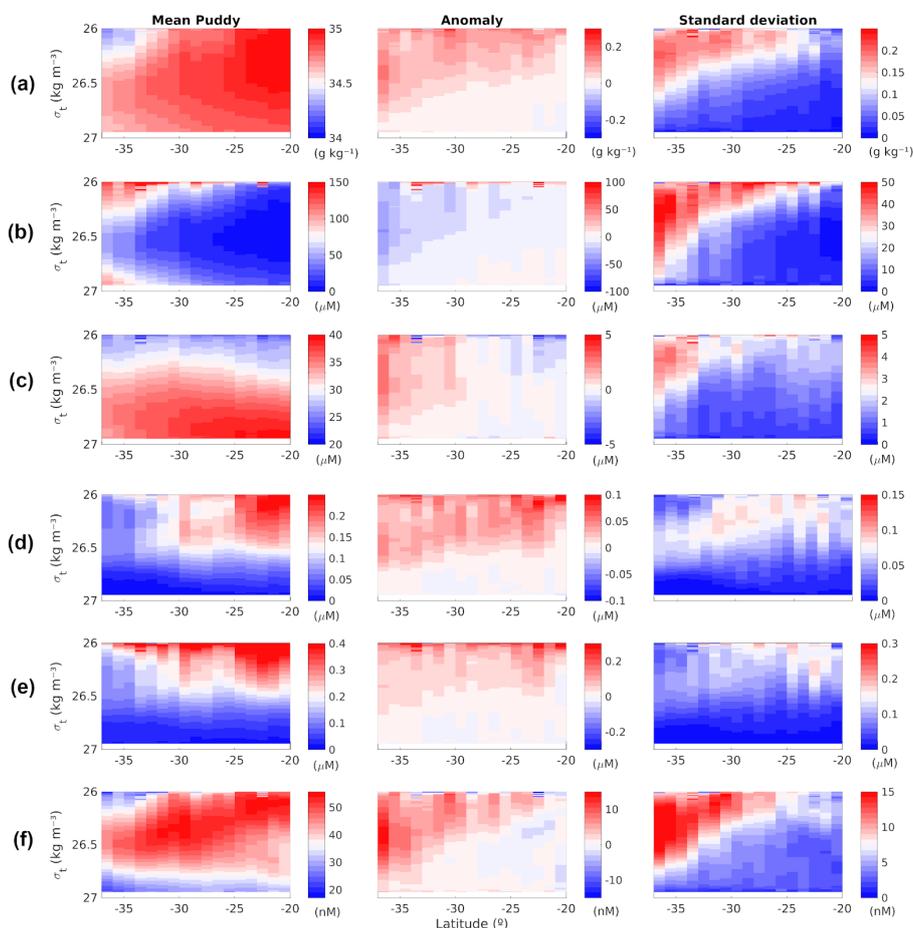

### 298 **3.1 Contrasting biogeochemical characteristics inside and outside the Puddies**

299 Over the 9-year study period in the simulated study region (Figure 1), a mean of approximately 14 Puddies  
300 were observed each day, resulting in a total of  $\sim 15,340$  Puddy profiles identified over the entire study period.  
301 If the same eddy remained within the same  $1^\circ \times 1^\circ$  grid area, it was counted multiple times (using a 3-day time  
302 step) until the center of the eddy moved to an adjacent  $1^\circ \times 1^\circ$  grid. The area with the highest density of  
303 identified Puddy profiles was concentrated in the coastal region (2,548), within the first  $\sim 100$  km from shore,  
304 with the maximum abundance noted between  $29^\circ - 35^\circ\text{S}$  (Figure 1c). It should be noted that the number of  
305 eddies in the coastal region may be slightly overestimated by our adopted algorithm due to difficulties in  
306 distinguishing between perturbations of the density surfaces generated by eddies, coastal upwelling events,  
307 coastally trapped waves or meanders of the coastal currents.

308 To assess the impact of Puddies along the coastal strip, we evaluated the mean distribution of several  
309 variables (salinity,  $\text{O}_2$ ,  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ ,  $\text{NH}_4^+$ , and  $\text{N}_2\text{O}$ ) in coastal boxes of approximately  $1^\circ \times 1^\circ$  between  $20^\circ\text{S}$   
310 and  $38^\circ\text{S}$ , and between the isopycnal surfaces  $S_{\text{upper}}$  and  $S_{\text{lower}}$  that define the OMZ core in the model (see

311 details in Section 2.6.1). Then, we calculated the mean profiles of these variables in the center of the Puddies  
 312 observed in each coastal box, and estimated anomalies of the profiles with respect to the general mean profile  
 313 of the corresponding box (Figures 2, see also Figure S1 in the supplementary material).

314 **Figure 2.** Average vertical profiles, standard deviation, and anomalies associated with biogeochemical features  
 315 within the center of the Puddies over the first ~100 km from the slope. Eddies' average profiles (left boxes) were  
 316 obtained by calculating the mean of total profiles identified during nine years in 1°x1° boxes along the coast  
 317 between the isopycnal layers  $\sigma_{\text{upper}}$  and  $\sigma_{\text{lower}}$  (See Methods 2.2, 2.3, 2.6.1). The standard deviation (right boxes) is  
 318 interpreted as the variability of the properties existing at the center, and the anomalies (middle boxes) were  
 319 calculated by removing the mean state related to the same volume element. (a) absolute salinity, (b) O<sub>2</sub>, (c) NO<sub>3</sub><sup>-</sup>,  
 320 (d) NO<sub>2</sub><sup>-</sup>, (e) NH<sub>4</sub><sup>+</sup>, and (f) N<sub>2</sub>O.

322 Meridional changes in water properties along the coastal strip impact the initial properties of the Puddies. In  
 323 the northern sector (between 20°S and 30°S), the waters are warmer, more saline, and have lower O<sub>2</sub>, with

324 higher concentrations of  $\text{NO}_2^-$  and  $\text{NH}_4^+$  (Figures 2e and 2d); whereas towards the south (south of  $30^\circ\text{S}$ ),  
 325 these characteristics generally show the opposite tendency, consistent with the water properties observed  
 326 within Puddy cores. However,  $\text{NO}_3^-$  and  $\text{N}_2\text{O}$  show maximum levels in the central region (near  $30^\circ\text{S}$ )  
 327 (Figures 2c and 2f), where eddies with the highest  $\text{N}_2\text{O}$  concentrations are also observed. Oxygen levels were  
 328 higher at the upper and lower limits of the OMZ (i.e., near  $\sigma_\theta = 26.3 \text{ kg m}^{-3}$  and  $\sigma_\theta = 26.7 \text{ kg m}^{-3}$ ) and  
 329 remained relatively low in the OMZ core ( $\sigma_\theta \sim 26.5 \text{ kg m}^{-3}$ ). Both  $\text{NH}_4^+$  and  $\text{NO}_2^-$  anomalies generated by the  
 330 Puddies showed maximum values in the upper limit of the eddy cores (near  $\sigma_\theta = 26.3 \text{ kg m}^{-3}$ ) and were fairly  
 331 uniform along the coastal strip, except between  $22^\circ - 24^\circ\text{S}$  and the north-central region, which showed  
 332 slightly higher anomalies (Figures 2d).

### 333 3.2 Biogeochemical characteristics inside the offshore Puddies

334 From the total of 15,340 Puddies profiles identified in the study region (more details in Section 2.2), the  
 335 number recorded for each region varied (Table 2, Figure 1b). The number presented in Table 2 were used as  
 336 sample size for different statistical estimation (see below). General characteristics associated with each  
 337 subregion are detailed in Table 1.

338

339 **Table 1. General characteristics of the study subregions.**

Regions	Number of pixels	Depth $S_{\text{upper}}$ (m)		Depth $S_{\text{lower}}$ (m)		Mean thickness (m)
		Min	Max	Min	Max	
A	5550	-140	-50	-510	-435	377
B	7632	-190	-85	-465	-435	313
C	10202	-240	-130	-495	-435	280
D	4016	-250	-190	-500	-450	255

340

341

342 **3.2.1 Conditions of Suboxia and Hypoxia in the Oceanic Puddies**

343 We assessed the number of Puddies exhibiting suboxia and hypoxia in each region by identifying the  
344 predominant type of low-oxygen cores in coastal and oceanic regions. The percentage of Puddies exhibiting  
345 hypoxia ( $O_2 < 45 \mu\text{M}$ ) and suboxia ( $O_2 < 20 \mu\text{M}$ ) was determined by classifying the range of  $O_2$   
346 concentrations observed in the center of the eddies. The presence of Puddies with these characteristics in the  
347 more remote regions was quantified (regions C, D and E in Table 2).

348

349 **Table 2. Percentage of total identified Puddies showing suboxic ( $O_2 < 20 \mu\text{M}$ ) and hypoxic ( $O_2 < 45 \mu\text{M}$ ) cores**  
350 **within each region.**

Regions	Total profiles	Mean thickness (m)	Suboxic cores (%)	Hypoxic cores (%)
A	2,295	475	100	0
B	2,114	317	70	30
C	2,492	317	13.8	60
D	731	335.6	< 1	3
E	1,754	445	0	0.1
F	3,027	505	< 1	9
G	1,941	540	9.3	60
H	986	551.6	30	70

351

352 **3.2.2 Relationship between internal biogeochemical components**

353 Each water mass acquires characteristics through physical and biochemical processes, producing particular  
354 relationships between the physicochemical variables. Low  $O_2$  waters are closely related to relatively salty  
355 ESSW waters. In our study region, this water mass is located between the low salinity and relatively well-  
356 ventilated water masses (i.e., ESPIW above and AIWW below). Thus, salinity and  $O_2$  show a linear inverse  
357 correlation between the upper and lower oxyclines that delimit the OMZ. Nevertheless, the occurrence of

358 biogeochemical processes can disrupt this relationship. Therefore, it is useful to quantify which regions show  
 359 these nonlinear biogeochemical processes in the context of a hypothesis that a linear relationship between  $O_2$   
 360 and salinity corresponds to an aging of the water mass due to lack of ventilation. A nonlinear relationship  
 361 would imply the presence of other processes such as denitrification. Linear regression was performed  
 362 between absolute salinity,  $O_2$ , and AOU on the  $S_{core}$  surface, where AOU provides a measure of the apparent  
 363  $O_2$  consumption since the ESSW formation (Table 3).

