**Abstract.** Four parameterizations have been developed to simulate global distributions of thundercloud streamer corona discharges (also known as Blue Luminous Events or BLUEs) mainly producing bluish optical emissions associated to the second positive system of N<sub>2</sub> accompanied by no (or hardly detectable) 777.4 nm light emission. BLUEs occur globally between about 7 and 12 times less frequently (Soler et al., 2022) than lightning flashes. The four schemes are based on nonlinear functions of the cloud top height (CTH), the product of the convective available potential energy (CAPE) and total precipitation (TP), the product of CAPE and specific cloud liquid water content (CLWC), and the product of CAPE and specific cloud snow water content (CSWC). Considering that thunderstorms occur on hourly timescales, these parameterizations have been tested using ERA5 hourly data (except for CTH, not available in ERA5) for the meteorological variables considered, finding that the proposed BLUE schemes work fine and are consistent with observations by ASIM. Moreover, the parameterizations have been implemented in a global chemistry-climate model that generates annual and seasonal global distributions for present day and end of 21st century climate scenarios. Present day predictions are in good agreement with recent observations by the Atmosphere Space Interaction Monitor (ASIM).

## 1 Introduction

The availability of regular space observations of total (intra cloud and cloud to ground) lightning since 1995 has generated large datasets that have allowed to derive annual and seasonal geographical distributions of total lightning, resulting in an annual average flash rate of  $\sim 45 \pm 2$  flashes s<sup>-1</sup> between  $\pm 52^\circ$  latitude (Christian et al., 2003; Cecil et al., 2014; Blakeslee et al., 2020). Prediction of global total lightning flash rate and geographical distribution are increasingly important, since lightning is a frequent natural hazard, considered a proxy for severe weather, a cause of large wildfires (Komarek, 1964; Pyne et al., 1998; Latham and Williams, 2001; Pérez-Invernón et al., 2021, 2022, 2023), and a direct source of nitric oxide (NO) (Huntrieser et al., 2002; Schumann and Huntrieser, 2007; Pérez-Invernón et al., 2022) in the troposphere that impacts the balance of important upper troposphere lower stratosphere (UTLS) chemical species such as nitrogen dioxide (NO<sub>2</sub>), ozone (O<sub>3</sub>) and key oxidizing

radicals such as hydroxyl (OH) and hydroperoxyl (HO<sub>2</sub>), (Schumann and Huntrieser, 2007; Finney et al., 2016; Gordillo-Vázquez et al., 2019). Besides this, recent studies also suggest a direct production of OH and HO<sub>2</sub> by lightning strokes (Brune et al., 2021). All these reasons supported the need to incorporate lightning into chemistry-climate models.

25 The sub-grid spatial dimensions of lightning require their parameterization using different input meteorological variables and functional forms (Price and Rind, 1992; Grewe et al., 2001; Allen and Pickering, 2002; Finney et al., 2014; Luhar et al., 2021). The implementation of lightning parameterizations in different global chemistry-climate models (Tost et al., 2007; Romps et al., 2014a; Finney et al., 2014; Gordillo-Vázquez et al., 2019) have been tested against total lightning observations from low earth orbit (Christian et al., 2003; Cecil et al., 2014; Blakeslee et al., 2020) and, very recently, also using data from  
30 geostationary satellites (Zhang et al., 2021).

Corona discharges, occurring both in the lab and in thunderclouds, are characterized by cold ionization waves known as streamers. Corona discharges are formed by numerous streamers. The electromagnetic counterpart of thundercloud corona discharges are Narrow Bipolar Events (NBEs) (Rison et al., 2016; Soler et al., 2020). They produce bluish optical emissions (250-450 nm), leading to the adoption of the term Blue Luminous Events (BLUEs) for their optical counterpart.

35 While the hot and thermal air plasma in lightning stroke channels mostly excites atomic species like oxygen atoms released from thermal dissociation of O<sub>2</sub> leading to 777.4 nm optical emissions typical of lightning flashes, streamer corona discharges are cold non-thermal plasmas where only heavy particles are cold and electrons are very hot (up to 10 eV). Thus corona discharges are able to activate (excite) molecular species like N<sub>2</sub>, O<sub>2</sub> and H<sub>2</sub>O by non-thermal equilibrium electron-impact collisions (Gordillo-Vázquez and Pérez-Invernón, 2021), which cause distinct bluish optical emissions mostly associated to  
40 second positive system of N<sub>2</sub> radiative de-excitations.

Research results since the early 1970s indicate that, in addition to lightning, thundercloud leaderless kilometer scale corona electrical discharges formed by hundreds of millions of streamers (Liu et al., 2019; Cooray et al., 2020) are relatively common ( $\sim 45 \pm 2$  lightning flashes s<sup>-1</sup> vs 6 - 3.5 Blue flashes s<sup>-1</sup> (Soler et al., 2022), that is,  $\sim 7$ -12 times less frequent than global average number of lightning flashes) in thunderclouds around the globe (Soler et al., 2020, 2021; Li et al., 2021; Liu  
45 et al., 2021). In particular, recent laboratory experiments (Jenkins et al., 2021) suggest that observations during thunderstorms reporting sudden local enhancements of O<sub>3</sub> (Shlanta and Moore, 1972; Brandvold et al., 1996; Zahn et al., 2002; Minschwaner et al., 2008; Brune et al., 2021), and OH and HO<sub>2</sub> (Brune et al., 2021) could be associated to dim leaderless corona discharges (BLUEs) in storm clouds (Brune et al., 2021). These episodes suggest a probable regional atmospheric chemistry impact of thundercloud coronas, a subject which is still poorly quantified (Gordillo-Vázquez and Pérez-Invernón, 2021).

50 In this study we present four parameterizations to simulate global distributions of thundercloud corona discharges producing BLUEs (Soler et al., 2020, 2021, 2022; Li et al., 2021). The proposed storm cloud corona schemes are based on a non-linear dependence of cloud top height (CTH), and on non-linear combinations of pairs of meteorological parameters such as convective available potential energy (CAPE), total precipitation (TP), cloud liquid water content (CLWC), and cloud snow water content (CSWC), which are all available from satellite data and atmospheric reanalysis (used to build the parameterizations)  
55 and in global chemistry-climate models. Some of these meteorological variables (CTH, Price and Rind (1992), TP, Allen and Pickering (2002); Romps et al. (2014b, 2018), CAPE, Romps et al. (2014b, 2018)) have been previously used to build different

lightning parameterizations (Price and Rind, 1992; Allen and Pickering, 2002; Romps et al., 2014b, 2018). Other variables, like CSWC and CLWC, had not been used before (to the best of our knowledge) but seem to work pretty well since both CSWC and CLWC contribute to the electrification of the thundercloud.

60 Most previous lightning parameterizations have been tested in a number of global atmosphere circulation models to explore how the different lightning schemes compare with available lightning observations in the present, to establish correlations with meteorological / climatic patterns and to predict possible future lightning occurrence global rates and geographical distributions in the context of a variety of future climatic scenarios. Our goal here is to proceed similarly using BLUE parameterizations since models allow looking into the future (end of the 21st century) to reach preliminary answers to how BLUEs geographical  
65 distribution and global occurrence rate will change in a warmer atmosphere (see supplementary material). Therefore, a global chemistry-climate model is used to (i) test the corona schemes against present day climatic scenarios (both annual and seasonal), when observations are available by the Atmosphere Space Interaction Monitor (ASIM), and to (ii) approximately predict the occurrence rate and annual geographical distribution of thundercloud coronas in future (2091-2095) climate scenarios (see supplementary material).

70 The next section describes the data, observations and modeling employed to build and test the proposed thundercloud corona parameterizations. Section 3 explains the procedures followed to develop the schemes for cloud corona discharges. Section 4 evaluates the climatological performance of the storm cloud corona parameterizations in present day while results for the end of the 21st century climate scenarios are briefly discussed and shown in the supplementary material. The last section of the paper presents the main conclusions.

## 75 2 Data description, observations and modeling

### 2.1 ECMWF ERA5 and COPERNICUS CLARA datasets

The European Centre for Medium-Range Weather Forecasting (ECMWF) provides the ERA5 global atmospheric reanalysis data product (Hersbach et al., 2020). ERA5 updates the previous ERA-Interim reanalysis (Dee et al., 2011) which were stopped being produced after 31 August 2019. The ERA5 data cover the Earth on a spatial resolution of  $0.25^\circ$  latitude and longitude  
80 and resolve the atmosphere using 137 levels from the surface up to a pressure of 0.01 hPa ( $\sim 80$  km height). Single or surface level data are also available. ERA5 combines large amounts of historical observations into global estimates using advanced modelling and data assimilation systems. ERA5 provides hourly (also sub-daily and monthly) estimates of a large number of atmospheric, land and oceanic climate variables.

In order to build our thundercloud corona parameterizations we have selected as input variables annual averages of the cloud  
85 top height (CTH), convective available potential energy (CAPE) and total precipitation (TP), which are single (surface) level variables, and the annual averages of the specific cloud liquid water content (CLWC) and specific snow liquid water content (CSWC) at 450 hPa. CAPE, TP, CLWC and CSWC are taken from ERA5 (Hersbach, H. et al., 2018a, b; Hersbach et al., 2020). CTH (not available in ERA5) is taken from the CLARA product family (Karlsson et al., 2017) of the Essential Climate Variable (ECV) Cloud Properties of COPERNICUS (the European Union's Earth observation programme).

90 Note that hourly data have been averaged to obtain daily values and then averaged again into monthly values and yearly values. We have tested the BLUE parameterizations with hourly data (except for CTH for which only monthly data are available) and the result is shown in Figure 1 (see section 3) based on hourly data of the meteorological parameters used.

## 2.2 Observations used

We use global observations of nighttime thundercloud corona discharges (also known as Blue LUMinous Events or BLUEs) recorded by the high sampling rate (100 kHz) photometer in the near UV (337 nm/4 nm) of the Modular Multispectral Imaging Array (MMIA) that is part of ASIM (Chanrion et al., 2019; Soler et al., 2020, 2021). ASIM is aboard the International Space Station (ISS) and, due to the inclination ( $\sim 52^\circ$ ) of the ISS orbit, locations near the equator are observed less frequently than those at higher latitudes.

The worldwide corona observations used here have been recently published (Soler et al., 2022) and span a period of two 100 years of MMIA level 1 (calibrated) data from 1 April 2019 to 31 March 2021 (Soler et al., 2022). In particular, we use the annual and seasonal averages associated with the global distribution of BLUEs obtained by the algorithm described in Soler et al. (2021) adding an extra step for filtering high energy (and cosmic ray) candidates, this distribution is described as GD-2 in Soler et al. (2022).

MMIA observations of storm cloud coronas exhibit strong features in the 337 nm/4 nm photometer with negligible (barely 105 above the noise level  $0.4 \mu\text{W}/\text{m}^2$ ) signal in the 777.4 nm/5 nm photometer, which is also continuously monitored (Soler et al., 2020, 2021; Li et al., 2021).

## 2.3 Modeling

As an illustration of their applicability, the developed BLUE parameterizations have been incorporated into a chemistry-climate model. We use the ECHAM / MESSy Atmospheric Chemistry (EMAC) model, which is a chemistry-climate model that couples 110 the fifth generation European Center HAMBURG general circulation model (ECHAM5) and the second version of Modular Earth Submodel System (MESSy) to link multi-institutional computer codes, known as MESSy submodels (Jöckel et al., 2010, 2016). Such submodels are used to describe tropospheric and middle atmosphere processes and their interaction with oceans, land, and influences coming from anthropogenic emissions.

The thundercloud corona parameterizations described below are used in MESSy for usage within the ECHAM / MESSy 115 Atmospheric Chemistry (EMAC) model. Cloud corona schemes are implemented as a new element of EMAC to account for atmospheric electricity phenomena that, so far, only includes lightning parameterizations. The variables CAPE, convective precipitation, and specific cloud liquid water content (CLWC) are calculated by the submodel CONVECT (Tiedtke, 1989; Nordeng, 1994), while the large scale precipitation is imported from the CLOUD submodel (Roeckner et al., 2006). The total precipitation is calculated as the sum of the convective and the large scale precipitation. Following the same approach as the 120 LNOX submodel for the calculation of lightning (Tost et al., 2007), corona frequencies are ignored below a certain cut-off, in order to avoid introducing artifacts in the simulations. We set the corona frequency to zero if the cloud thickness is lower than 3 km.