364 **Table 3.** Linear regression between  $\underline{AOU}$ ,  $\underline{O_2}$  ( $\mu\text{M}$ ) and absolute salinity ( $\text{g kg}^{-1}$ ) within the  $S_{core}$  ( $\sigma_\theta = 26.6$   
 365  $\text{kg m}^{-3}$ ) layer for each subregion.  
 366

Regions	$\underline{AOU}/\underline{S}$			$\underline{O_2}/\underline{S}$		
	$R^2$	Slope	Intercept	$R^2$	Slope	Intercept
A	0.88	112.5±0.57	-3664.6±21	0.92	-142±0.6	4963.5±20.1
B	0.85	199.2±1	-6685.2±33.5	0.88	-229±0.9	7998.6±33.4
C	0.92	301.8±0.8	-10252±28.8	0.94	-332.4±0.8	11590±28.6
D	0.94	457.45±1.7	-15642±59.6	0.95	-488.6±1.7	16999±59.2
E	0.39	302.8±3.4	-10308±117.9	0.45	-339.9±3.4	11872±117.3
F	0.44	202±2.3	-6807.9±80.5	0.53	-236.6±2.3	8281.6±79.8
G	0.95	294.5±1	-9989.3±36.2	0.96	-327.1±1	11396±36
H	0.98	200.8±0.7	-6737±25.2	0.99	-232±0.7	8097±25.6

367

368 Oxygen and AOU exhibited a strong linear relationship with absolute salinity ( $R^2 > 0.85$ ) in regions where  
 369 there is a greater contribution from ESSW (Regions A, B, C, D, H, G). The correlation coefficients varied  
 370 between 112.5 and 457.45, whereas regions F and E did not show a linear relationship ( $R^2 < 0.45$ ), which can  
 371 be explained by the influence of SAAW and AAIW waters mixing properties with ESSW (Figure S2a, Table  
 372 3). Region H ( $R^2 = 0.99$ ) showed the strongest relationship, which decreased in regions A and B ( $0.85 < R^2 <$   
 373  $0.9$ ) where denitrification processes are more evident.

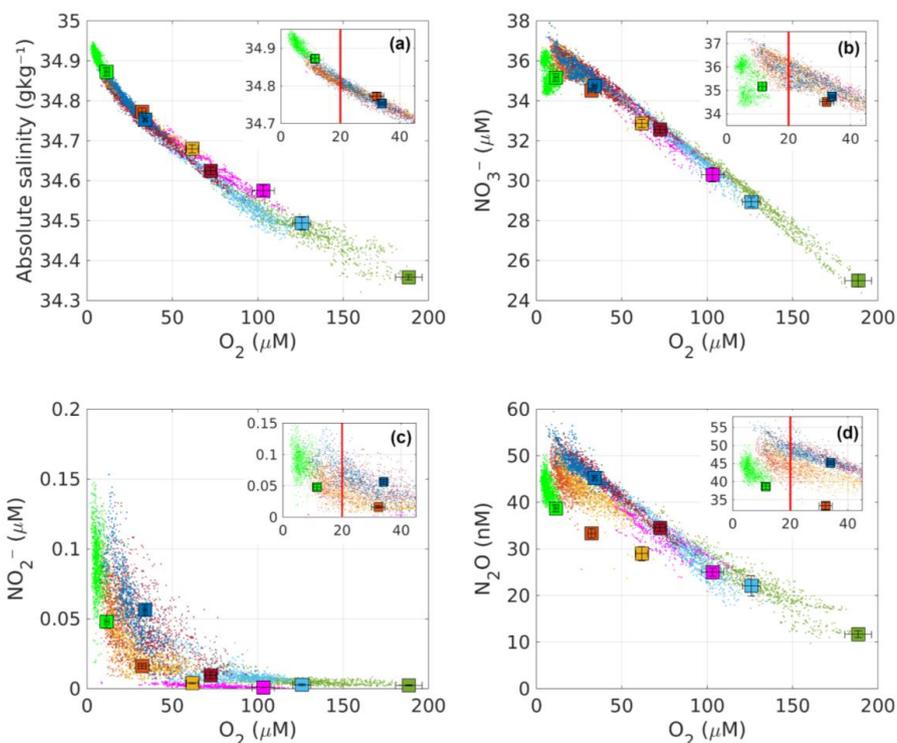

374 On the other hand, the asymptotic behavior of  $\text{NO}_2^-$  was similar to that of  $\text{NH}_4^+$ , occurring when  $O_2 < 45 \mu\text{M}$   
 375 (regions: A, B, and H) and tending towards undetectable in regions where  $O_2 > 45 \mu\text{M}$  (Figure 3c, S3).

376 Nitrous oxide decreased under suboxic conditions, increased under hypoxic conditions in regions G and H,

377 but decreased in regions B and C under similar  $O_2$  conditions to those observed in G and H regions (Figure  
378 3d).

379

380

381 **Figure 3. Relationship between  $O_2$  concentration and the absolute salinity,  $NO_3^-$ ,  $NO_2^-$ , and  $N_2O$  at the  $S_{core}$  layer**  
382 **for all identified Puddies. Color dots corresponding to the mean property at the core of Puddy (section 2.5) are**  
383 **contrasted with the mean state (color squares, section 2.3). The colors used for the regions are the same as Figure**  
384 **1b. Vertical error bars show the y-axis standard deviation, whereas the horizontal error bars are the standard**  
385 **deviation of  $O_2$ . The smaller box shows a magnification of the larger box for hypoxic and suboxic conditions, the**  
386 **red line indicates the threshold of  $O_2 = 20 \mu M$ .**

### 387 3.2.3 Differences between biogeochemical properties inside and outside Puddies

388 To understand the biogeochemical impacts of eddies in oceanic waters, the values found in the core of the  
389 Puddies were compared with the "mean conditions" of each region (Figures 3, 4, S2b, S2c, S2d; see  
390 Methodology in sections 2.5, 2.6.1). The presence of Puddies manifests a change in layer thickness ( $\delta h$ ) with  
391 respect to the average  $\delta h$  by region (Table 1 and 2) with greater contrast observed away from the coast in the  
392 south. Values of  $AOU'$ ,  $\Delta NO_3'$  and  $\Delta N_2O'$  observed inside the Puddies were higher than  $AOU$ ,  $\Delta NO_3$  and  
393  $\Delta N_2O$  observed outside (Table 4) confirming that eddies maintain hypoxic or suboxic cores that impact

394 regions farther offshore, as shown in the Section 3.2.2 (Table 2). Nonlinear biogeochemical processes  
 395 observed in the OMZ (Section 3.2.2) were commonly observed in the Puddies that arrived in regions C and G  
 396 (Figure 3), but less frequently in those arriving in regions D, E, and F. Additionally, in the hypoxic/suboxic  
 397 regions where these nonlinear processes are usually more pronounced, signals were intensified within the  
 398 Puddies (Regions A, B, and H; Figure 3). In general, in the coastal areas (A and H regions), Puddies  
 399 exhibited an increment of  $> 0.15$  salinity,  $1 - 4 \mu\text{M NO}_3^-$  (+2.25 – 3.4%), up to  $0.05 \mu\text{M NH}_4^+$  similar to  
 400  $\text{NO}_2^-$  (+12.5 – 83%), and  $3 - 12 \text{ nM N}_2\text{O}$  (+8.5 – 15%) associated with an increase of the  $7 - 9 \mu\text{M AOU}$   
 401 (+2.5 – 4%) higher than the "mean conditions" (Table 2). These anomalies were close to the P75 (P90 for the  
 402 salinity) indicating a significant elevation over mean state contributed by the Puddies (Table 5). Offshore, the  
 403 contrast over mean state was greater, reaching  $>300\%$  of  $\text{NH}_4^+$  (region F),  $+50\%$  of  $\text{NO}_3^-$  (region E),  $>85\%$   
 404  $\text{N}_2\text{O}$  (region F),  $30 - 60\%$  for AOU and  $0.17$  for salinity (Table 4). These values exceed the P90 in region E  
 405 and C, and P75 in other oceanic regions. Clearly, the perturbations to the mean state contributed by Puddies  
 406 in open sea is more significant than near the coast (Table 5). Salinity and biogeochemical tracers decrease as  
 407 the core becomes more oxygenated (Figures 3a, 4a; Table 4).

408 **Table 4. Average values of AOU ( $\mu\text{M}$ ), absolute salinity (g/kg),  $\text{NH}_4^+$  ( $\mu\text{M}$ ),  $\Delta\text{NO}_3^-$  ( $\mu\text{M}$ ), and  $\Delta\text{N}_2\text{O}$  (nM) inside and**  
 409 **outside the Puddies (mean state) on the  $S_{\text{core}}$  surface ( $\sigma_\theta = 26.6 \text{ kg m}^{-3}$ ).  $\underline{\quad}$  indicate the mean value of the**  
 410 **corresponding variable in the corresponding region, while  $\underline{\quad}'$  is the value of the variable inside the Puddies (see**  
 411 **Methods 2.3 and 2.6.1).**

412

413 The  $AOU/\Delta NO_3^-$  ratio allows us to quantify the remineralization of organic matter through aerobic processes,  
 414 which is determined by the Redfield ratio ( $R_{N/O}$ ;  $16/138 = 0.11$ ; Redfield et al., 1963). Changes in this  
 415 relationship indicate the presence of other biological processes that contribute/consume nitrogen in a system,  
 416 such as nitrogen fixation ( $\Delta NO_3^-/AOU > R_{N/O}$ ) and denitrification ( $\Delta NO_3^-/AOU < R_{N/O}$ ). On the other hand,  
 417 the  $\Delta N_2O/AOU$  ratio provides a measure of  $N_2O$  accumulation, so that a high  $\Delta N_2O/AOU$  is associated with  
 418 the denitrification process (Sarmiento & Gruber, 2006).

419 We observed a  $\Delta NO_3^-/AOU < R_{N/O}$  inside and outside the Puddies (Figure 4d), indicating a deficit of  $NO_3^-$   
 420 and high  $O_2$  consumption due to the high remineralization in subsurface waters. The ratio is higher in the  
 421 suboxic region (Region A, Figure 4d) with an  $AOU:\Delta NO_3^- = 15:1$ , while in the other regions this signal of  
 422 old and poorly ventilated waters also extends, albeit in different proportions (Table 4). When  $\frac{\Delta NO_3^-}{AOU} < \frac{\Delta NO_3^-}{AOU}$ , it  
 423 must be the case that  $\underline{AOU'} > \underline{AOU}$  or  $\underline{\Delta NO_3^-} < \underline{\Delta NO_3^-}$ . Since the second assumption is not met, it follows  
 424 that  $\underline{AOU'} > \underline{AOU}$  (Table 4). However, in regions B and C,  $\underline{\Delta NO_3^-} < \underline{AOU'}$ , indicating that  $\underline{\Delta NO_3^-} > \underline{\Delta NO_3^-}$   
 425 or  $\underline{AOU'} < \underline{AOU}$ . Given that  $\underline{AOU'} > \underline{AOU}$ , it must have occurred that  $\underline{\Delta NO_3^-} > \underline{\Delta NO_3^-}$ , so the production of  
 426  $NO_3^-$  was greater in the Puddies found in these regions compared to others (Table 4). On the other hand, it  
 427 holds that  $\frac{\Delta N_2O'}{AOU'} > \frac{\Delta N_2O}{AOU}$ . Since  $\underline{AOU'} > \underline{AOU}$ , it also follows that  $\underline{\Delta N_2O'} > \underline{\Delta N_2O}$ , therefore the production  
 428 of  $N_2O$  was proportionally larger than  $O_2$  consumption in the Puddies (Table 4). Note that although in regions  
 429 H and G the eddies exhibited the highest values of  $\frac{\Delta N_2O'}{AOU'}$ ,  $\frac{\Delta N_2O}{AOU}$  was also high (Figure 4d). Additionally, the  
 430 variability of physicochemical conditions in the core increased with distance from the coast and with  
 431 oxygenation.