Two sets of simulations are performed, one that covers the present day climatic state and another one for the end of the 21st century under the Representative Concentration Pathway 6.0 (RCP6.0) to estimate future (see supplementary material) occurrence and geographical patterns of thundercloud coronas. We do not have enough computational resources to run all the possible future scenarios. Therefore, we had to choose only one of them. We chose the RCP6.0 scenario that is one of the two intermediate stabilization pathways (higher medium). The EMAC simulations are performed with 720 seconds time step length and in the T42L90MA resolution, i.e., with a  $2.8^\circ \times 2.8^\circ$  quadratic Gaussian grid in latitude and longitude with 90 vertical levels starting at the surface and reaching up to the 0.01 hPa pressure level (Jöckel et al., 2016). Present day simulations are set-up by using the namelist setup for purely dynamical simulations (referred to as the E5 setup, no chemistry) in the mode of free-running simulations. Present-day simulations are started in January, 2000 using ERA-Interim reanalysis meteorological fields (ECMWF, 2011) as initial conditions. The RCP6.0 simulation is set-up following the simulation RC2-base-04 of Jöckel et al. (2016) and Pérez-Invernón et al. (2023). The sea surface temperatures (SSTs) and the sea-ice concentrations (SICs) are prescribed from simulations with the Hadley Center Global Environment Model version 2 - Earth System (HadGEM2-ES) Model (Collins et al., 2011; Bellouin et al., 2011). Projected mixing ratios of the greenhouse gases and SF<sub>6</sub> are incorporated from Eyring et al. (2013). Anthropogenic emissions are taken from monthly values provided by Fujino et al. (2006) for the RCP6.0 scenario. We refer to Jöckel et al. (2016) for more details about the simulation set-up.

We start the 6-years RCP6.0 in January, 2090 and consider 1 year of spin-up to reach equilibrium. The supplementary material shows comparison of the results of implementing thunderstorm corona schemes in EMAC for the years 2091 to 2095 with present day observations (recorded by ASIM) and with simulations for the years 2000 to 2009. We are aware of the limitations of this comparison in terms of the short period of available space observations. However, it is important to highlight that this is the first global scale continuous observations of BLUEs and, though limited, we consider it is worth showing such comparison between present day and the warmer atmosphere expected for the end of the 21st century.

### 3 Thundercloud Corona Parameterizations

Electrical activity in thunderclouds in the form of lightning flashes have been previously correlated with CAPE (Williams et al., 1992; Pawar et al., 2012), with precipitation (Battan, 1965; Petersen and Rutledge, 1998; Allen and Pickering, 2002), and even with a linear combination of both of them (Romps et al., 2014a, 2018).

The experimental finding that thunderstorm electrification (in terms of substantial charge transfer) needs the presence of water droplets (Saunders et al., 1991) indicates that the liquid water content in thunderclouds can be a good proxy for electrical activity.

We have chosen the convective available potential energy (CAPE) as a proxy of deep convection as shown by Ukkonen and Mäkelä (2019). As shown in Figure S12 of the supplementary material of Soler et al. (2021), the seasonal CAPE show that, in general, there are stronger CAPEs in regions with more BLUEs. However, CAPE can also be very high in the ocean where it is not that common to find many BLUEs. Accompanying Figure S12, the seasonal CAPE vs BLUEs per second relationships were quantified using the Pearson linear correlation coefficient (R) (varying between -1 and +1, with +1 being

perfect linear correlation, 0 null linear correlation, and -1 perfect linear anti-correlation). The correlations resulted better for the zonal distributions ( $0.77 < R < 0.89$ , with DJF and MAM being the best) than for the meridional distributions ( $0.42 < R < 0.64$ , with DJF and JJA being the best).

Following the above results, Figure 5b in Husbjerg et al. (2022), showed that by clustering the BLUE discharge data set, 160 cells which generate fast (close to cloud top) BLUE discharges have a median CAPE of  $1390 \text{ Jkg}^{-1}$  compared to  $1128 \text{ Jkg}^{-1}$  for cells generating only slow (deep in the cloud) BLUE discharges, further indicating that stronger cells are more likely to generate fast BLUE discharge. For comparison, the median CAPE for lightning flashes was  $816 \text{ Jkg}^{-1}$  in Husbjerg et al. (2022).

The above results lead us to use CAPE as a plausible meteorological variable to track the occurrence of BLUEs. Thus, three of the proposed parameterizations are based on CAPE times another meteorological variable like the total precipitation 165 (previously used in lightning schemes like the one proposed in Romps et al. (2014b) or the Cloud Liquid (or Snow) Water Contents (CLWC or CSWC), which presence in thunderclouds can contribute to cloud electrification. He et al. (2022) developed a parameterization based on the product of CAPE times the charging rate of collisions between graupel and other types of hydrometeors. Finally, we used the Cloud Top Height (CTH) variable to somehow test its "quality" as it was proposed in the popular lightning scheme presented by Price and Rind (1992).

170 We propose four parameterizations for corona discharges in thunderclouds based on (i) a nonlinear dependence of the cloud top height (CTH (km)) and nonlinear combinations of (ii) the convective available potential energy ( $\text{CAPE} (\text{J Kg}_{air}^{-1})$ ) and the total precipitation (TP (m)), (iii) CAPE and the specific cloud liquid water content ( $\text{CLWC} (\text{Kg}_{liquid} \text{ Kg}_{moist-air}^{-1})$ ), and on (iv) CAPE and the specific cloud snow water content ( $\text{CSWC} (\text{Kg}_{ice} \text{ Kg}_{moist-air}^{-1})$ ), where the CLWC and CSWC are defined as the mass of cloud liquid and snow water droplets per kilogram of the total mass of moist air.

175 We build the thundercloud corona schemes by using them in the two year data period (1 April 2019 to 31 March 2021). We consider the annual average number of thundercloud coronas per second given in each grid cell by the GD-2 distribution provided by Soler et al. (2022), and the annual average of the meteorological variables. The CTH, CAPE, TP and the specific CLWC and CSWC are taken within  $2^\circ \times 2^\circ$  grid cells where cloud coronas take place according to GD-2.

The detailed procedure to build the corona parameterizations follows a number of steps: First, we take both  $2^\circ \times 2^\circ$  maps 180 – observed global annual averaged cloud corona occurrence rate (BLUEs  $\text{s}^{-1}$ ) and annually averaged of monthly averaged meteorological variables chosen as proxys – and transform them into 1D arrays. Second, we sort the meteorological dataset array following ascending values. Third, we sort the coronas array doing the same index changes we made in the second step. Fourth, we divide each array into 40 chunks, cutting each interval where the percentile distribution is a divisor of 2.5 % (neglecting the geographical position). We choose 40 chunks as an optimum, if we take more chunks we may have too much 185 repeated information between one chunk and the next, and if we take less values it may not be enough to characterize the curve. Fifth, we calculate the mean of each chunk, this will result in 40 points for the predictor (meteorological data) and 40 points for the predict (corona data). Note that the previous procedure is performed at global scale. Finally, we approximate the data with the equation  $y = \alpha \times x^\beta$  by a least squares fit, where  $x$  are the values of the selected meteorological variables used as proxys and  $y$  corresponds to the occurrence rate (in events  $\text{s}^{-1}$ ) of thundercloud coronas. Note that the chosen mathematical 190 formulae ( $y = \alpha \times x^\beta$ ) for the parameterization of BLUEs are based on previous ones for lightning flashes (Price and Rind,

1992; Michalon et al., 1999; Luhar et al., 2021; Romps et al., 2014b) including the product of two magnitudes, a constant  $\alpha$  multiplied by a variable  $x$  raised to a power ( $\beta$ ), where  $x$  can be a single meteorological variable (Price and Rind, 1992; Michalon et al., 1999; Luhar et al., 2021) or the product of two meteorological variables (Romps et al., 2014b).