432

444

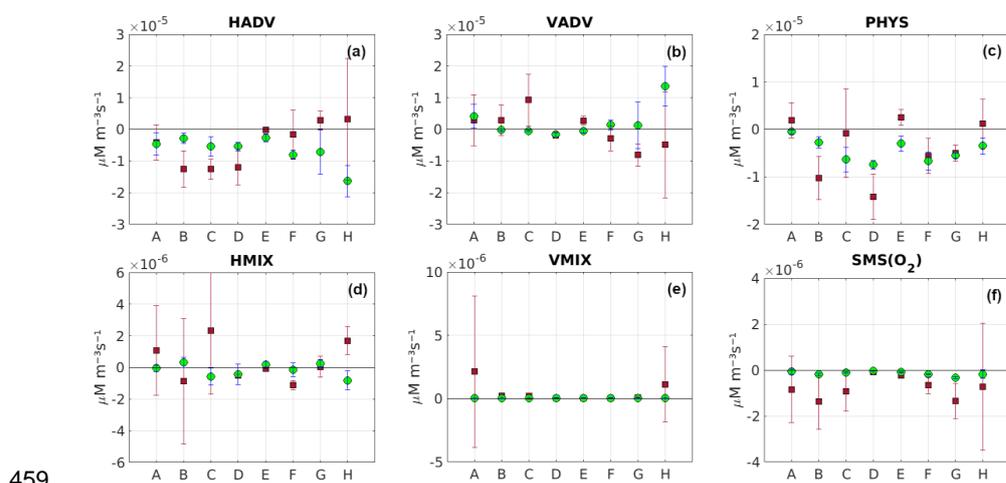

445 To sum up, according to our model results, Puddies generate significant changes with respect to the mean  
 446 conditions observed in all regions, particularly large differences were found in AOU and  $\Delta\text{N}_2\text{O}$  in region E.  
 447 In contrast the differences in the variables  $\Delta\text{NO}_3^-$  and AOU were not significant in regions A and H.

### 448 3.3 Oxygen Budget in the Puddies

449 The processes that contribute to the modulation of the total  $\text{O}_2$  content are represented in the advection-  
 450 diffusion equation (Eq. 1, Section 2.1). One part of the equation is associated with  $\text{O}_2$  changes due to

451 physical processes (denoted by *PHYS*) and another part is related to the production/consumption of O<sub>2</sub>  
 452 through biogeochemical processes (*SMS*), so we can write  $\frac{\partial O_2}{\partial t} = PHYS + SMS(O_2)$ . *PHYS* comprises  
 453 horizontal advective processes ( $HADV = XADV + YADV$ ), horizontal mixing (*HMIX*) in the *x-y* plane,  
 454 vertical advection (*VADV*) and vertical mixing (*VMIX*) in the *z*-direction so that  $PHYS = HADV + VADV$   
 455 + *HMIX* + *VMIX*. Note that *HMIX* and *VMIX* are mainly related to small-scale (subgrid-scale processes)  
 456 mixing (e.g., Pizarro-Koch et al., 2019). On the other hand, the *SMS*(O<sub>2</sub>) (source minus sink processes of O<sub>2</sub>)  
 457 includes primary production, remineralization, nitrification, and zooplankton excretion ( $SMS(O_2) = PP +$   
 458 *Rem* + *Nitrif* + *Exc*).

459  
 460 **Figure 5.** Mean terms involved in the O<sub>2</sub> budget (see equation 1). The different terms were temporally averaged  
 461 inside the eddies in each subregion. *PHYS* is the sum of physical processes, which encompasses horizontal  
 462 advection ( $HADV = XADV + YADV$ ), vertical advection (*VADV*), horizontal mixing (*HMIX*), and vertical mixing  
 463 (*VMIX*). The biogeochemical processes are included as sources minus sinks (*SMS*) processes impacting O<sub>2</sub>. In  
 464 particular, *SMS* includes the O<sub>2</sub> fluxes by primary production, nitrification, remineralization, and excretion of the  
 465 zooplankton. Positive (negative) values indicate processes contributing to increasing (depleting) O<sub>2</sub> inside the  
 466 eddy. A) *HADV* B) *VADV*, C) *PHYS*, D) *HMIX*, E) *VMIX*, and F) *SMS*. The averaging was conducted by dividing  
 467 the eddy into 2 parts to estimate the contribution above (red squares) and below (green circles) the isopycnal  
 468 surface 26.5 kg/m<sup>3</sup> which was asymmetric in the eddies.

469 We analyzed the contribution of each component of the equation to the O<sub>2</sub> balance in the center of the  
 470 Puddies (Figure 5). Large changes in variance were observed in the upper part of the eddy cores (the  
 471 skewness also changed along the vertical profile, reflecting a marked vertical variability in the probability  
 472 density function of the different terms involved in the O<sub>2</sub> balance, Figure S4). In Figure 5, we separated the  
 473 average contribution of the different terms above and below the *S<sub>core</sub>*. Positive (negative) values indicate O<sub>2</sub>  
 474 increasing/production (decreasing/consumption). In general, we observed that the contribution of the *PHYS*  
 475 was negative, mainly in the lower part of the eddy, whereas there was greater variability in the upper part,  
 476 with positive values dominating in some regions (A, E, and H), indicating O<sub>2</sub> increasing within the core  
 477 (Figure 5c). On the other hand, O<sub>2</sub> consumption through *SMS* (maximum in regions B and G) occurred in the

478 upper part of the Puddies (Figure 5f). This proves that elevated biological activity is maintained in the eddies  
479 far from shore, with higher intensity in younger eddies but weakening in eddies that reach regions very  
480 distant from the coast (regions D and E). Although the SMS fluxes are on the order of  $O(10^{-6})$ , one order of  
481 magnitude lower than the PHYS of  $O(10^{-5})$ , small changes in  $O_2$  due to SMS can also result in a sharp local  
482 spatial gradient in  $O_2$  that induces strong changes in the advection of  $O_2$ . This could have a significant impact  
483 on the behavior of biogeochemical components that are highly sensitive to minimal changes in  $O_2$   
484 concentration, especially under hypoxic or suboxic conditions.

485 The advection components ( $O(10^{-5})$ ) can be interpreted as the ability to maintain  $O_2$  at the center of the eddy  
486 during the eddy's displacement. They dominate the  $O_2$  budget compared to mixing processes ( $O(10^{-6})$ )  
487 involving diffusion of  $O_2$  (Figures 5a, 5b). The lateral fluxes (HADV) showed  $O_2$  leakage (HADV < 0) from  
488 the core mainly in the northern eddies, but not in the southern eddies (HADV > 0) where  $O_2$  influx to the  
489 core was evident (Figure 5a). Given that  $VADV = w \frac{\partial O_2}{\partial z}$ , in cases where VADV < 0, it can occur in the first  
490 case where  $w > 0$  and  $\frac{\partial O_2}{\partial z}$ , or a second case where  $w < 0$  and  $\frac{\partial O_2}{\partial z}$  (Figure 5b). When it occurs in the upper part  
491 of the eddy (regions F, G, and H), the first case may be more probable due to the lifting of isopycnals and the  
492 increase in  $O_2$  to the upper part of the eddy from the core. If VADV > 0, two possibilities can occur:  $w > 0$   
493 and  $\frac{\partial O_2}{\partial z}$  or, in the second case,  $w < 0$  and  $\frac{\partial O_2}{\partial z}$ . If it occurs in the upper part of the eddy (regions A, B, C, E),  
494 the second case is more likely to be fulfilled because there is always more  $O_2$  outside the core, indicating  $w <$   
495 0. On the other hand, the lower part of the eddies (regions A and H, mainly) should experience the opposite  
496 since the  $O_2$  gradient is generally negative, then  $w > 0$ . Vertical mixing fluxes were positive in newly formed  
497 eddies (mainly in regions A and H), while lateral diffusion fluxes showed high variability in magnitude and  
498 direction (Figures 5d, 5e).

#### 499 **3.4 Biogeochemical evolution inside the Puddies: study cases**

500 We considered two Puddies originated in coastal regions characterized by contrasting  $O_2$  conditions, with one  
501 was formed in suboxic waters (i.e.,  $O_2 < 20 \mu M$ ) and the other in hypoxic waters (i.e.,  $O_2 < 45 \mu M$ ). We  
502 quantified the lifespan and transformation of the biogeochemical compounds enclosed by the eddies. The  
503 trajectories of these Puddies are shown in Figure 1b.

##### 504 a) Case 1: Suboxic Puddy

505 The suboxic Puddy (SP) was first detected in region A (24°S, 71.85°W) from where it moved northwest for  
506 420 days (~60 weeks) with an average radius of ~82 km. Its trajectory spanned between 22.36°S and 25.32°S  
507 and 71.85°W and 86.53°W, passing through regions B and C, where it disappeared (Figures 1b). In week 11,  
508 it showed a subsurface core with positive vorticity between  $S_{upper}$  and  $S_{core}$ , with velocity in the edge  
509 delimited by the  $r_{mean}$  exhibits around  $10 \text{ cm s}^{-1}$  (Figure S5a). Within the suboxic environment ( $O_2 < 20 \mu M$ ),  
510 the puddy showed peak concentrations of  $NH_4^+$ ,  $NO_2^-$  (> 0.15  $\mu M$ ),  $NO_3^-$  (30-40  $\mu M$ ), and  $N_2O$  (60 nM), and  
511 a small volume where  $O_2 < 1 \mu M$  (i.e., close to anoxic conditions). The maximum  $NO_3^- > 40 \mu M$  was found in  
512 the lower part of the eddy (between 450 - 600 m depth) associated with  $O_2$  values between 20  $\mu M$  and 45  
513  $\mu M$ ; the periphery showed  $O_2 < 45 \mu M$ , and a decrease of  $NH_4^+$ ,  $NO_2^-$ , and  $N_2O$  (Figures S5b, S5c, S5d).