Figure 1(a)-(d) represents the global annual average (based on hourly data for CAPE, TP, CLWC and CSWC, and monthly data for CTH) of the nighttime corona occurrence rate (coronas  $s^{-1}$ ) versus CTH, CAPE  $\times$  TP, CAPE  $\times$  CLWC and CAPE  $\times$  CSWC, which result in the four proposed schemes  $C_{F1} = \alpha_1 \times (CTH)^{\beta_1}$ ,  $C_{F2} = \alpha_2 \times (CAPE \times TP)^{\beta_2}$ ,  $C_{F3} = \alpha_3 \times (CAPE \times CLWC)^{\beta_3}$  and  $C_{F4} = \alpha_4 \times (CAPE \times CSWC)^{\beta_4}$  where the parameters  $\alpha_1 = 0.010 \pm 0.004$  and  $\beta_1 = 3.36 \pm 0.17$ ,  $\alpha_2 = 5.1 \pm 0.3$  and  $\beta_2 = 0.83 \pm 0.04$ , and  $\alpha_3 = 1100 \pm 200$  and  $\beta_3 = 0.78 \pm 0.04$ , and  $\alpha_4 = 250 \pm 40$  and  $\beta_4 = 0.67 \pm 0.04$  are obtained from the best approximations of nighttime corona occurrence rate observed by ASIM as a function of values of CTH, CAPE  $\times$  TP, CAPE  $\times$  CLWC and CAPE  $\times$  CSWC. The quality of the approximations covering the two years (1 April 2019 to 31 March 2021) is evaluated with  $R^2$  metrics that results in  $R^2 = 0.94$  for the CTH scheme,  $R^2 = 0.96$  for the CAPE  $\times$  TP scheme,  $R^2 = 0.96$  for the CAPE  $\times$  CLWC scheme, and  $R^2 = 0.96$  for the CAPE  $\times$  CSWC scheme. In all cases, the fitting produces a  $R^2$  score equal or above 0.94 which indicate a strong correlation between BLUEs and the meteorological variables used. The dashed black lines in Figure 1(a)-(d) show the upper and lower limits of the fitting curve associated to the upper/lower errors in the fitting coefficients.

## 4 Results

### 4.1 ERA5, CLARA and Model Simulations vs Observations

Figure 2 shows two-year average (1 April 2019 through 31 March 2021) nighttime geographical distribution of global corona (BLUE) electrical activity in thunderclouds according to the GD-2 distribution derived from ASIM observations (Soler et al., 2022) (a), and annual global predictions for BLUE occurrence rate based on ERA5 hourly data introduced in the corona (BLUE) parameterizations  $C_{F2}$  (b), and  $C_{F3}$  (c). Note that the colorbars have the same scale. Considering that thunderstorms occur on hourly timescales, these plots show that when ERA5 hourly data for the meteorological variables are considered, the proposed BLUE parameterizations work fine and are consistent with observations by ASIM. The global annual average BLUE rates obtained from the four adopted parameterizations using ERA5 hourly data (for CAPE, TP, CLWC and CSWC) and CLARA monthly data (for CTH) produce 3.53 BLUEs  $s^{-1}$  for the  $C_{F2}$  scheme, 3.42 BLUEs  $s^{-1}$  for the  $C_{F3}$  scheme, 3.20 BLUEs  $s^{-1}$  for the  $C_{F4}$  scheme, and 4.41 BLUEs  $s^{-1}$  for the  $C_{F1}$  scheme. These numbers agree reasonably well with the observed mean global occurrence rate of 3.5 BLUEs  $s^{-1}$  measured by ASIM (Soler et al., 2022). The  $C_{F1}$  scheme (for CTH) produces a larger occurrence rate probably due to the fact that we took all CTH values available in CLARA for the period considered without neglecting low CTH values below 5 km (the CTH fit shown in Price and Rind (1992) for lightning flashes exhibit a cut-off at about 5 km). Figure S1 in the supplementary material shows two-year average (1 April 2019 through 31 March 2021) nighttime geographical distribution of global corona (BLUE) electrical activity in thunderclouds according to the GD-2 distribution derived from ASIM observations (Soler et al., 2022) (a), and annual global predictions for BLUE occurrence

rate based on CLARA monthly data introduced in the corona (BLUE) parameterizations  $C_{F1}$  (b), and ERA5 monthly data introduced in the corona (BLUE) parameterizations  $C_{F2}$  (c), and  $C_{F3}$  (d).

225 Figure 3 illustrates the comparison between the two year average (1 April 2019 through 31 March 2021) nighttime corona GD-2 distribution observed by ASIM (a), and synthetic annual global average distributions obtained for the present day climate state model simulations applying the  $C_{F1}$  (b),  $C_{F2}$  (c), and  $C_{F3}$  (d) cloud corona schemes, respectively. Figure S2 in the supplementary material shows synthetic annual global average distributions of cloud coronas obtained using  $C_{F4}$ . We calculated the synthetic annual global average by accounting for all time steps throughout the diurnal cycle assuming that daytime  
230 coronas in thunderclouds causing BLUEs are equally probable as those occurring at nighttime. Both, observations and simulation results, show three thundercloud corona chimneys clearly distinguishable over the Americas, Africa / Europe and Asia / Australia. While the observed maximum in the Americas is located north of Colombia, model predictions locate it in a region partly covering the north of Peru, southern Colombia and eastern Brasil.

Though the global annual average rate for observations and predictions is the same ( $3.5 \text{ coronas s}^{-1}$ ), the geographical  
235 distribution of coronas in thunderclouds predicted by the  $C_{F1}$  and  $C_{F2}$  schemes resemble ASIM observations more faithfully. For instance, according to available ASIM observations, the west of North America and the south of Australia hardly exhibit thundercloud corona activity. The Tornado Alley shows the highest activity in North America. These features are better reproduced by the  $C_{F1}$  and  $C_{F2}$  schemes than by  $C_{F3}$ . In addition, the predicted cloud corona discharge geographical distribution in Africa / Europe given by the  $C_{F2}$  scheme follows observations better than those predicted by the  $C_{F3}$  scheme or the  $C_{F4}$   
240 scheme (shown in the supplementary material).

Thundercloud corona recordings by ASIM are conditioned by nighttime only observations, the South Atlantic Anomaly (SAA) and the relatively reduced number of detections due to the short period of observations (two years). These circumstances constrain the parameterizations developed in this study. However, when implemented in global atmospheric chemistry climate  
245 models, simulations are able to predict BLUEs occurrence rate and geographical distribution in space-time regions where observations were not completely available.

Figure 4 presents a comparison of the seasonal behavior of in-cloud coronas resulting from the GD-2 distribution of ASIM observations (left column) and the model predicted (right column) seasonal distribution according to the  $C_{F2}$  corona scheme for the present day climate scenario. We notice that the  $C_{F2}$  scheme correctly reproduces the seasonal global average occurrence rate, placing the maximum during the boreal summer (JJA) and the minimum in the boreal winter (DJF). In particular, ASIM  
250 nighttime observations indicate that the seasonal global average occurrence rates of in-cloud coronas are: 3.73 (SON), 2.60 (DJF), 3.75 (MAM) and 4.01 (JJA) events  $\text{s}^{-1}$ . Model predictions based on the  $C_{F2}$  corona scheme result in 3.44 (SON), 3.32 (DJF), 3.47 (MAM) and 3.71 (JJA) events  $\text{s}^{-1}$ , respectively. The seasonal distributions of the  $C_{F1}$ ,  $C_{F3}$ , and  $C_{F4}$  schemes are shown in the supplementary material (Figures S3, S4 and S5) and all of them exhibit their maxima in JJA (3.69 for  $C_{F1}$ , 3.90 for  $C_{F3}$ , and 3.77 events  $\text{s}^{-1}$  for  $C_{F4}$ ).

255 Model simulations based on the  $C_{F2}$  scheme indicate that during the boreal winter (DJF), electrical activity in the form of thundercloud coronas is more important in the north of South America. However, this is not evident from DJF observations in South America, which exhibits disperse in-cloud corona activity probably due to limited ASIM observations in this region

due to the presence of the SAA. The model predicted in-cloud corona discharge activity in the central and southern parts of Africa, its surrounding seas and the Asia / Australia region during the boreal winter is similar to available ASIM observations including the peak of thundercloud corona activity in the north of Australia.

The in-cloud corona observations by ASIM during the boreal summer season is in good agreement with model predictions. In particular, model simulations show that thundercloud corona discharges in Africa are mainly restricted to its central region, also significant in-cloud corona activity is predicted in India and surrounding seas including Indonesia and the eastern region of China. Model simulations also predict the largest number density of in-cloud coronas in North America during boreal summer, which is in agreement with ASIM seasonal observations of thundercloud corona discharges.

During the boreal autumn and spring seasons, the observed in-cloud corona maxima in America appear between the north of Colombia and central America reaching up to the west coast of Mexico (in the boreal spring). Model predictions of in-cloud activity maxima during these seasons point to southern Colombia and the maritime region next to the east coast of Mexico (in the boreal spring). ASIM observations indicate that corona activity in central Africa is more important during the boreal spring season than during the autumn, the same is predicted by the global chemistry-climate model using the  $C_{F2}$  corona scheme.

The end of the 21st century climate scenario results in BLUE occurrence rates between 28 % larger ( $\sim 7$  % per K) (for the  $C_{F1}$  scheme based on CTH), 24 % larger ( $\sim 6$  % per K) (for the  $C_{F2}$  scheme based on  $CAPE \times TP$ ) and 17 % larger ( $\sim 4$  % per K) (for the  $C_{F3}$  scheme based on  $CAPE \times CLWC$ ) than present day. Figure S6 shows a comparison between predicted global annual average geographical distributions of in-cloud coronas in the present day and by the end of the 21st century climate scenarios using the  $C_{F1}$ ,  $C_{F2}$  and  $C_{F3}$  thundercloud corona schemes. The globally averaged temperature at the surface increases by about 4 K (Pérez-Invernón et al., 2023) by the end of the 21st century (RCP6.0 scenario, 2091-2095) compared with present-day scenario (2000-2009). It is important to note that the projections have been based on only 2 years of data, whereas climate projections typically rely on more than 2 decades of data. Therefore, we would like to emphasize the significant uncertainty in the BLUEs "climatology" obtained for the end of the 21st century.

#### 4.2 Robustness of BLUE parameterizations on the 1-hourly timescale

We have developed the four BLUE parameterizations using ERA5 hourly (for CAPE, TP, CLWC and CSWC) and COPERNICUS CLARA monthly (for CTH) data since the temporal resolution in chemistry transport models is of the order of minutes. To check that the BLUEs parameterizations behave reasonably well at model time scales, 1-hourly BLUE flash densities are built for the period 1 April 2019 to 31 March 2021 for the 3 parameterizations ( $C_{F2}$ ,  $C_{F3}$ , and  $C_{F4}$ ) as shown in Figure 5. All the tested parameterizations exhibited approximately 95% of cells with values less than  $10^{-4}$  Blues  $\text{km}^{-2} \text{h}^{-1}$ . It can be seen that  $C_{F4}$  produces the most homogeneous occurrence of BLUEs in time and space, while  $C_{F2}$  exhibits the most inhomogeneous distribution, with more cells experiencing a high rate of BLUEs. The simulated distributions of BLUEs density in a chemistry-climate model can be compared with the distributions of flash density obtained by using lightning parameterizations (Finney et al., 2014, Fig. 5). The distributions of BLUEs obtained in this work show decreasing trends similar to those of flashes concerning the number of cells versus the density value. Therefore, we can conclude that the parameterizations of BLUEs obtained in this study are as applicable to chemical-climate models as those of lightning.

## 5 Conclusions

Corona discharge activity in thunderclouds is found to be positively, but non-linearly correlated with: CTH, CAPE  $\times$  TP, CAPE  $\times$  CLWC, and CAPE  $\times$  CSWC. These findings allowed us to develop four parameterizations for global chemistry-  
295 climate model simulations of in-cloud corona activity.