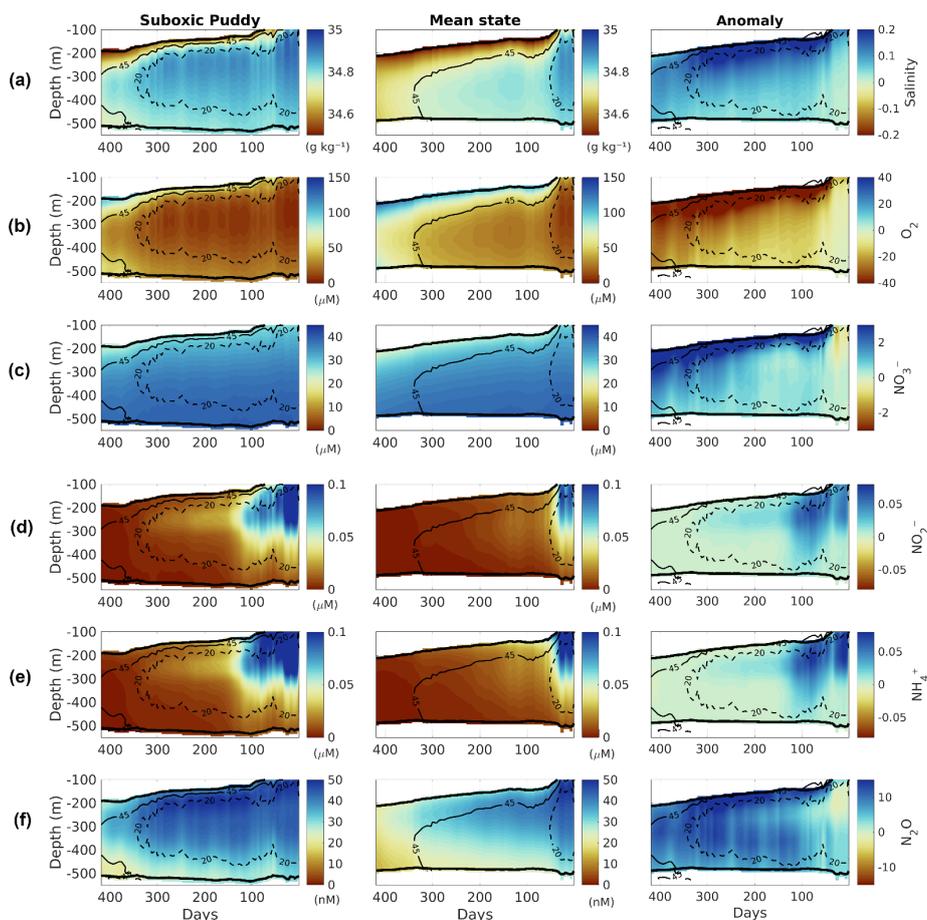

514 SP showed a suboxic core for a year following formation (>80% of the eddy's lifespan; Figure S6), then,  
 515 becoming hypoxic for the rest of its lifespan. The coefficients associated with the exponential fit for the  
 516 Puddy were greater than mean state coefficients, except for O<sub>2</sub> where the relationship was inverse (Table 6).  
 517 For the first 50 days, the biogeochemical conditions remained similar to initial conditions with positive  
 518 anomalies of NO<sub>2</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>, and salinity but negative anomalies of O<sub>2</sub>, N<sub>2</sub>O and NO<sub>3</sub><sup>-</sup> (the last two at the top of  
 519 the eddy). Subsequently, the largest positive anomalies in the variables occurred in the upper part of the SP  
 520 above S<sub>core</sub> (Figure 6). The increment in salinity after 50 days indicates intrusion of external waters (Figure  
 521 8a); however, the SMS < 0 indicated biological activity that consumes O<sub>2</sub> (ammonification, zooplankton  
 522 excretion and nitrification), prolonging the lifespan of NO<sub>2</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> by around 6 months (see SMS term in  
 523 Figure 9c, Figure 8). PHYS predominantly exhibited positive flows that increased after 100 days, where the  
 524 dominant mechanisms were lateral advection (HADV; Figures 9a, 9b) as evidence for ventilation of the SP.  
 525 Concentrations of NO<sub>2</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> declined with a high decay rate of  $k < 0.011$ , which is lower than the  
 526 average state rate ( $k > 0.011$ ; Table 6; Figures 6c, 6e, 8c, 8e). For salinity, NO<sub>3</sub><sup>-</sup>, and N<sub>2</sub>O, the decay rate was  
 527 lower than that of NO<sub>2</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> because even though their concentration decreased, they were not fully  
 528 depleted; however, these decreased more slowly in the SP than in the average state indicative of the capacity  
 529 of the eddy to enclose and maintain the initial source waters (Table 6; Figures 6a, 6d, 6f, 8a, 8d, 8f). At the  
 530 same time, O<sub>2</sub> had a higher rate of increase inside the SP than outside it, with rapid ventilation after 8 months  
 531 (Table 6; Figures 6b, 8b).

532 **Table 6. The salinity (g kg<sup>-1</sup>), NO<sub>3</sub><sup>-</sup>, NO<sub>2</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>, O<sub>2</sub> (μM), and N<sub>2</sub>O (nM) decay rates at the mean volume of the**  
 533 **suboxic Puddle (SP), hypoxic Puddle (HP), and their respective mean state of the same path. It was calculated**  
 534 **from exponential fit  $y = Ae^{-kx}$ , where  $k$  is the decay rate.**

535

537

538 **Figure 6. Vertical section of the biogeochemical components during the trajectory of the suboxic Puddy (SP)**  
 539 **which originated in region A with a radius of 72.8 km and a lifetime of ~400 days (left boxes). The mean state**  
 540 **(central boxes) and anomalies (right boxes) correspond to the same path of the SP. a) Absolute salinity, b) O<sub>2</sub>, c)**  
 541 **NO<sub>2</sub><sup>-</sup>, d) N<sub>2</sub>O, e) NH<sub>4</sub><sup>+</sup>, and f) NO<sub>3</sub><sup>-</sup>. The vertical section was obtained by averaging the volume of the eddy,**  
 542 **delimited by a cylinder of its mean radius within the intrathermocline band whose boundaries are the isopycnals**  
 543 **layers S<sub>upper</sub> and S<sub>lower</sub> (blue contours). Black contours show values of O<sub>2</sub> < 45 μM (solid line) and O<sub>2</sub> < 20 μM**  
 544 **(dotted line). The trajectory of this puddy is shown in Figure 1b.**

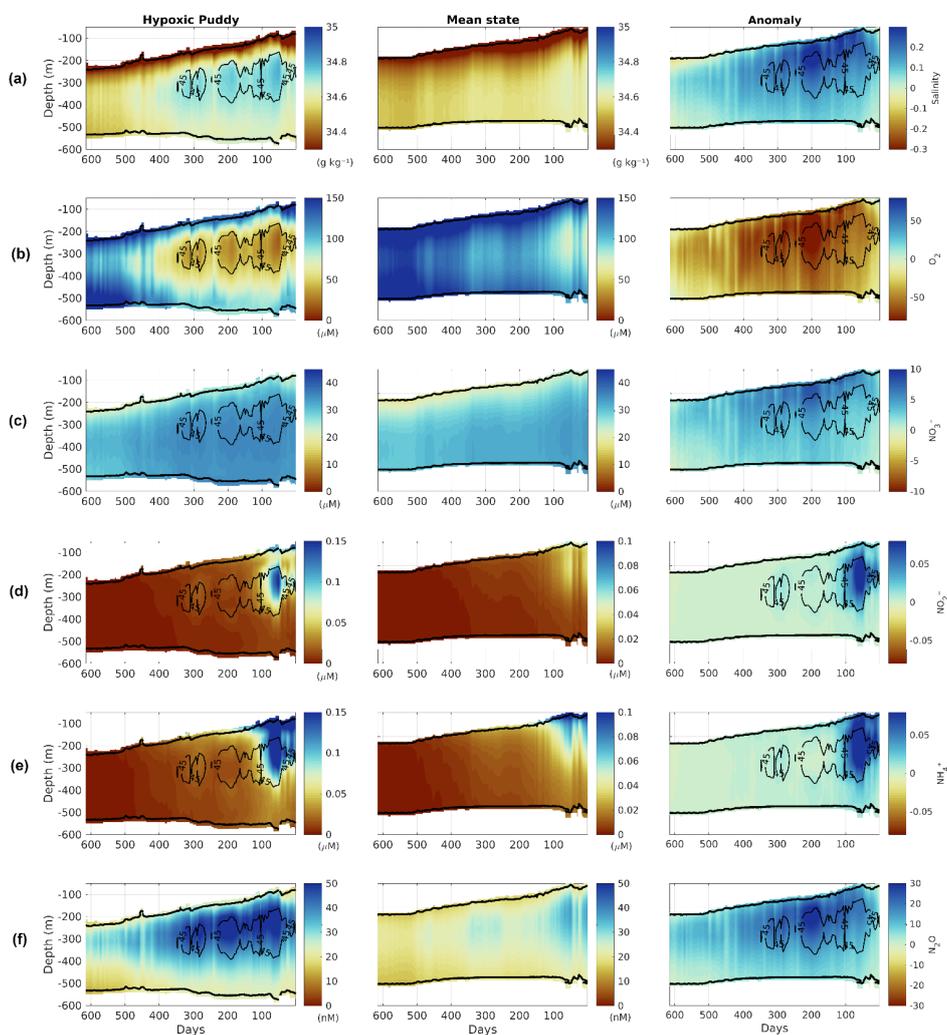

545

546 b) Case 2: Hypoxic Puddy

547 The Hypoxic Puddy (HP) was first observed in region G very close to the coast (36.2°S, 74.2°W), and its  
 548 northwest trajectory lasted approximately 600 days (~86 weeks) with an average radius of 76 km. The Puddy  
 549 moved within the area between 30.3°S, 74.2°W, and 36.9°S, 85.3°W, crossing through regions F and E  
 550 (Figures 1b) and showing positive vorticity in the core. Concentrations of O<sub>2</sub> < 20 μM were observed initially,

551 despite forming in an environment where generally characterized by hypoxia, and where  $\text{NO}_2^-$  (max  $\sim 0.05$   
 552  $\mu\text{M}$ ) and  $\text{N}_2\text{O}$  (70 nM) showed maximum concentrations (Figure S5e). In the range of  $20 < \text{O}_2 < 45 \mu\text{M}$ ,  $\text{NO}_3^-$   
 553 reached its maximum (35 - 38  $\mu\text{M}$ ) whereas other nitrogen compounds decreased (Figures S5f, S5g, S5g).