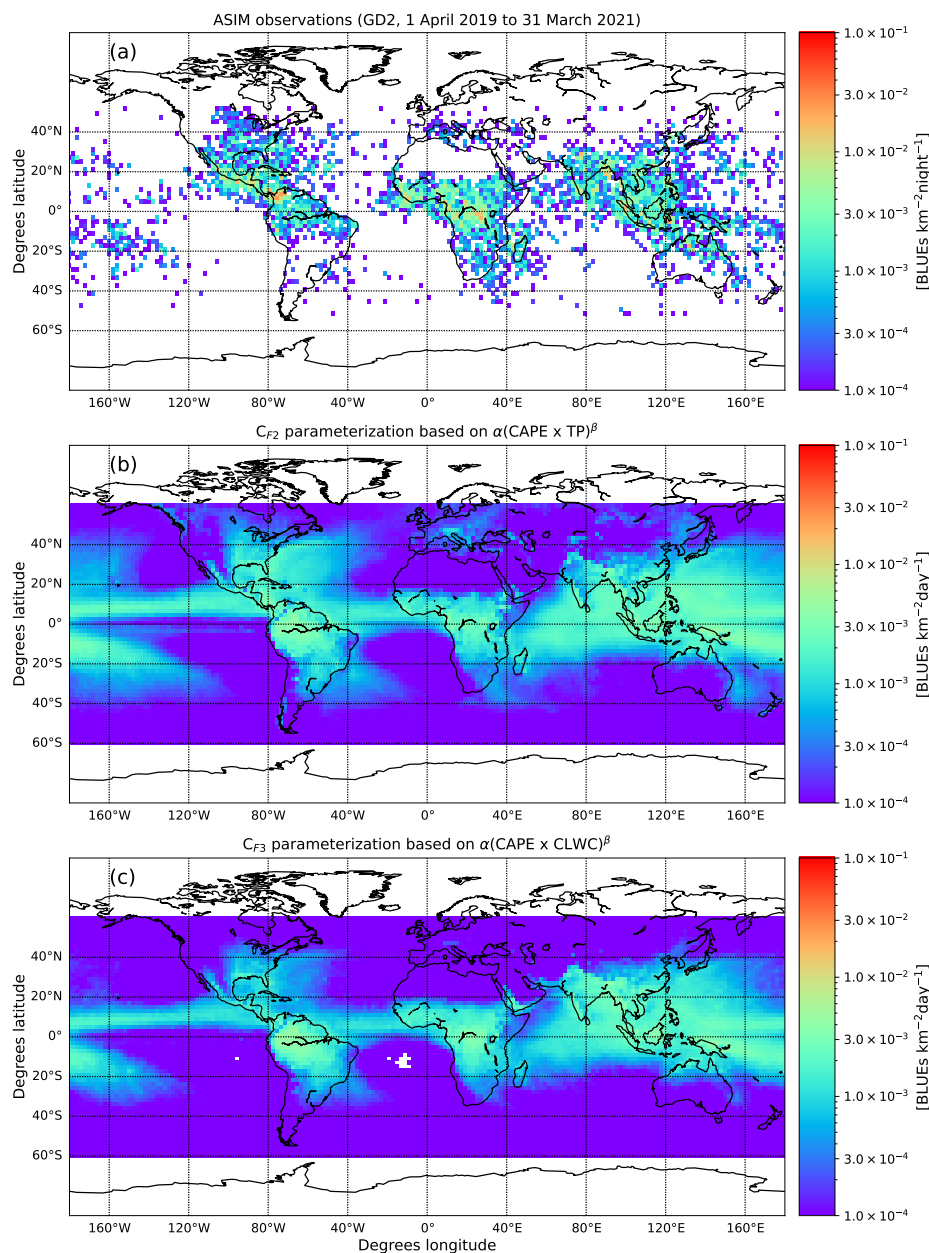

The four corona schemes were tested against a two-year dataset of worldwide nighttime in-cloud corona observations recorded by ASIM between 1 April 2019 and 31 March 2021.

The global annual average BLUE rates obtained from the four adopted parameterizations using ERA5 annual averaged data (for CAPE, TP, CLWC and CSWC) and CLARA annual averaged data (for CTH) produce 3.53 BLUEs  $s^{-1}$  for the  $C_{F2}$  scheme, 300 3.42 BLUEs  $s^{-1}$  for the  $C_{F3}$  scheme, 3.20 BLUEs  $s^{-1}$  for the  $C_{F4}$  scheme, and 4.41 BLUEs  $s^{-1}$  for the  $C_{F1}$  scheme. These numbers agree reasonably well with the observed global average occurrence rate of 3.5 BLUEs  $s^{-1}$  measured by ASIM (Soler et al., 2022). In addition, all the corona parameterizations have been implemented in a global chemistry-climate model that generates annual and seasonal global distributions for present day and future (end of the 21st century) climate scenarios (only for  $C_{F2}$  and  $C_{F3}$ ). Present day model predictions are in good agreement with recent observations by ASIM but predictions for 305 the end of the 21st century (included in the supplementary material) suggest BLUE occurrence rates that range between 28 % larger ( $\sim 7$  % per K) (for the CF1 scheme based on CTH), 24 % larger ( $\sim 6$  % per K) (for the  $C_{F2}$  scheme) and 17 % larger ( $\sim 4$  % per K) (for the  $C_{F3}$  scheme) than present day global average occurrence rate of BLUEs.