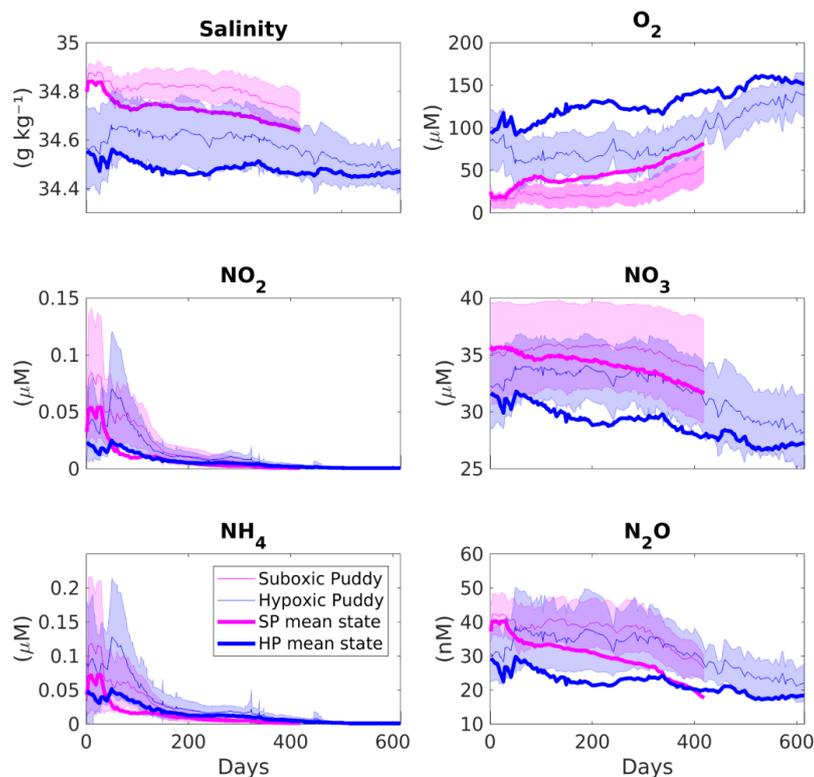

554  
 555 **Figure 7.** Same as Figure 6 but for a selected hypoxic Puddy (HP) originated in region G with a radius of 82.7 km  
 556 and a lifetime of  $\sim 600$  days. The trajectory is shown in Figure 1b.

557 The mean hypoxic condition in the core was associated with higher salinity,  $\text{NO}_2^-$ , and  $\text{N}_2\text{O}$  concentrations  
 558 that persisted for  $>1$  year (60% of the eddy's lifespan); however, on the periphery,  $\text{O}_2$  concentrations were  
 559 higher than 120  $\mu\text{M}$  (Figures 7a, 7b, 7c, 7d). In the first 50 days,  $\text{O}_2$  concentrations decreased to suboxic  
 560 levels, and later to 220 days, when oxygenation was observed,  $\text{O}_2$  levels were subsequently decreased to  
 561 hypoxic range by respiration associated with biological activity ( $\text{SMS} < 0$ , Figure 9c, S6). A significant

562 contrast was observed between the properties within the HP and the average state throughout the lifespan of  
 563 the eddy (Figure 7). Negative  $O_2$  anomalies ( $> 50 \mu M$ ), positive absolute salinity anomalies ( $> 0.2 \text{ g/kg}$ ),  $N_2O$   
 564 anomalies ( $> 20 \text{ nM}$ ),  $NO_3^-$  anomalies ( $> 8 \mu M$ ), and  $NH_4^+ - NO_2^-$  anomalies were observed during the first  
 565 250 days ( $> 0.08 \mu M$ ; Figure 7) when the negative SMS fluxes were greatest, indicating  $O_2$  consumption  
 566 (Figures 8 and 9c).

567 Simultaneously, negative PHYS fluxes were dominant where vertical advective processes occurred, although  
 568 in general, the dominant mechanism controlling the  $O_2$  balance was lateral advection, which increased  
 569 positively after 300 days (Figures 8a, 8b, 9a, 9b, 9c, 9d). Horizontal and vertical mixing also supplied  $O_2$  into  
 570 the eddy during the life of the HP, but these are one or two orders of magnitude smaller than advective  
 571 processes (Figures 9e, 9f).

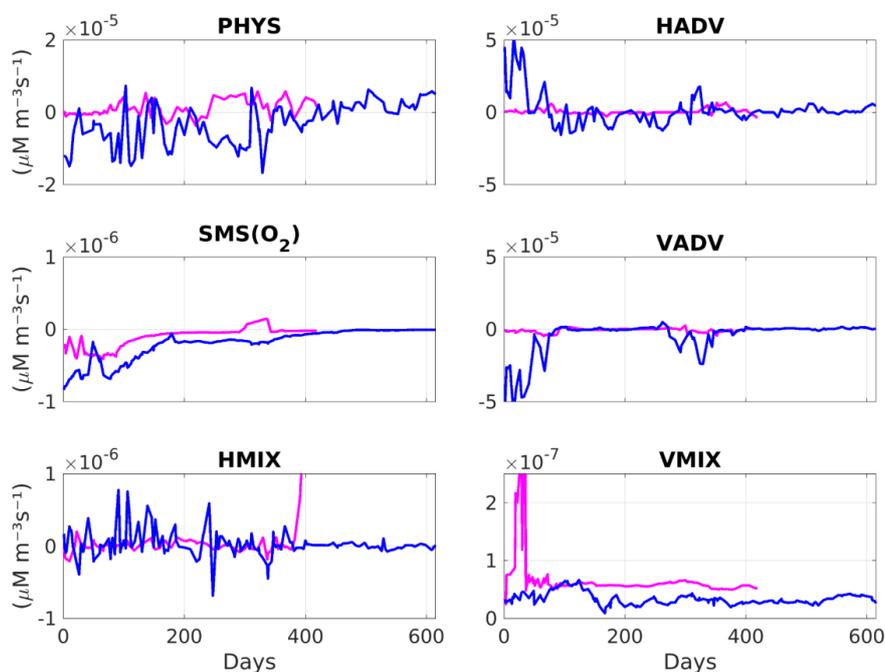

572

573 **Figure 8. Comparison between the temporal evolution of the average biogeochemical properties into the suboxic**  
 574 **(SP, magenta) and hypoxic (HP, blue) puddies shown in Figures 6 and 7. (a) Absolute salinity, (b)  $O_2$ , (c)  $N_2O$ , (d)**  
 575  **$NO_3^-$ , (e)  $NO_2^-$ , and (f)  $NH_4^+$ . Shading is the standard deviation indicating the range of concentration of each tracer**  
 576 **within the eddies. Trajectories are shown in Figure 1b.**

577 The coefficients A of the exponential fit for the HP and the decay rate were greater than the coefficients for  
 578 the mean state (Table 6). In the case of O<sub>2</sub>, coefficient A corresponding to the Puddy was almost half of the  
 579 coefficient outside. However, the HP maintained higher biogeochemical conditions than the average state for  
 580 an extended period, which may suggest that there is local production of these compounds as observed for the  
 581 increase of NO<sub>2</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> concentrations after 50 days with SMS < 0 (Figure 8c, 8e, 9c).

582  
 583 **Figure 9.** Comparison between the temporal evolution of the terms involved in the O<sub>2</sub> budget corresponding to  
 584 suboxic (SP, magenta) and hypoxic (HP, blue) puddies shown in Figures 6 and 7. The terms are described in  
 585 Figure 5. (a) PHYS fluxes, (b) HADV fluxes, (c) SMS fluxes, (d) VADV fluxes, (e) HMIX fluxes, and (f) VMIX  
 586 fluxes.

587

#### 588 4 Discussion

589 Several studies have reported on *in situ* subsurface eddies with similar biogeochemical characteristics to  
 590 those observed in the present study (Stramma et al., 2013; Stramma et al., 2014; Cornejo et al., 2016;  
 591 Arévalo-Martínez et al., 2016; Grundle et al., 2017; Hormazabal et al., 2013; Kartensen et al., 2017) but little  
 592 detail has been presented on the recycling of bioelements within these eddies. While recent studies have used  
 593 high-resolution coupled models to describe and quantify more complex processes involved in the O<sub>2</sub>,  
 594 nutrient, or organic matter balance within eddies (José et al., 2017; Frenger et al., 2018; Loveccio et al.,

595 2022), the agents generating natural variability in the lifespan of these bioelements associated with the  
596 nitrogen cycle during their trajectory from the OMZ to oceanic waters have not been analyzed in detail.

#### 597 **4.1 Biogeochemical anomalies in Puddies from their formation**

598 Subsurface anticyclonic eddies appear to be formed by the separation of the Peru-Chile Undercurrent from  
599 the slope (e.g., Molemaker et al., 2015; Thomsen et al., 2016; Contreras et al., 2019). Here, we observed a  
600 higher recurrence of Puddies in certain sectors, namely, between 29°-35°S (Figure 1c), related to the  
601 widening of the continental shelf. This change in topography may lead to greater separation of the PCUC  
602 from the slope creating favorable conditions for generation of Puddies, as previously observed by Chaigneau  
603 et al. (2009). Puddies appear to originate from instabilities forced in the bottom boundary layer at the upper  
604 continental slope – where the core of the PCUC interacts with the sea bottom (Contreras et al., 2019), and  
605 where the core of the OMZ is observed – and this source water is characterized by positive  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ ,  
606  $\text{NO}_2^-$  and  $\text{N}_2\text{O}$  anomalies, and very low  $\text{O}_2$ , as described in Section 3.1. However, unlike  $\text{O}_2$  and salinity,  
607 which exhibit a more uniform gradient along the coast, several other biogeochemical components have more  
608 irregular spatial distributions depending in particular on whether conditions are hypoxic or suboxic.

609 In the northern part of the coastal zone, limited ventilation creates an environment with suboxic conditions  
610 and denitrification, resulting in deficits of  $\text{NO}_3^-$  and  $\text{N}_2\text{O}$ , and enrichment of  $\text{NO}_2^-$  and  $\text{NH}_4^+$ . In contrast, the  
611 central coastal waters exhibit increased  $\text{NO}_3^-$ , with the southern part showing higher  $\text{N}_2\text{O}$  concentrations.  
612 Additionally, as the formation of Puddies is associated with cross-shore velocities – exchanging nutrients  
613 between the continental shelf and open sea (Thompson et al., 2015) – the mixture of ESSW and SAAW  
614 waters, affected also by the southward reduction of in contribution of ESSW (Silva et al., 2009), enhances  
615 the biogeochemical variability of the Puddies generated along the Chilean coast (Figure 2).

#### 616 **4.2 Biogeochemical Anomalies of Puddies and Mean State**

617 In each subregion shown in Figure 1b, the Puddies resulted in positive anomalies of nutrients and low-  
618 oxygen values, and these varied with latitude. These data were summarized in Figures 3 and 4. For the  
619 tracked Puddies, HP exhibited greater anomalies during its trajectory compared to SP, even though some  
620 bioelements were found in lower concentrations in SP (Figures 6 and 7). This is related to the dominance of  
621 SAAW in the southern regions, where hypoxic Puddies are more common and contain higher  $\text{O}_2$   
622 concentrations and lower levels of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{NO}_2^-$ , and  $\text{N}_2\text{O}$  than Puddies further north (Silva et al., 2009).  
623 Consequently, Puddies that capture a larger fraction of ESSW during their formation have a biogeochemical  
624 contribution nearer to the P75 (Table XX) and a larger  $\text{O}_2$  deficit than the mean state. This suggests that the  
625 southern regions are experiencing more deoxygenation and nutrient enrichment due to the influence of  
626 Puddies than the northern regions where the OMZ is much wider.

627

628

629

#### 630 4.3 Persistence of Biogeochemical Anomalies Away from the Coast

631 Through the case studies, we observed changes inside Puddies formed under suboxic (SP case) and hypoxic  
632 (HP case) conditions. In both cases, there was a decrease in dissolved inorganic nitrogen compounds as the  
633 Puddies aged and mixed with external waters. Similar results were observed by José et al. (2017) in the  
634 upwelling system off Peru, Frenger et al. (2018) in the four EBUS, and Loveccio et al. (2022) in the Northern  
635 Canary upwelling system. Our results indicate that Puddies have a rather permeable boundary, but the level  
636 of coherence and isolation can be important in the lifespan of compounds inside the Puddy core. The lifespan  
637 of macronutrients was similar to what was observed by Frenger et al. (2018), but in our case,  $N_2O$ , although  
638 found in minimal concentrations, has a path similar to other macronutrients like  $NO_3^-$  (Figures 6, 7). In both  
639 the SP and HP cases,  $NO_2^-$  and  $NH_4^+$  decay rates were faster than those for  $NO_3^-$  and  $N_2O$ . Nitrate showed  
640 higher concentrations than other micronutrients, additionally, as long as there is  $NH_4^+$  and  $NO_2^-$ , nitrification  
641 increases the  $NO_3^-$  pool in subsurface waters where it is not consumed by photosynthesis. On the other hand,  
642 the production of  $N_2O$  is a function of  $[NH_4^+]$ ,  $[NO_2^-]$ , and  $[O_2]$ , and depends on processes such as  
643 nitrification and denitrification. Thus, according to the parameterization of the model (see Gutknecht et al.,  
644 2013a), the part of the equation that is a function of  $O_2$  in  $SMS(N_2O)$  is calculated, for  $[O_2] \geq 1$   $\mu M$ , as a  
645 function of the form  $\alpha e^{-O_2}$ . Hence, for very large values of  $O_2$ , the production of  $N_2O$  tends towards zero,  
646 and as  $O_2$  decreases,  $N_2O$  production increases exponentially. However, this production is diminished when  
647 there is less  $NO_2^-$  and  $NH_4^+$  available for nitrification because during denitrification, they are depleted more  
648 rapidly until the production of  $N_2O$  stops. Since the model does not consider  $N_2O$  consumption by biological  
649 processes (by denitrification or fixation), only during exchange with the atmosphere, the decrease in  $N_2O$   
650 observed within the Puddies that move away from the coast can only be due to the physical processes  
651 involved that allow exchange with exterior waters. Therefore, Puddies are a source of this gas outward from  
652 the coast. The evidence of higher  $O_2$  consumption during the first 100 days due to  $SMS(O_2)$  suggests greater  
653 biological activity in newly formed Puddies that must be supported by dissolved organic nitrogen from the  
654 source water, as proposed by Loveccio et al. (2022). In addition, although the decay rate is higher in the HP,  
655 the SMS negative values are also higher than in the SP, which could suggest a greater local production of  
656 nutrients due to the effect of remineralization that could extend the lifetime of these elements in the HP, as  
657 we mentioned in Section 3.4. The biological activity allows low-oxygen cores to persist longer, facilitating  
658 the maintenance of  $O_2 < 20$   $\mu M$  in the cores of the Puddies, where denitrification processes continue, while  
659 the edges ventilate the eddy generating unique conditions. In fact, this could explain the high biogeochemical  
660 variability observed in the core of the Puddies identified in all regions, which increased the farther they were  
661 from the coast (Figure 3, 4). The eddies characterized in each subregion provide insight into how and to what  
662 extent these eddies evolved from their formation to their arrival anywhere in the SEP.

#### 663 4.4 Advantages and Disadvantages of the Model for Low Oxygen Conditions

664 AOU: $NO_3^-$  ratios of 250:30 (up to 20:1) have been documented in the Atlantic from *in situ* monitoring of  
665  $NO_3^-$  within eddies (Kartensen et al., 2017), with  $NO_3^- < 25$   $\mu M$  observed in eddy cores with  $O_2 < 5$   $\mu M$  in  
666 the SEP (Stramma et al., 2013). The eddies modeled here showed AOU values similar to those found by  
667 Karstensen et al. (2017) in the eastern tropical North Atlantic, although  $NO_3^-$  was overestimated by 3 - 5  $\mu M$

668 with a ratio  $\text{AOU}:\Delta\text{NO}_3^-$  of 5:1 (Figures 3b, 4b, 5c; Stramma et al., 2013). Suboxic Puddies build up  $\text{NO}_2^-$   
669 and the maximum concentration appears underestimated in the model compared to previously reported in situ  
670 results (Stramma et al., 2013; Cornejo et al., 2012; Cornejo-D'Ottone et al., 2016). The relationship between  
671  $\text{NO}_2^-$  and  $\Delta\text{N}_2\text{O}$  in the northern zone also showed underestimation for both parameters, particularly  $\text{NO}_2^-$ . At  
672 the  $\text{N}_2\text{O}$  maximum produced by the model ( $>30$  nM, Figure 4), field data shows  $\text{NO}_2^-$  values  $>1$   $\mu\text{M}$  (Cornejo  
673 et al., 2012), but we obtained a  $\text{NO}_2^-$  maximum of  $0.15$   $\mu\text{M}$  (Figures 3c, 4c). Comparing our results with  
674 eddies monitored in the Southeastern Pacific, the  $\text{N}_2\text{O}$  concentrations observed in open ocean eddies agrees  
675 with those measured by Cornejo et al. (2016; Figure 3d, 7 case 1, S4) in an eddy originated in front of  
676 Concepcion (south zone), although there are differences of up to  $20$  nM with the eddy reported by Arévalo-  
677 Martínez et al. (2016; Figure 7, S4) in north zone of Chile. These results indicate better representation of  
678 biogeochemical processes by the model in a hypoxic than suboxic environment.

679 Biogeochemical components are challenging to model due to the numerous physical, biogeochemical, and  
680 biological processes involved. Specifically, under hypoxic or suboxic conditions, the nitrogen cycle is more  
681 complex due additional processes that occur within a narrow  $\text{O}_2$  range, which increases the sensitivity of the  
682 system. Processes such as denitrification remove nitrogen from the system but generate by-products such as  
683  $\text{N}_2\text{O}$  and  $\text{NO}_2^-$  through the alternative metabolic pathways that are less significant under oxic conditions (e.g.,  
684 denitrification,  $\text{NO}_3^-$  reduction). Denitrification is a complex process to parameterize, involving a range of  
685 steps for each nitrogen component and various rates of decomposition of particulate (large and small) and  
686 dissolved material. However, despite the attempt to consider these processes realistically, the model remains  
687 an approximation, but does reasonably represent the processes involved, primarily within the  
688 intrathermocline band (see Appendix 1). In the suboxic zone, while the model underestimated  $\text{O}_2$ ,  $\text{NO}_3^-$   
689 remained overestimated, but in the subsurface band associated with the core of OMZ, the model represented  
690 the lowest biases in  $\text{O}_2$  and nitrogen evaluated with CARS (see Appendix 1). This allowed us to present a  
691 more robust statistical analysis of biogeochemical properties inside and outside the eddies. Despite the  
692 difficulty in simulating realistically sharp mean gradients in water mass properties, the model did highlight  
693 typical features, such as  $\text{NO}_3^-$  consumption and production of  $\text{NO}_2^-$  and  $\text{N}_2\text{O}$ , processes that persist within  
694 Puddies far from their origin within the OMZ.

695

## 696 5 Conclusions

697 Using a high-resolution coupled simulation of the Southeast Pacific, we characterize the changes in internal  
698 biogeochemistry, their differences with external properties, and the processes involved in the  $\text{O}_2$  balance of  
699 Puddies during their transport to oceanic waters. The model resolved eddy dynamics and biogeochemical  
700 processes related to the nitrogen cycle, which exhibit characteristic processes of EBUS, such as  
701 denitrification. This methodology allowed us to make a statistical approximation of the biogeochemical  
702 changes that occur within these Puddies, and the dominant mechanisms involved in modulating the  
703 concentrations of these compounds during their trajectories from the formation zone to hundreds of  
704 kilometers offshore.

705 During formation, Puddies capture the biogeochemical signal that varies according to their origin, which is  
706 associated with the core of the Peru-Chile Undercurrent. Permeability at the periphery enables exchange with  
707 external waters that modulate the original signature, however, the core signal retains certain characteristic  
708 negative anomalies of O<sub>2</sub> and positive anomalies of other biogeochemical tracers. These disturbances  
709 associated with Puddies may contribute to the average properties being > P90 in the open ocean, contrasting  
710 with the formation zone where it is over P50. Although a high percentage of Puddies near the coast exhibit  
711 suboxic cores (all in the north and 70% in central-south Chile), the proportion decreases with distance from  
712 the coast, where hypoxic cores become more predominant (60% in C and G regions) indicating core  
713 ventilation during their trajectory, as observed in the OMZs of the SP and HP in Section 3.4. The dominant  
714 mechanism for O<sub>2</sub> input or output to/from the eddy core is lateral and vertical advection, with vertical mixing  
715 supply two orders of magnitude smaller. Consumption of O<sub>2</sub> through biological activity was observed for  
716 around 6 - 12 months, allowing longer term persistence of low O<sub>2</sub> conditions in the core despite ventilation at  
717 the periphery of the Puddy. This, in turn, can sustain processes – such as denitrification, which occur under  
718 hypoxic or suboxic conditions within the OMZ – into areas far beyond the OMZ contained within niches in  
719 the core with O<sub>2</sub> < 20 μM. The southern regions experience more deoxygenation and nutrient enrichment due  
720 to the influence of Puddies than the northern regions, where the OMZ is wider, and where water mass  
721 transition occurs. Clearly, the formation of Puddies is an important process in the zonal extension of  
722 boundaries at the Southern tip of the OMZ.