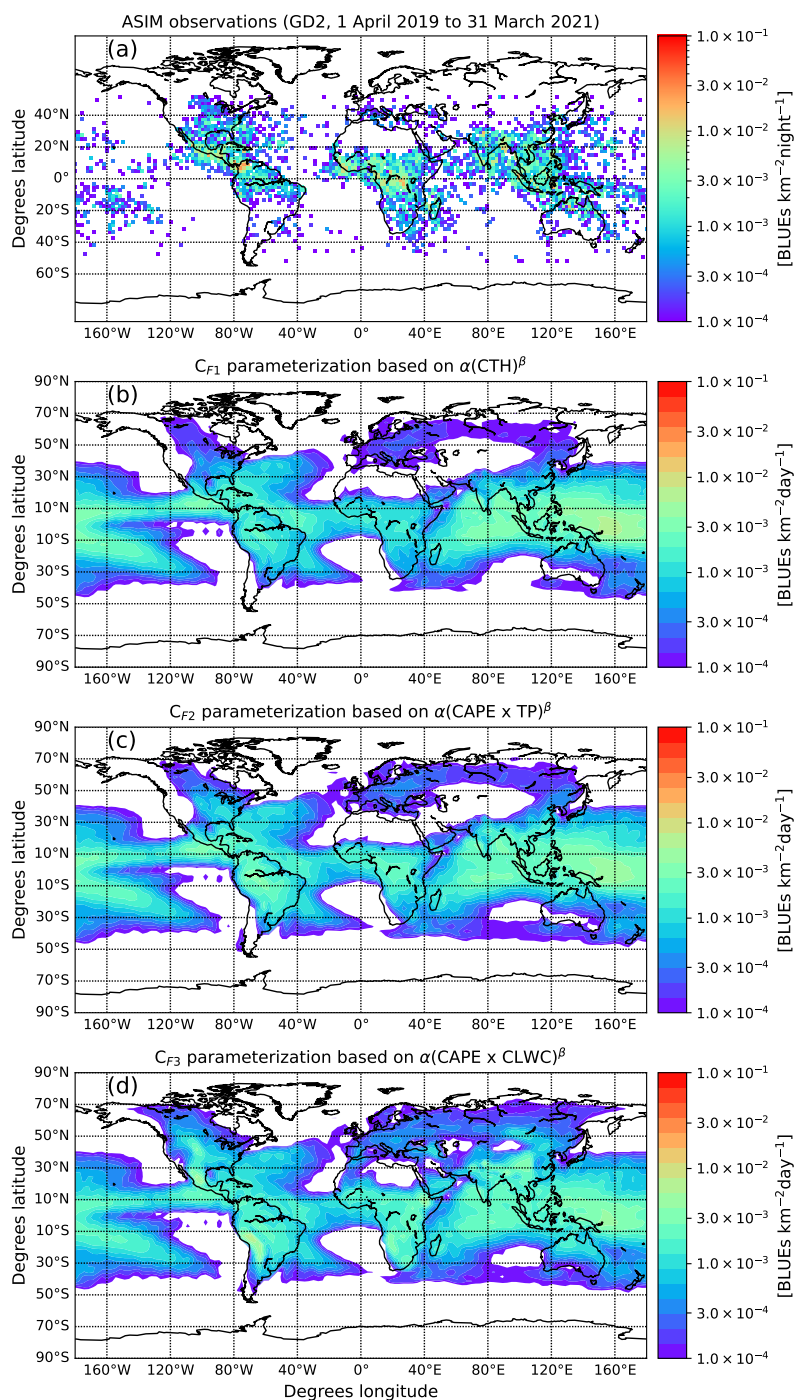

In-cloud corona schemes can be helpful to test global and / or regional chemical impact of corona discharges in thunderstorms since in-cloud coronas are known to directly produce not only greenhouse gases such ozone ( $O_3$ ) and nitrous oxide ( $N_2O$ ) but 310 also oxidant species such as hydroxyl (OH) and hydroperoxyl ( $HO_2$ ).