723 Biogeochemical tracers have a variety of lifespans depending on original concentration, and rates of demand  
724 and production. Ammonium and NO<sub>2</sub><sup>-</sup> tend to decline within the first 6 months, most strongly the first 100  
725 days of the life of the eddy, while other components decrease in concentration but persist longer. Despite  
726 being produced in low concentrations, N<sub>2</sub>O is retained in Puddies further from the coast, thus serving as a  
727 proxy of denitrification in the source water and also increasing the subsurface reservoir of this greenhouse  
728 gas in the open ocean.

729 Higher-resolution models allow us to characterize the mixing processes involved in eddy core ventilation and  
730 the exchange of properties with external waters by submesoscale dynamics. Coupling more complex  
731 biogeochemical models will serve to quantify the effects of other SMS processes within Puddies that are not  
732 considered in the present study. Validation and supplementary statistics of Puddies through further  
733 observations in the study area are recommended in order to deepen our understanding of coupled processes  
734 occurring in surface and subsurface eddies.

736

737

738

739

740 **Appendix 1: Biogeochemical model assessment**

741

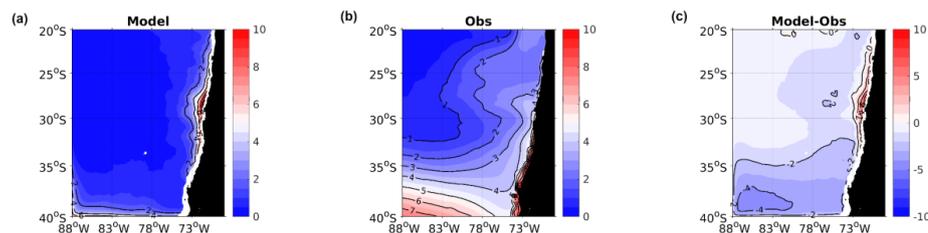

742 **A1.1 Data**

743 Climatological  $O_2$  and  $NO_3^-$  fields were taken from the CSIRO Atlas of Regional Seas (CARS2009;  
744 [www.marine.csiro.au/~dunn/cars2009/](http://www.marine.csiro.au/~dunn/cars2009/)) for the biogeochemical model assessment, which has a spatial  
745 resolution of 0.5 degrees for each month. For the study region, a depth of 800 m was adopted, distributed  
746 every 10 meters to the first 300 m, every 25 meters to 500 m, and then every 50 meters down to 800m.

747 **A1.2 Model Assessment**

748 **A1.2.1 Surface Nitrate**

749 Modeled concentrations of surface  $NO_3^-$  were compared to data from CARS. Model predictions showed low  
750  $NO_3^-$  ( $< 2 \mu M$ ) in general, except in the areas near the coast and in the southwest where concentrations  
751 reached  $8 \mu M$  (Fig. A1a). The observed concentrations were higher, particularly in the south (Fig. A1b).  
752 Overall, the model underestimated  $NO_3^-$  concentrations in most of the domain, although the differences  
753 compared to CARS were relatively minor, ranging between 0 -  $4 \mu M$  south of  $30^\circ S$  and between 0-2  $\mu M$   
754 north of  $30^\circ S$  (Figs. A1a, A1c). Adjacent to the coast between  $25^\circ$ - $35^\circ S$ , the model overestimated  
755 concentrations by  $\sim 7 \mu M$  (Fig. A1c). In general, differences were minimal over most of the study area, and it  
756 can therefore be considered that the model fairly well represents surface  $NO_3^-$ .

757

758 **Figure A1. Spatial distribution of mean surface  $NO_3^-$ . (a) ROMS-BioEBUS simulation, (b) CARS climatology, and**  
759 **(c) BIAS (model - observations).**

760

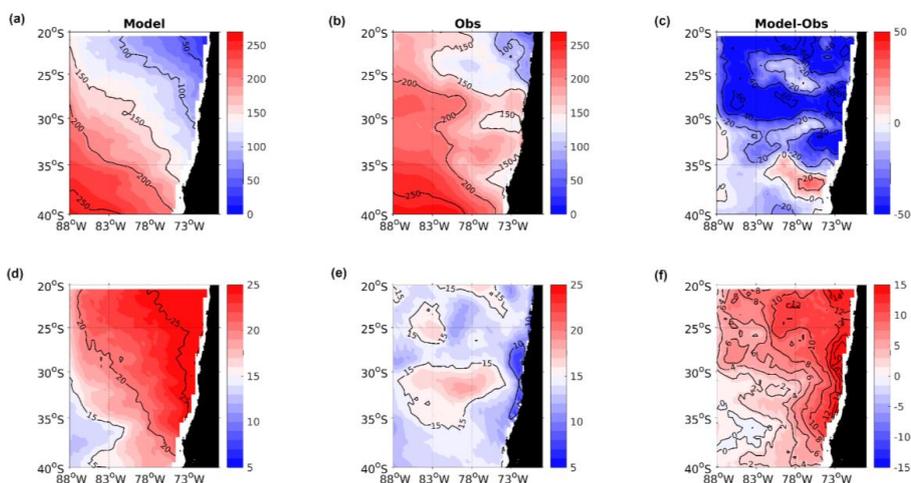

761 **A1.2.2 Oxygen and nitrate on the isopycnal layers**

762 Observed data from CARS were used to assess the average  $O_2$  and  $NO_3^-$  modeled in different density layers  
763  $S_{upper}$ ,  $S_{lower}$  and  $S_{core}$  (Figures A2, A3, A4). The model captured the principal characteristics of  $O_2$  and  $NO_3^-$ ,  
764 displaying a similar structure and latitudinal and zonal gradients. Compared with observed data, lower  $O_2$   
765 concentrations and higher  $NO_3^-$  concentrations were predicted near the coast and north of  $30^\circ S$  associated  
766 with the meridional changes of the offshore extension of the OMZ.

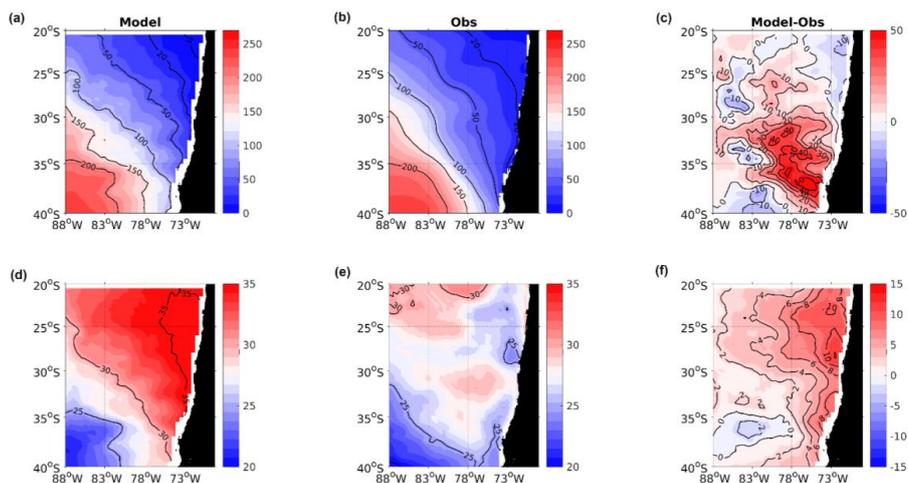

767 In the  $S_{upper}$  surface, observations revealed discontinuous areas with lower  $O_2$  concentrations north of  $25^\circ S$   
 768 ( $O_2 < 100 \mu M$ ), between  $30 - 31^\circ S$  and  $35 - 36^\circ S$  ( $O_2 < 150 \mu M$ ). The model mostly underestimated these  $O_2$   
 769 concentrations by  $40 \mu M$  north of  $30^\circ S$ , by around  $20 \mu M$  between  $30 - 35^\circ S$ , and overestimated them by  $20$   
 770  $\mu M$  between  $35 - 38^\circ S$  near the slope, but performed better south of  $35^\circ S$  offshore. For  $NO_3^-$ , observations  
 771 indicated very low concentrations mainly along the coast between  $23 - 35^\circ S$  ( $< 10 \mu M$ ), with an increase  
 772 to  $> 15 \mu M$  in the oceanic region. Therefore, the model overestimated concentrations in the coastal zone ( $> 10$   
 773  $\mu M$ ) and in the northern oceanic zone ( $4 - 8 \mu M$ , Figures A2).

774 Regarding the  $S_{core}$  layer, the model performed better in the northern region, underestimating  $O_2$   
 775 concentrations between  $0 - 10 \mu M$ . Off the coast, the bias ranged from  $-10$  to  $10 \mu M$ . However, south of  $30^\circ$   
 776  $S$ , between  $75 - 80^\circ W$ , the model overestimated  $O_2$  concentrations by over  $40 \mu M$ , whereas west of  $82^\circ W$ ,  
 777 the bias varied between  $-10$  to  $10 \mu M$ . Nitrate overestimation was observed in the coastal region with  
 778 concentrations exceeding  $6 - 8 \mu M$ , particularly in the northern oceanic area ( $2 - 4 \mu M$ ). The model better  
 779 reproduced real  $NO_3^-$  data in the region west of  $78^\circ W$  and south of  $30^\circ S$  (Figure A3).

780

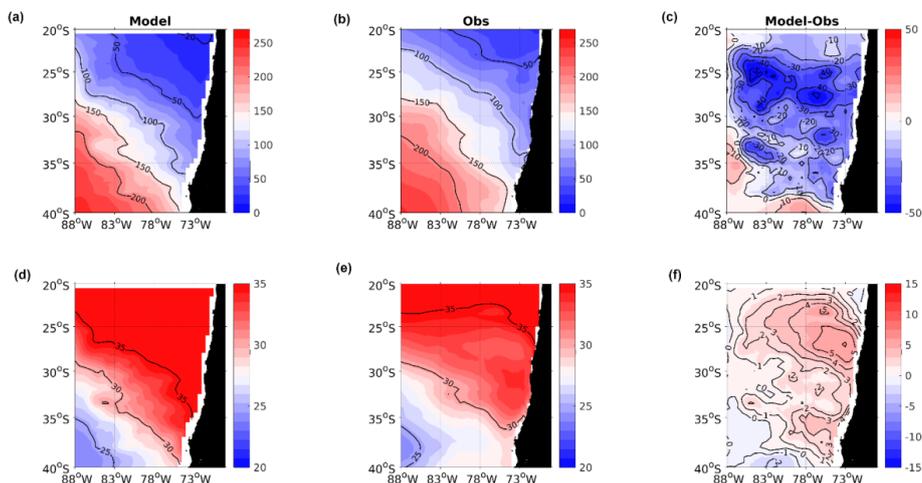

781 **Figure A2. (a-c) Mean  $O_2$  and (d - f) mean  $NO_3^-$  concentration in the isopycnal layer  $S_{upper} = 26.0 \text{ kg/m}^3$  from the**