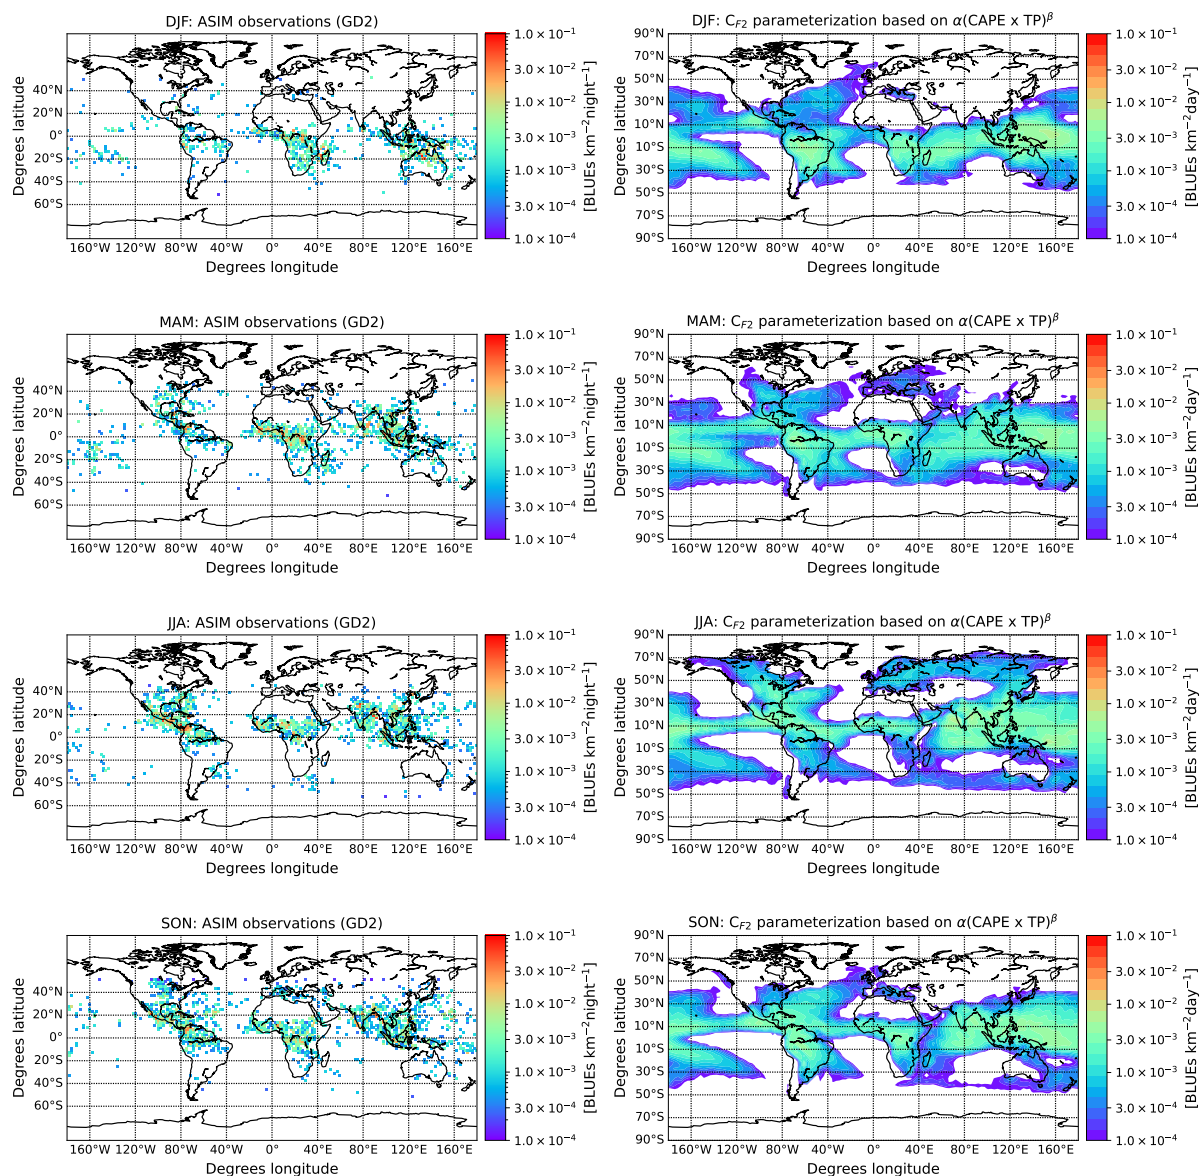

**Figure 1.** Global annual average occurrence rate (coronas  $s^{-1}$ ) of nighttime thundercloud coronas observed by ASIM between 1 April 2019 and 31 March 2021 (blue dots) (a) versus corona discharge schemes based on the Cloud Top Height (CTH) (b),  $CAPE \times TP$  (c), and versus the  $CAPE \times$  specific CLWC (d), and versus  $CAPE \times$  specific CSWC (d). The red line corresponds to the functional forms for the nighttime corona occurrence rates of the four proposed schemes:  $C_{F1} = \alpha_1 \times (CTH)^{\beta_1}$ ,  $C_{F2} = \alpha_2 \times (CAPE \times TP)^{\beta_2}$ ,  $C_{F3} = \alpha_3 \times (CAPE \times CLWC)^{\beta_3}$  and  $C_{F4} = \alpha_4 \times (CAPE \times CSWC)^{\beta_4}$  where the parameters  $\alpha_1 = 0.010 \pm 0.004$  and  $\beta_1 = 3.36 \pm 0.17$ ,  $\alpha_2 = 5.1 \pm 0.3$  and  $\beta_2 = 0.83 \pm 0.04$ , and  $\alpha_3 = 1100 \pm 200$  and  $\beta_3 = 0.78 \pm 0.04$ , and  $\alpha_4 = 250 \pm 40$  and  $\beta_4 = 0.67 \pm 0.04$  are obtained from the best approximations of nighttime corona occurrence rate observed by ASIM as a function of values of CTH taken from the Essential Climate Variable (ECV) Cloud Properties of COPERNICUS (the European Union’s Earth observation programme), from  $CAPE \times TP$ ,  $CAPE \times CLWC$  and  $CAPE \times CSWC$  taken from ERA5 reanalysis. The quality of the approximations covering the two years (1 April 2019 to 31 March 2021) is evaluated with  $R^2$  metrics that results in  $R^2 = 0.94$  for the CTH scheme,  $R^2 = 0.96$  for the  $CAPE \times TP$  scheme,  $R^2 = 0.96$  for the  $CAPE \times CLWC$  scheme, and  $R^2 = 0.96$  for the  $CAPE \times CSWC$  scheme. The dashed black lines in panels (a)-(d) show the upper and lower limits of the fitting curve associated to the upper/lower errors in the fitting coefficients.

**Figure 2.** Two-year average (1 April 2019 through 31 March 2021) nighttime geographical distribution of global corona (BLUE) electrical activity in thunderclouds according to the GD-2 distribution derived from ASIM observations (Soler et al., 2022) (a), annual global predictions for BLUE occurrence rate based on ERA5 hourly data introduced in the corona (BLUE) parameterizations  $C_{F2}$  (b), and  $C_{F3}$  (c). Note that the colorbars have the same scale. Considering that thunderstorms occur on hourly timescales, these plots show that when ERA5 hourly data for the meteorological variables are considered, the proposed BLUE parameterizations work fine.

**Figure 3.** Two-year average (1 April 2019 through 31 March 2021) nighttime geographical distribution of global corona (BLUE) electrical activity in thunderclouds according to the GD-2 distribution derived from ASIM observations (Soler et al., 2022) (a), annual global chemistry-climate model predictions (using 10 year simulations) for BLUE occurrence rate according to corona parameterizations  $C_{F1}$  (b),  $C_{F2}$  (c), and according to  $C_{F3}$  (d). Note that the colorbars have the same scale.

**Figure 4.** Two-year average (1 April 2019 through 31 March 2021) nighttime seasonal climatology of global corona (BLUE) electrical activity in thunderclouds according to GD-2 distribution derived from ASIM observations (Soler et al., 2022) resulting in 2.60 (DJF), 3.75 (MAM), 4.01 (JJA) and 3.73 (SON) coronas (or BLUES)  $s^{-1}$  (left column), and global annual average chemistry-climate model predictions (using 10 year simulations) for seasonal BLUE occurrence rate and geographical distribution according to the corona parameterization  $C_{F2}$  resulting in 3.32 (DJF), 3.47 (MAM), 3.71 (JJA) and 3.44 (SON) coronas (or BLUES)  $s^{-1}$  (right column). Note that the colorbars have the same scale.

**Figure 5.** Curves show different 1-hourly BLUE flash densities in the period 1 April 2019 to 31 March 2021 for the  $C_{F2}$  (blue line),  $C_{F3}$  (green line), and  $C_{F4}$  (orange line) BLUE parameterizations.

*Code and data availability.* The Modular Earth Submodel System (MESSy) is continuously developed and applied by a consortium of institutions. The usage of MESSy and access to the source code are licensed to all affiliates of institutions which are members of the MESSy Consortium. Institutions can become a member of the MESSy Consortium by signing the MESSy Memorandum of Understanding. More information can be found on the MESSy Consortium website (<http://www.messy-interface.org>, last access: 22 November 2023). As the MESSy code is only available under license, the code cannot be made publicly available. The parameterization of in-cloud corona discharges has been developed based on MESSy version 2.55. ASIM level 1 data are proprietary and cannot be publicly released at this stage. Interested parties should direct their request to the ASIM Facility Science Team (FST). ASIM data request can be submitted through <https://asdc.space.dtu.dk> (last access: 22 November 2023) by sending a message to the electronic address [asdc@space.dtu.dk](mailto:asdc@space.dtu.dk). The work performed was done by using the CLARA product data family (Karlsson et al., 2017) from EUMETSAT's Satellite Application Facility (SAF) on Climate Monitoring (CM SAF): <https://cds.climate.copernicus.eu/cdsapp#!/dataset/satellite-cloud-properties?tab=overview> (last access: 22 November 2023). ERA5 reanalysis data Hersbach, H. et al. (2018a, b); Hersbach et al. (2020) were downloaded from the Copernicus Climate Change Service (C3S) Climate Data Store <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels?tab=overview> (last access: 22 November 2023). The data from the simulations presented in this study are freely available under <https://zenodo.org/records/10409961> (Soler et al., 2023)