783

784 **Figure A3. (a-c) Mean O<sub>2</sub> and (d - f) mean NO<sub>3</sub><sup>-</sup> concentration in the isopycnal layer S<sub>core</sub> = 26.6 kg/m<sup>3</sup> from the**

785 **ROMS-BioEBUS simulation (left boxes), CARS climatology (middle boxes), and BIAS (right boxes).**

786

787 **Figure A4. (a-c) Mean O<sub>2</sub> and (d - f) mean NO<sub>3</sub><sup>-</sup> concentration in the isopycnal layer S<sub>lower</sub> = 26.9 kg/m<sup>3</sup> from the**

788 **ROMS-BioEBUS simulation (left boxes), CARS climatology (middle boxes), and BIAS (right boxes).**

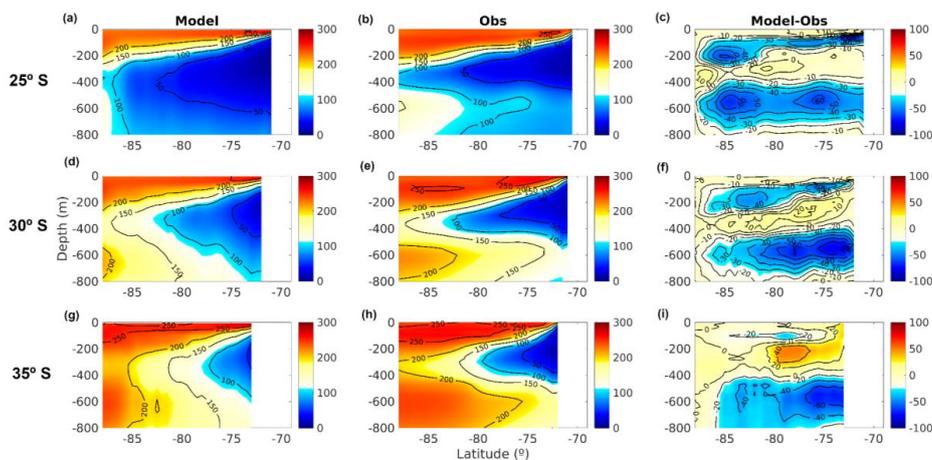

789 In the S<sub>lower</sub> layer, the model underestimated O<sub>2</sub> concentrations north of 30° S by between 10 - 40 μM, with a  
 790 smaller underestimation south of 30° S (10 - 30 μM) and an overestimation in the southwest (0 - 10 μM). The  
 791 model represented NO<sub>3</sub><sup>-</sup> well, with deviations from observations ranging from -2 to 5 μM and with the  
 792 greatest overestimation occurring in the region where O<sub>2</sub> < 50 μM (Figure A4).

793

794 **A1.2.3 Vertical Structure**

795 The vertical structure of  $O_2$  and  $NO_3^-$  was evaluated by comparing the model with the CARS climatology  
 796 along zonal sections at 25°S, 30°S, and 35°S (Figures A5, A6). Along the latitudinal gradient, the contour of  
 797 50  $\mu M$   $O_2$  decreased towards the south. Observations show an elongated low-oxygen tongue in subsurface  
 798 waters compared to model predictions, along with an intrusion of oxygenated waters both at the surface and  
 799 at depth (~600 m), enclosing the low-oxygen water with pronounced oxyclines (Figure A5). This is  
 800 consistent with a greater bias within the oxyclines, where the model tended to underestimate observed data,  
 801 particularly in the lower oxycline (underestimated by up to 60  $\mu M$ ). In the subsurface layer between 200 -  
 802 400 m, the model better represented  $O_2$  levels, especially at 25 - 30°S where differences ranged from 0 - 10  
 803  $\mu M$  (Figure A5c, A5f). At 35°S, there was an overestimation (40  $\mu M$ ) between 75-80°W low 200 - 300 m  
 804 depth (Figure A5i).

805

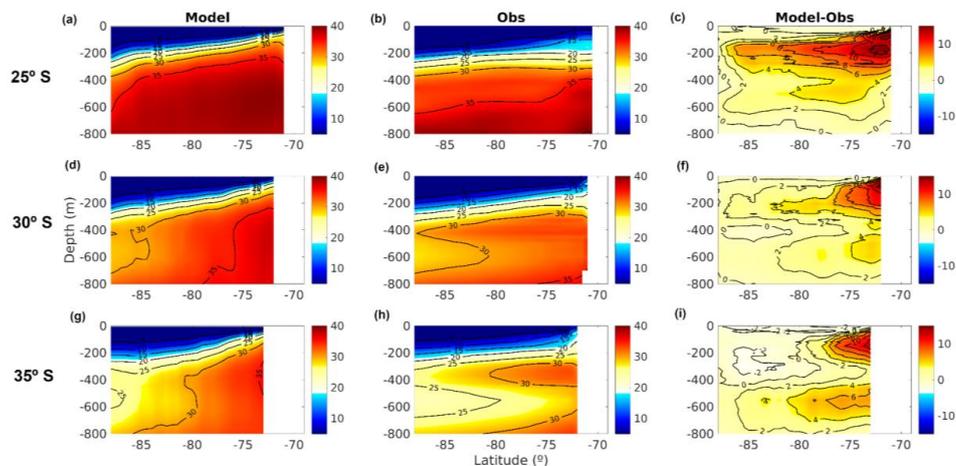

806 **Figure A5. Zonal section of mean  $O_2$  concentration at (a - c) 25°S, (d - e) 30°S, and (f - h) 35°S. (a, d, g) from the**  
 807 **ROMS-BioEBUS simulation (left boxes), CARS climatology (middle boxes), and BIAS (right boxes).**

808 Along 25° S the model predicted higher subsurface  $NO_3^-$  concentrations near the coast compared to  
 809 observations, showing differences of up to 15  $\mu M$ . Below 400 m of depth, overestimations ranged from 0 - 4  
 810  $\mu M$  (Figure A6a, A6b, A6c). These differences decreased towards the south; at 30° S and 35° S, the most  
 811 significant differences extended from the coast to 76° W and below -300 m (overestimations of 8 - 12  $\mu M$ ),  
 812 whereas elsewhere, differences remained between 0 - 4  $\mu M$ . Subsurface  $NO_3^-$  was underestimated by 2  $\mu M$   
 813 by the model at 35° W and west of 80° W (Figures A6f, A6i).

814 The Taylor diagram summarizes an annual average statistic of  $O_2$  and  $NO_3^-$  for each of the subregions by  
 815 comparing the model to the CARS climatology in the upper 800 m of the water column (Figures A7, A8).  
 816 Estimates of standard deviation, correlation, and RMSE reveal that the current model configuration is  
 817 generally in reasonable agreement with observations, primarily in the subsurface layer where most of the

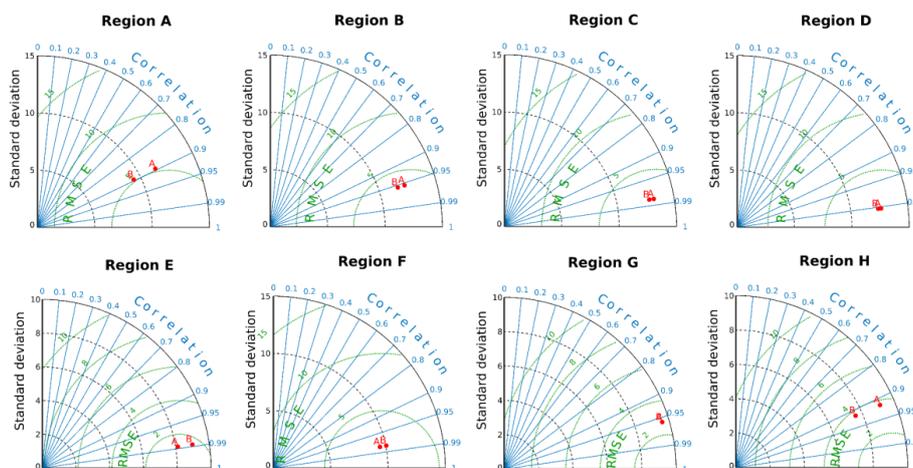

818 properties of Puddies were computed. Therefore, there is confidence in using the model for the  
 819 biogeochemical characterization of these mesoscale processes.

 827 simulation (A, red circle) was compared with CARS climatology (B). The X-Y axis refers to the standard deviation  
 828 (black lines), correlations in the radial axis (blue lines) and RMSE is indicated by curved lines (green).

829

830 **Figure A8.** Annual mean Taylor diagram for  $\text{NO}_3^-$  concentrations in the eight subregions of the study zone (20-40  
831 °S, from the coast to 88°W). The average was calculated for the water column between 0-800 m. ROMS-BioEBUS  
832 simulation (A, red circle) was compared with CARS climatology (B). The X-Y axis refers to the standard deviation  
833 (black lines), correlations in the radial axis (blue lines) and RMSE is indicated by curved lines (green).

834

#### 835 **Code availability**

836 ROMS model code is available at <http://www.croco-ocean.org>. All input data set and configuration of our  
837 ROMS/BIOEBUS simulations are described in section and in the references therein. This work was granted  
838 access to the HPC resources of CALMIP supercomputing center at the Toulouse University under the  
839 allocations 2017-1044 and 2018- 1044.

#### 840 **Author contribution**

841 LOC, OP, MC and BD designed the study. BD performed the simulation. LOC made the assessment, eddy  
842 identification and statistical analysis of the model outputs. OP supervised the project. LOC interpreted the  
843 results and wrote the manuscript with contributions from all co-authors.

#### 844 **Competing interests**

845 The authors declare that they have no conflict of interest.

846 **Acknowledgements:** We thank M. Pizarro-Koch for their valuable contributions to this work. LOC  
847 was supported by ANID doctoral scholarships and the R20F0002 (PATSER) ANID program. This research  
848 was partially supported by ANID (FONDECYT projects: 1181872 & 1241203). OP thanks support from

849 (Millennium Institute of Oceanography grant IC-120019). Additional support was provided by the BD  
850 acknowledges support from ANID (Concurso de Fortalecimiento al Desarrollo Científico de Centros  
851 Regionales 2020-R20F0008-CEAZA, Anillo Eclipse ACT210071 and Centro de Investigación  
852 Oceanográfica en el Pacífico Sur-Oriental COPAS COASTAL FB210021, Fondecyt Regular N°1190276).  
853 B.D. is supported by the EU H2020 FutureMares project (Theme LC-CLA-06-2019, Grant agreement  
854 No 869300) and the CE2COAST project funded by ANR (FR), BELSPO (BE), FCT (PT), IZM (LV), MI  
855 (IE), MIUR (IT), Rannis (IS) and RCN (NO) through the 2019 “Joint Transnational Call on Next Generation  
856 Climate Science in Europe for Oceans” initiated by JPI Climate and JPI Oceans.
